As to the *origin*, the primary patch may be inoculated from some outside source, or may arise by the implication of the skin from pre-existent tuberculosis of deeper structures in the same subject, e.g. from glands, bones, and synovial sheaths. In the latter case it may present the characteristic nodules, or the more diffuse form of infiltration to which the term *Scrofulodermia* is applied. This glandular origin is very frequently seen over the parotid region, or from ear to ear beneath the jaws. Lupus is said to originate commonly by auto-inoculation from the discharges from the lungs, and not uncommonly from a mucous membrane, especially that of the nose. Dubreuilh maintains that there is a tubercular catarrh of the nose without neoplastic tendency, and if so, the analogy with leprosy is interesting. Lastly, there is a rare phenomenon, generally occurring in children after some systemic infection such as measles, characterised by the sudden evolution of more or less numerous disseminated small nodules, sometimes of an acneiform type. All or many may gradually disappear, but in some cases a number persist and assume the recognised characters of lupus. Such eruptions must be studied in connection with the '*tuberculides*' to be discussed later on. Baumgarten thought most cutaneous tubercloses had such a blood-origin.

The *elementary lesion* is a nodule in the derma, superficial or deeper-seated, imbedded or projecting; varying in size from a mere speck to a pin-head, hemp-seed, or pea; of a notably soft consistence, a

reddish-yellow colour and semi-transparent, recalling apple-jelly, especially when the blood is pressed out of the tissues; very indolent, as a rule, and with slow evolution; and unaccompanied by pain or itching. It may persist, or pustulate, or ulcerate, or disappear spontaneously, leaving a cicatrix.

A patch of lupus is formed, and spreads excentrically, by infection of the vicinity of the primary nodule, and the evolution of 'satellite' nodules, which become confluent with the enlarging older lesions. The latter are often replaced by scars, while the excentric spread is maintained around or on one side. Its *infective power* may be little marked, and often after a certain spread, lupus may remain quiescent for years, without infecting other tissues. The attenuation of the virus may also be evidenced by the difficulty in finding bacilli, and by the special conditions required for successful inoculation in animals. Usually, however, lupus pursues a very indolent spreading course, but sometimes takes on quite a rapid extension over large tracts. Infective power, however, may be evidenced, not only by the method of spread in the skin, but by the involvement of the related lymphatic glands, and on a limb of the lymphatic vessels. Much diversity of opinion exists as to the frequency of a systemic infection; for instance, the late J. S. Bristowe made the remarkable statement that 'local skin-tubercle or lupus, instead of producing general tuberculosis, seems to prevent it.' On the other hand, it is common experience that a certain proportion of lupus eventually die of visceral tuberculosis, but we must attach due weight in this connection to the hospitalisation, the confinement, the wretchedness brought about by their disfigurement, and the poverty of many of these sufferers. As to *localisation*, any region may be attacked, but in about 80 per cent. of cases lupus is seated on the face, and especially about the nose and its neighbourhood. It may extend to the forehead, but is of great rarity on the scalp. It is not infrequent about the parotid region, and especially in a band beneath the jaw. The hands are particularly exposed. It is said to be rare on the external genitals, and Dubreuilh says that the *Esthiomène* of the vulva of Huguier is a chronic ulceration of different nature. The mucous membranes of the mouth and nose are frequently involved, usually secondarily to the skin; also the conjunctivæ, the pharynx and larynx; the tongue rarely. In the mucous membranes the redness is accentuated, the surface mammillated and easily bleeding, the infiltration soft. Ulceration is frequent and leads to destruction of the uvula and soft palate, and of the cartilages of the nose with mutilation as in syphilis and leprosy.

The *clinical phases* are infinitely diverse, owing to variations in size, form, aspect, and number of the patches, and to the predominance of certain reactions, such as marked vascularity, epithelial growth with hyperkeratosis (*L. papillosus*, *L. verrucosus*), hypertrophy of collagenous tissue or fibromatosis (*L. hypertrophicus*, *L. scleroticus*), or sero-fibrinous exudation without loss of underlying substance (*L. crustosus*, Unna). Mixed infections cause suppuration and necrosis (*L. vorax*, *L. phagedenicus*).

In size the patches may range from that of a small coin upwards, or the lupus may advance over an extensive tract, e.g. up a limb or from the face over the neck and greater part of the trunk. There may be only one patch present or others may

arise by auto-inoculation, or by lymphatic infection. The number is usually few, except in the exanthematic outbursts mentioned.

There is an old division into non-ulcerating (non-exedens) and ulcerating (exedens) lupus. Non-ulcerating lupus forms red patches, yellowish-brown when the blood is pressed out, generally projecting somewhat, with distinct contours, always distinctly infiltrated and thickened, with a smooth or exfoliating surface. A typical indolent patch of this kind is often seen in the centre of the cheek. Usually the older infiltrations disappear, and atrophic scarring results. The primitive rounded outline of the patch may be lost owing to the extension only in certain directions. On the thigh a circinate form is often preserved, but on the buttocks lupus-patches become hypertrophic. On the hands, and sometimes other parts, the lupus-infiltration is disguised by the warty growth as mentioned under warty tuberculosis.

On the feet lupus-nodules are deeply imbedded beneath the thick corneous layer and present difficulties in diagnosis. The ears may be enormously increased in size and shapeless with myxomatous degeneration. Occasionally soft exuberant red papillæ become very prominent over patches on the face, and exudation takes place *through the thinned epithelium* with crusting.

Ulcerated lupus may be heavily encrusted, and thus the primary infiltration be masked. Granulations may sprout from the surface, and form a picture not to be confounded with papillomatous lupus.

Cedema with lymphatic inflammation may occur in the arm and leg so as to simulate elephantiasis, or in the face.

Mutilations of a distressing character are brought about by the destruction of the cartilages of the ears and nose; by ulceration and suppuration of the hands and feet with loss of digits; and by the more or less contractile character of the scars formed about the eyelids, nose, mouth, and bends of the limbs.

The **Primary Tubercular Ulcer** is produced by the primary inoculation of tuberculosis into punctures, breaches of surface, or other deeper wounds, in various regions of the body. It would be more correct, however, to describe it as a tubercular nodule with a strong tendency to pustulation and ulceration, either from the virulence of the bacilli, the character of the soil, the method of inoculation, or the presence of other organisms. It is questionable whether we are justified in placing these inoculations in a special category. This phase may commence as a little red infiltration, which may pustulate, or ulcerate, and crust; or as a little abscess; or as onychia; or a wound may suppurate and ulcerate. The infective nature may be shown by the intractability to simple healing measures, the excentric spread of the lesion, and the implication of the related lymphatic vessels and glands and production of adenitis, 'cold abscesses,' and 'gummata,' for instance up the arm. Many striking examples of such tubercular inoculations have been recorded. The fingers may be the site of attack, but inoculation has followed the wearing of infected earrings (Unna), a cut on the scalp from falling on the sputum-receiver of a phthisical mother (Dencke), and so on. Various series of cases on record of tuberculosis inoculated by a tuberculous operator in the Jewish rite of

circumcision and again in tattooing are well known. Bacilli are often easily found.

The early recognition of the nature of these lesions is obviously important, that they may be thoroughly destroyed or removed.

Verrucose Tuberculosis (Riehl and Paul-tauf) is a manifestation of cutaneous tuberculosis also due to exogenous inoculation, and is moulded by the influence of site, for it occurs nearly always on the dorsal aspect of the hand or fingers, whence it may extend to the palms. It may be seen on occasion about the forearms and elsewhere. The peculiar features are due to the masking of the granuloma by hypertrophy and down-growth of the epithelium, and sclerotic changes. There is also a marked tendency to the formation of superficial milium abscesses, whence pus oozes between the warty cones, but the lupus-nodules never suppurate (Unna). There may be hardly any signs of congestion, but generally the extending painless warty patch has a violet-red border, and may cicatrise in the central parts. Sometimes the patch is indolent, and may remain stationary for years, while at other times the excentric spread is comparatively rapid, and occasionally the infective nature is further evidenced by the implication of a chain of lymphatic vessels and glands up the limb, and possibly of the viscera. The bacilli present are very variable in number. Bécère says this warty tuberculosis may be secondary to phthisis. Lupus in similar situations tends to assume a similar morphology, and it is difficult to draw a very sharp line of distinction between the two phases.

Verruca Necrogenica (Wilks), **Anatomical Tubercle**, or **Post-mortem Wart**, is a similar persistent thickened keratotic or warty condition of the hands, especially of the finger-points. It is often due to tubercular inoculation, but probably a similar condition is excited by contact with the morbid fluids of diseased bodies. It may begin without breach of surface as a keratotic or warty thickening, or in a wound, or as a pustule.

The Secondary Granular Tubercular Ulcer; Tuberculosis propria seu miliaris (Kaposi).—This is very similar to that met with on the tongue, and is found in the neighbourhood of the lips or anus, where it is secondary to pulmonary or intestinal tuberculosis. Kaposi says that, though rare, it is commoner than generally supposed. In this country it is certainly rare. The ulcer is peculiarly painful, irregular in outline, with ragged undermined borders and a reddish-grey uneven floor, studded with yellow milium granulations (tubercles), which may be seen in the borders and beyond, and which by their degeneration and softening cause the formation and spread of the ulcer. There is little tendency to spontaneous cicatrization. This ulcer is very rare in childhood, but has been recorded in the anal region. Bacilli can be readily detected in the secretion or in scrapings. The attentive and alert observer can hardly confound this ulcer with a syphilide.

Tubercular Gumma.—This term is applied to certain circumscribed tuberculous masses which originate in the hypoderm, and somewhat resemble syphilitic gummata. Two phases are met with. The first is the multiple and bilateral cutaneous cold abscess, the scrofulo-tuberculous gumma of Besnier, so commonly seen in early childhood and frequently associated with other signs of tuberculosis, as dactylitis, glandular trouble, &c. The nodules

are mostly seen about the limbs and commence in the hypoderm as a rounded, indolent, firm infiltration. As they increase from the size of a pea or nut, the overlying skin becomes violet, and then involved more intimately in the process. The softening mass may discharge its contents through a little hole, or sometimes breaks down to form an ulcer. These 'gummata' are of endogenous origin. The second form is seen in the adult. They sometimes assume a chain-formation up a limb from lymphatic infection, but on rare occasions occur in a disseminated phase.

Scrofuloderma we may pass over with an explanation. The term formerly denominated all the supposed phases of the so-called scrofulous diathesis implicating the skin, and so had a very extended use, varying with different authors. In the present day the term is for the most part applied to the so-called gummatous form and to secondary tubercles of the skin arising from disease of deeper structures, as glands, bones, &c. The latter lesions usually present a violaceous diffuse infiltration and they ulcerate.

Tuberculides.—Of late years particular attention has been drawn to certain regional, or more or less generalised, eruptions of multiple lesions, probably of endogenous origin, described under a great variety of names, and ranging from the grouped micro-papular *Lichen scrofulosorum* through some acneiform and nodular eruptions, to the more massive gumma-like *Erythema induratum* (Bazin). These eruptions may occur in various combinations. The representatives of the beginning and end of this series have been described separately elsewhere. The acneiform and nodular tuberculides vary in size from a linseed to a pea or larger, and implicate the derma superficially or more deeply. They often form about a follicle, and hence have been described as folliculites, hydradenites, acnites, folliclis, &c. The lesions are apt to be capped by a little pustular head; they pursue an indolent course and may undergo some necrosis, in any case tending to leave pits. These so-called tuberculides may evolve in one crop, or in several over a course of years. The generalised eruptions have a striking analogy with various acneiform syphilides, and among the regional forms may be specially mentioned an acneiform eruption of the face, simulating *acne necrotica*, and affecting the backs of the hands, which may possibly be confounded with chilblains in subjects with a bad circulation.

There can be no question about the intimate association of these eruptions with tuberculosis, and their occurrence in subjects either infected with the bacillus of Koch or legitimately suspected of so being. However, in some cases the subjects appear healthy. Researches for the bacilli and inoculation-experiments generally prove futile. In some cases a characteristic tubercular structure is disclosed, in other cases not, but the two conditions may be associated. In view of the insufficient proof of the tubercular nature of these eruptions, the hypotheses have been advanced (1) that the lesions may be due to a secondary infection on a tuberculous soil; (2) that they are excited by tubercular toxins; (3) that they originate from emboli of bacilli which are attenuated and come by way of the blood-current and rapidly succumb. This last theory seems to explain most of the facts observed.

PATHOLOGICAL ANATOMY.—Lupus is usually described as composed of a granulation-tissue,

divided into lobes here and there by fibrous bands, and formed of lymphoid cells lodged in the meshes of a fine reticulum. In this tissue are disseminated groups of giant-cells, surrounded by a zone of fusiform epithelioid cells. There is, however, little tendency to caseation, though a molecular necrosis may occur, ending in ulceration. Bacilli may be found, but are often very few and far between, and demand sometimes prolonged search in many sections or in portions crushed between slides. Unna points out that 'areas,' similar to the 'tubercles' of other organs, are not always well characterised in lupus, though recognisable in every case of nodular lupus. He draws a distinction between the circumscribed nodular forms tending to be encapsuled by a firm membrane of compressed healthy tissue without increase of peripheral vascularity, and the *diffuse* forms with more vascular surroundings, and therefore greater tendency to stream radially in all directions in the lymph-spaces and to form crusts by sero-fibrinous exudation. The elementary isolated nodules, according to Unna, often, but not necessarily, arise from the adventitia of a blood-vessel, and consist of a rounded compact collection of large, almost cubical, cells, with unusually large and very granular cell-bodies, and one, rarely two, large vesicular nuclei. These cells are derived mainly from the perithelium of the blood-vessels, but also from simple connective tissue-cells, and he calls them plasma-cells and the whole tissue a plasmoma. The elastic tissue disappears and the collagenous almost completely, leaving a fine reticulum. Secondly, as the nodules increase in size, a remarkable and characteristic degeneration occurs in groups of cells which undergo a 'homogeneous swelling'; and around these groups the cells with well-staining protoplasm and nuclei are compressed and arranged in rings or semilunar form. Thirdly, giant-cells are formed, corresponding to a homogenised group of cells with their ring-formed compressed surroundings. Circumscribed lupus may thus remain for years enclosing reposing bacilli, 'latent, but not dead.' The central homogenised parts have been regarded as the 'tubercle,' and the cellular surrounding as a reactive leucocytic wall, but Unna looks on the whole as a plasmoma with peripheral matrix and central degenerated part.

The diffuse plasmoma has from the commencement a non-distinctive retiform aspect, with thicker strands following the vessels, the follicles and glands, while the finer ones surround the collagenous bundles. Later on more and more collagenous and elastic bundles are liquefied in the centre of the area, and the capillaries are converted into plasmoma-tissue. Diffuse lupus consists mainly of unaltered tubercular plasmoma, which does not always go on through homogeneous swelling to giant-cell formation. Nevertheless, these changes may be slowly brought about. Between these two types all degrees and admixtures may be met with. The lupus-process, especially in the diffuse forms, is almost always accompanied by sero-fibrinous inflammation, which the bacilli are capable of exciting. The papillary layer and the granular layer of the epidermis may disappear and the remaining cells may exfoliate. Secondary hyperplastic processes, however, may occur in the epithelial structures (warty lupus), and in the collagenous tissue (hypertrophic and sclerotic lupus). The *tubercular miliary ulcer* presents the miliary nodules seen in internal organs,

with the typical caseation, breaking down, and formation of ulcers.

DIAGNOSIS.—It is important to appreciate the significance of the characteristic *soft*, yellowish-red, imbedded nodule, though the appearance may be simulated by other nodules covered with tense epithelium. Nodules may often be detected as satellites on the border of a patch, or recurring in scars. Lupus, however, is not always nodular, but often diffuse. Typical cases of *L. erythematosus* and *vulgaris* are easily distinguished, but occasionally a more than usually infiltrated patch of *L. erythematosus* or a congested area of *L. vulgaris* may render the diagnosis exceedingly difficult. Exfoliating dry patches, especially in rare cases where the patches are multiple and bilateral, may simulate psoriasis, but the infiltration will generally attract attention. Both nodules and diffuse areas may be masked by crusting, by ulceration, by the thick corneous coating of the soles, and by verrucose growth. Diffuse infiltrations have to be distinguished from chronic glanders, actinomycosis, sarcoma, leprosy, and especially blastomycotic affections. Tertiary syphilides present the most frequent difficulty, but have a firmer infiltration, pursue a less indolent course, and do not recur in scars. The age of onset is of great assistance. Serpiginous rodent cancer with its firm polished cartilaginous border or nodules should not present any difficulty.

TREATMENT.—Local treatment is always called for, and general measures sometimes. If the patient manifests signs of a feeble constitution, or impaired nutrition, or actual tuberculosis elsewhere, all possible steps should be taken to build up the strength by the administration of cod-liver oil, iron, and other medicaments, and by placing the patient in a position to benefit by good food and air.

Resolvent effects have on rare occasions been claimed for the iodides, but the most striking results are obtained from the judicious hypodermic injection of Koch's tuberculin, especially the one first discovered. Tuberculin is certainly of very great use in certain cases, and it is to be regretted that, because the remedy did not fulfil all expectations, the preparation has been so summarily discarded.

Local treatment.—The choice must depend on the form of the tuberculoderma, the extent of the tissue involved, the locality implicated, and the age, sex, and position of the patient. Combinations of methods are often desirable. It is very rarely that the tubercular infiltration can be removed by simple resolvent or parasiticide measures, such as the application of iodine or perchloride of mercury, and resort until quite recently was made to the destruction of the diseased tissues by such methods as caustics or burning, or their removal by scraping or scarification or excision. Now these methods will be in great measure supplanted by the Finsen-Light method or its modifications and the Röntgen-Ray method.

Of *caustics* in vogue we may mention arsenical paste which is said to be elective, and others such as caustic potash and acid nitrate of mercury which indifferently destroy all tissues. For ulcerated surfaces repeated applications of pure lactic acid are effective; also a ten-per-cent. pyrogallol-acid ointment applied for two or three days and repeated; and a succession of Unna's strong salicylic-acid and creosote plasters are convenient and often useful. Recurrent nodules are easily broken up and bored out by toughened pencils of silver nitrate, zinc

chloride, or by a wooden match moistened with chloride-of-zinc cream, or by the Dental Burr or Paquelin's Cautery. Hollander's method of cauterising by directing a stream of hot air on the lupus is said to be successful. The objection to caustics as to burning is the pain and the difficulty in regulating the amount of destruction. They either do too little and necessitate repeated operations, or too much and cause unnecessary disfigurement. For we must remember that the problem set is to eradicate the lupus with the least possible disfigurement, especially when the face is involved. Consequently even the character of the scar is of great importance.

Surgical treatment has been largely in vogue in late years. Free excision possesses such manifest advantages that it must continue to be largely practised. The wound can often be closed so as to leave only a linear scar, and even when skin-grafting is necessary the degree of disfigurement compares most favourably with that left by many other methods. Large areas can be thus dealt with. The scraping away of the friable diseased tissue by curettes and sharp spoons, even when followed by mild caustic applications as chloride of zinc cream, is on the whole disappointing. It generally necessitates repetitions and the keeping of the case under prolonged observation so that recurrent nodules can be detected and destroyed. Recurrences occur because the scraping only removes the massed friable tissue and not the diseased strands which wander away in the resistant tissues.

Scarification was formerly much used and often gave very beautiful results. The objection is the necessity of repeated, often a great many, weekly operations. A special instrument fitted with closely arranged parallel knives is drawn across the diseased skin to the required depth, and then again at right angles. When the surface has healed, the operation is repeated, and so on. Besnier, who thinks seriously of the danger of systemic infection from bloody operations, has devised a system of *Iguipuncture*. He has arranged a number of small instruments in the form of points and blades, which may be carried to any desired temperature by regulating a battery. Dull heat is employed. He punctures with the electro-caustic needle or scarifiers, or with the galvano-caustic knife, and repeats the operation every eight days or so. Local anaesthesia is not necessary, but the proceeding is painful.

Most of these proceedings are likely to be supplanted by the Light-Method devised by Finsen and by the use of Röntgen Rays. Finsen employs the concentrated actinic rays of light from the sun or generated by electricity by means of an elaborate and very expensive apparatus, which can only be available in certain institutions. The treatment is also a prolonged one, and not well suited to certain regions, as mucous membranes. The results unquestionably are very beautiful. It is very satisfactory to find that modifications of this apparatus are making their appearance at a cost which will enable them to be widely distributed, and of a size manageable in a consulting-room. The careful and expert application of the less expensive Röntgen Rays produces highly satisfactory results in certain cases and is likely to be effective for lupus of mucous membranes.

T. COLCOTT FOX.

SKODAIC RESONANCE.—A peculiar high-pitched resonance, found chiefly at the sterno-clavicular region of the chest, in some cases of pleural effusion and certain other conditions. The importance of this physical sign was first pointed out by Skoda of Vienna. See PHYSICAL EXAMINATION; and PLEURA, Diseases of.

SKOLIOSIS (*σκολιός*, crooked).—A synonym for lateral curvature of the spine. See SPINE, Diseases and Curvatures of.

SKULL, Diseases and Deformities of.—**SYNON.**: Fr. *Maladies du Crâne*; Ger. *Krankheiten des Schädels*.—The principal diseases and deformities of the skull will be discussed in the following order: (1) Changes of shape; (2) Variations in size; (3) Meningocele and Encephalocele; (4) Cephalæmatoma; (5) Inflammation; (6) Rickets; (7) Craniotabes; (8) Syphilis; (9) Tumours; and (10) Other diseases of the skull which form parts of general morbid conditions.

1. **Changes of Shape.**—The shape of the skull not only varies much among the different races of mankind, but in each race variations are to be found, sometimes depending upon, sometimes independent of, disease in the individual. A glance at any extensive collection of crania is sufficient to indicate how much longer some skulls are than others, in proportion to their width; how in some the vertical diameter is proportionately great, in others small; how some have wide cheekbones, some depressed noses, and others projecting jaws.

The skull is seldom perfectly symmetrical; the asymmetry being usually more marked behind than in front. This is shown not only by a coarse examination of the exterior, but by referring to the differences between the sulci and foramina on the two sides, which are so commonly met with. A familiar illustration is afforded by the fact that the nose is rarely, if ever, exactly in the mid-line of the body; but much more striking deviations from perfect symmetry may occur, as, for instance, in a case reported by Pearce Gould, in which one half of the cerebellum was absent, and there was a corresponding deficiency of the cerebellar fossa on the occipital bone. Many savage races produce abnormalities of the shape of the skull, by the application of external pressure during early infancy; and a similar result has been supposed to be consequent on the method of wrapping up the heads of children that is adopted in some parts of France. A marked asymmetry of the skull accompanies 'hemiatrophy of the face' (see FACIAL ATROPHY). There are also recorded cases of enlargement of the bones of the face and skull. A remarkable instance of this disease, or rather of the development of enormous hyperostoses, is recorded by Hutchinson. Here the hyperostoses appeared closely confined to parts which were supplied by branches of the fifth nerve. Some of these hypertrophic cases are, no doubt, examples of exostosis, others of inflammatory enlargement. An uniformly thickened skull, depending presumably, though not certainly, on the latter cause, may be either porous like cancellous bone, or dense and heavy like ivory. There are in the museum of the College of Surgeons examples of both varieties, each of which measures in many parts no less than $\frac{3}{8}$ in. in thickness; in the porous variety the sutures are usually more or less completely ossified. The

writer has seen a case in which, without apparent cause, the growth of one half of the lower jaw appeared to be arrested about the age of puberty, which gave a peculiar inequality to the face. Great deformity of the skull may result from the constrained position in which the head is held by patients suffering from torticollis.

2. Variations in Size.—The size of the skull is also subject to considerable variations in different races. It is somewhat larger, on the average, in men than in women. Among individuals also there are very great differences. Great intellects have sometimes been associated with large crania, but oftener there has been no such relationship, and not infrequently the opposite has been the case. Far greater, however, are the modifications of size which depend upon pathological conditions and defects of development. Some of these are briefly as follows:—

(a) *Microcephalic idiots.*—Among this class of idiots, which must be made to include the cretins, the skull is remarkably deficient in size. Microcephalic skulls may be caused by a too early union of the sutures, in which case the want of development of the brain may be looked upon as a result of this synostosis; or there may be a normal condition of the sutures as regards union, but both the brain and the skull may remain undeveloped. The low forehead and animal face which are characteristic of this condition give a strangely repulsive appearance to the child. The degree of idiocy depends upon the size and structure of the brain, and the development of the convolutions. See CRETINISM; and IDIOCY.

(b) *Anencephalic monsters.*—This class exhibits a more or less complete deficiency in the development of the cranial bones, as well as of the brain. See MONSTROSITIES AND MALFORMATIONS.

(c) *Hydrocephalic infants.*—The skulls of these infants are of a size proportionate to the amount of fluid which is present, and they may thus sometimes reach enormous dimensions. The forehead reaches far over the face, so that the plane of the upper wall of the orbit is continuous with that of the perpendicular part of the frontal bone. The bones become excessively thin, and are often in part replaced by membrane. The sutures gape, and the fontanelles remain open far beyond the normal time of closure, occasionally indeed beyond the period of infancy. See HYDROCEPHALUS, CHRONIC.

3. Meningocele and Encephalocele.—Closely related also to hydrocephalus are the cases of meningocele and encephalocele. It may briefly be stated here that they involve the existence of a deficiency at some point of the skull, through which the membranes of the brain, containing either cerebro-spinal fluid only, or some part of the brain itself, may protrude. The most frequent seat of this disease is the occipital bone, and the next in frequency the nasal part of the frontal bone, but tumours of this nature have been met with in other situations. It is of the highest importance to diagnose these two kinds of tumour from those developed in the bones of the skull or outside them; mistakes in diagnosis have not infrequently led to most disastrous results, as, for example, when a meningocele has simulated a polypus of the nose, and its removal has been undertaken. If patients who have suffered from meningocele or encephalocele recover—a most rare occurrence—a small hole may remain in the bone which presented the

deficiency, or the opening may be completely obliterated.

4. Cephalhæmatoma.—See p. 267.

The term ‘cephalhæmatoma’ might equally well be applied to collections of blood between the dura mater and the skull. Such effusions are probably always traumatic, and result from the rupture of a meningeal artery or vein. If serious results do not immediately follow from pressure on the brain, considerable thickening of the dura mater may be set up, accompanied by the symptoms resulting from pachymeningitis. See MENINGES, CEREBRAL, Inflammation of, Simple Traumatic.

5. Inflammatory Diseases.

(a) *Inflammation of the diploë and its veins.*—In cases of injury to the skull, whether of the nature of fracture or of simple exposure in a scalp-wound, inflammation of the diploic veins is not uncommon, if the wound be allowed to become septic. In a bone so affected, if the outer table be removed, the whole diploë and its veins are found to be filled with pus, or, on applying a trephine, the pus may be seen to exude from the divided veins. The dura mater, under such circumstances, may be inflamed, or pus may collect between it and the bone. Pyæmia, with its characteristic concomitant symptoms, is the frequent, if not the invariable, result. It is not assumed that in this affection the outer and inner tables of the skull escape, but it is only in the diploë that the pathological process is obvious to the naked eye.

The only treatment that has been suggested—trephining—does not offer any hope of curing the disease.

(b) *Chronic osteitis.*—This may affect the bones of the skull without apparent cause, but in the majority of cases it depends upon the syphilitic taint. Sometimes all the bones of the skull become thickened and enormously massive, the surface being much roughened and often worm-eaten. At other times irregular hyperostosis may be the result. Considerable thickenings of some of the cranial bones, the result of an imperfect vascular osseous deposit, are found in some infants affected with congenital syphilis. These are mostly met with about the fontanelles, especially on the frontal and parietal, and sometimes the temporal bones. The irregular hyperostoses are mostly the result of local periostitis; in fact, they are ossified nodes. Chronic osteitis is the cause of the falling-in of the bridge of the nose, or the massive condition of the same part, which gives such a characteristic appearance to a child suffering from congenital syphilis. It is also the cause of some of the exostoses of the external auditory meatus.

The treatment must be directed against the constitutional taint, if any is to be discovered.

(c) *Caries.*—Chronic osteitis can hardly be considered apart from caries, which, again, in the majority of cases, depends upon syphilis, though less commonly on the strumous diathesis. It is usually caused by the penetration of a superficial ulcer into the deeper structures, or by the separation of the periosteum resulting from periostitis. It is frequently associated with more or less chronic osteitis and necrosis. One of the most frequent seats of caries of the skull is the forehead, as a sequel of tertiary syphilitic ulceration (*corona Veneris*). Another common seat is the hard palate, which is often perforated as the disease advances. Caries may occur in the occipito-

atlantal articulation (Pott's disease), followed by a train of symptoms which will be found discussed in other parts of this work. Caries of the temporal bone, either of the petrous or mastoid portions, frequently follows *otitis media*, and is not uncommonly the intermediate stage between this disease and thrombosis of the lateral sinus, meningitis, or cerebral abscess. It usually arises by extension of disease from the middle ear to the mastoid antrum and mastoid cells.

TREATMENT.—Beyond the administration of iodide of potassium and of mercury, the cautious scraping away of the diseased bone, and the adoption of precautions for maintaining cleanliness, little or nothing can be done to relieve syphilitic caries by the surgeon; and with regard to other cases of caries of the skull, whether considered pathologically or clinically, nothing can be added which does not apply to the same disease in other parts of the body. Caries of the occipito-atlantal articulation is best treated in the early stages by the actual cautery.

(d) *Necrosis*.—Necrosis of the skull not infrequently depends upon a traumatic cause, such as a scalp-wound or a burn; but here again the syphilitic form is the most common. It may also depend upon disease of the middle ear. Simple traumatic necrosis leads to the separation of a sequestrum in the usual way; it often consists of a superficial scale of bone. Syphilitic necrosis often depends upon some form of ulceration, or upon periostitis, and may be accompanied by extensive caries and chronic osteitis. It often results from a gumma of the diploë, causing separation of the inner and outer tables. The separation of syphilitic sequestra is generally an exceedingly tedious process; and they are, moreover, often surrounded by little or no reparatory callus, so that after their removal it is no rare occurrence to find the dura mater pulsating over a large area at the bottom of the wound. At the same time, this rule is not invariable; it is common to find great thickening if necrosis of the bones of the orbit occur, which may cause permanent displacement of the eyeball. The writer has seen a large piece of the body of the sphenoid separated as a sequestrum, including the sella turcica, and removed through the nose without any apparent evil result to the patient. Tubercular necrosis sometimes involves the whole thickness of the skull, sequestra of varying size being thrown off and leaving the dura mater exposed; the outer part of the skull is usually more extensively affected than the inner.

Necrosis is not infrequently met with affecting the bones of the face. Thus a part or the whole of the upper or the lower jaw may die, and come away as a sequestrum. Necrosis of the jaws often depends on inflammation set up by carious teeth. It sometimes accompanies actinomycosis. Another cause, happily not now frequently met with, is the poisonous effect of the fumes of phosphorus in persons employed in the manufacture of this substance, and in that of lucifer matches (*see PHOSPHORUS, Poisoning by*). The same remarks apply to the abuse of mercury. But, besides these more special causes, necrosis of the bones of the face may depend upon those more general states which are supposed to stand to necrosis of other bones in the relation of cause and effect; such as fevers and the like. The amount of thickening round a necrosed upper jaw has not infrequently led

to its removal in mistake for a tumour; it is, therefore, of the highest importance to examine all swellings in this region with great care.

TREATMENT.—If the membranes be left exposed, some protection must be provided for the cranial contents; in other respects the treatment of necrosis of the skull must be conducted on general principles. Sequestra in the mastoid process or around the tympanum should be carefully dealt with, on account of the danger of setting up meningitis or injury of the internal carotid or lateral sinus which any surgical interference involves. In dealing with necrosis of one half of the lower jaw it must be remembered that, unless sufficient callus have been thrown out before the removal of the sequestrum, the other half will lose its support and assume an altogether unnatural and almost useless position, being drawn to the opposite side and leaving the patient in a condition in which he can hope for but little relief from surgery.

(e) *Periostitis*.—Periostitis of the skull has been already referred to. It may depend upon syphilis or tuberculosis—most commonly the former; and give rise to what are known as *nodes*. The inflammatory subperiosteal effusion may be fluid or solid (*soft and hard nodes*); and it may undergo true or spurious suppuration or ossification, or may be completely absorbed. The most common but by no means the invariable position for cranial nodes is the frontal bone. As in the case of periostitis elsewhere, nodes are the seat of characteristic nocturnal pain, which is extremely distressing and exhausting to the patient.

TREATMENT.—The treatment in any case is by the administration of iodide of potassium; the effect of which is most marked, however, in syphilitic cases, the pain being usually removed in two or three days. If suppuration occur, incision may be required.

6. *Rickets*.—In a rickety infant the skull looks large; though it may be questioned whether this appearance does not depend on a deficient development of the bones of the face. The frontal and parietal eminences appear too prominent; the fontanelles remain patent much longer than in a healthy infant; and in some cases the anterior fontanelle may be unclosed as late as the fourth or even sixth year. The skulls of rickety children have a peculiarly massive feel; they are sometimes long in proportion to their width, conforming to the shape known as dolichocephalic. The head of an adult who has been the subject of rickets in his childhood has often a very characteristic appearance: an apparently large square skull, with a prominent forehead towering above a diminutive and pinched-up face, giving to the individual a decidedly intellectual aspect.

Craniotabes occurs occasionally in rickety skulls, but, as will be afterwards shown, we do not yet know how far, if at all, it depends upon the constitutional condition.

7. *Craniotabes*.—By this term is meant the occurrence of spots of remarkable thinness in the skull, such that an indentation may be produced by the pressure of the finger. True craniotabes, as opposed to the gelatiniform degeneration of the outer table (Parrot), attacks the inner aspect of the skull. For its production an undue softness of the bone appears to be necessary, together with the occurrence of pressure, either from within or from without. It is rarely found congenitally, and it then

affects the anterior part of the skull. It is common in syphilitic infants under one year of age, and is then usually met with in the posterior parts of the parietal bones. These positions, it will be noticed, are those most subjected to pressure under the two conditions mentioned. Craniotabes has been, by some observers, associated with rickets, but the relation of the one to the other is at present doubtful. It disappears as age advances, and requires no special treatment.

8. Syphilitic Affections.—From the foregoing observations it will be seen that syphilis, congenital or acquired, has much to account for among diseases of the skull. It may cause periostitis, with consequent nodes; chronic osteitis, with consequent hypertrophy, local or general; caries; necrosis; and craniotabes. As a general rule, it may be stated that syphilitic affections of bone are among the later manifestations of this disease. The inflammatory forms are usually accompanied by severe nocturnal pains, and they may be expected in most cases to yield to the administration of iodide of potassium.

9. Tumours.—It is necessary to refer in the briefest possible way to the tumours of the skull. Primary growths may spring from the diploë, or from the inner and outer tables of the cranial bones. Perhaps the most common are exostoses and some of the various kinds of sarcoma, either of which may reach an enormous size. The former may assume various characters (*see* TUMOURS). These, in certain cases, admit of removal by the surgeon. In connection with the bones of the face, tumours of the antrum or of the upper jaw, of various kinds, and tumours of the lower jaw, are not uncommon. In the latter position the various forms of epulis—myeloid, fibrous or malignant—and cystic tumours, are frequently met with. Exostoses often grow from the jaws and the orbit, and in connection with the former the different kinds of odontoma must be mentioned. Secondary tumours of all kinds may affect the skull; thus more than one instance is on record of a pulsating growth, occurring secondarily to a similar growth in the thyroid gland; and scirrhus, following cancer of the breast, is by no means unknown. Of these secondary affections the commonest are those which affect the skull by the direct extension of tumours from within or without; for example, the epitheliomata of the scalp or mouth, or rodent ulcer of the face.

10. Miscellaneous.—Certain characteristic modifications of the shape and size of the skull are met with in such diseases as acromegaly (*see* ACROMEGALY), osteitis deformans (*see* BONE, Diseases of), and leontiasis ossea (*see* BONE, Diseases of). As they have been described in the articles referred to, no further account of them is necessary.

R. J. GODLEE.

SLEEP, Disorders of.—SYNON.: Fr. *Troubles du Sommeil*; Ger. *Störungen des Schlafes*.—A proper amount and kind of sleep is needful in order that the body may be maintained in a state of health; but the actual amount of sleep taken and necessary for persons in health varies, within wide limits, according to age, the soundness of the sleep itself, and individual idiosyncrasy.

Age is a very important modifying factor. Thus an infant may sleep for twenty hours out of the twenty-four, and young children up to the age of ten commonly sleep for fourteen or at least twelve

hours. In children from ten to fifteen years old the duration of sleep usually varies between twelve and ten hours. In persons from fifteen to twenty-five the period should not sink below eight hours; from the latter age on to fifty it may fall to seven hours; and after this age about the same amount of sleep is required by the majority of persons, though some find six hours sufficient, and a few can (without apparent injury) take habitually even as little as five hours' sleep. The instances in which a duration of sleep habitually less than this is needed are altogether rare and exceptional.

Soundness of sleep, too, is subject to much individual variation. In childhood and in early life, sleep is commonly more profound than it is in adults, and much sounder than in old age. But, over and above these variations incident to age, there are individual differences; some persons are naturally 'light' and others 'heavy' sleepers. As a rule, those who can do with a small amount of sleep belong to the latter category. And similarly in regard to amount there are individual differences: some persons, as above indicated, are able to do with a comparatively small amount, while others seem to require to sleep decidedly beyond the average periods above stated.

The disorders of sleep—that is, the variations outside the above limits—belong to three principal categories, in the first of which may be ranged all those cases where sleep is *excessive* in amount; in the second those in which it is *defective* in soundness or in amount; and in the third those in which it is *unnatural* in character.

I. Amount of Sleep Excessive.—This occurs commonly in more or less demented persons or in idiots, whose brain-activity is below the usual level. Such persons, when their natural wants are satisfied, are apt, like many of the lower animals, to sleep away a large portion of their time.

But some individuals of notable intellectual power may occasionally, even in a state of health, after greatly prolonged labours with previous deprivation of rest, continue to sleep soundly for twenty-four or even thirty-six hours.

In many brain-affections, and in some cases of blood-poisoning, a condition of unnatural sleep bordering upon stupor may be present for many days. Obscure cases in which sleep is prolonged for weeks, or even months, are occasionally met with in this country. This rare condition only supervenes in persons of an obviously 'nervous' temperament, and the state itself seems generally to be a kind of trance allied to catalepsy. *See* also NEGRO-LETHARGY; and TRANCE.

II. Amount of Sleep Defective.—Under this head we have to do with two kinds of failure—a defect of quality (*disturbed or restless sleep*); and a defect in quantity (*wakefulness, insomnia, pervigilium*). These two defects often co-exist, though in many cases we may have the former condition existing alone.

(a) *Disturbed or restless sleep.*—This is a very common complaint, apt to occur in persons of all ages, and under the influence of many different causes, some of the most frequent of which are these: Indigestible food, or food of excessive or unaccustomed quantity, taken not long before going to bed; painful conditions of any kind, whether due to mere neuralgia or to serious organic disease of any organ; discomfort induced by undue cold or excessive heat; mental excitement or worry;

chronic alcoholism; the menopause; prolonged overwork (mental); over-fatigue (bodily); febrile conditions; inflammations; gouty states of the system; imperfect action of the liver and various forms of dyspepsia; excessive hæmorrhages; acute and chronic illnesses of various kinds, such as delirium tremens, bronchitis, polyuria, and different forms of heart-disease; the state of convalescence from many acute diseases; the taking of tea or coffee, either too strong or too late at night. Lastly, sleeping in a novel or uneasy condition, or in the midst of unaccustomed noises, may also be mentioned as not infrequent causes. Under any of these various conditions sleep may be fitful and disturbed, the persons often starting or turning about uneasily, dreaming much, and from time to time waking under the influence of dreams of a distressing or oppressive character. In one of the most extreme of the latter conditions, especially when it has been evoked by indigestible food, the state known as *nightmare* is induced. See NIGHTMARE.

TREATMENT.—The treatment of disturbed sleep must of course vary widely according to the nature of the influences under which it has arisen. These may at times be easily corrected, but in other cases, where the disturbed rest is dependent upon pain difficult to annul, or upon some acute or chronic disease, it may be impossible or extremely difficult to ensure sound sleep, notwithstanding the best-directed efforts to correct or neutralise the disturbing causes in operation. It may then be necessary to have recourse to some of the measures recommended under the next heading.

(b) *Insomnia or wakefulness.*—Under this head we may have either complete or partial insomnia. The condition is complete when the person gets no sleep at all for night after night, as in acute mania, delirium tremens, in those suffering from some very severe pain, or in persons under the influence of profound grief or mental anxiety. On the other hand, we may have partial insomnia of different kinds. In the one set of cases the persons who suffer from it may lie awake for long periods (one to several hours) before being able to get to sleep at all, and then sleep may be more or less sound and continuous till morning. In other cases, patients do not experience so much difficulty in getting to sleep, though after they have slept for one, two, or more hours they awake and cannot again fall asleep, or only into sleep of a fitful or restless nature; they may, however, lie awake in a state of mental depression, or even actually tortured by gloomy or horrible forebodings.

Various cases are on record in which absolute insomnia has lasted not only for days but even for weeks, interrupted only by mere snatches of sleep during brief intervals.

In this whole class of cases, however, the sufferers themselves are apt to form exaggerated estimates of the amount of their wakefulness, and to become more or less hypochondriacal upon the subject.

TREATMENT.—In many of these cases the art of the physician is very severely taxed. Whenever it is possible, insomnia should be corrected by a studious attention, to the general health and habits of the patient, and by endeavouring to ensure the presence, as far as possible, of the physiological conditions which favour sleep. Mental repose, bodily comfort, a sufficient degree of warmth, a

certain amount of fatigue, combined with perfect quietude—one or more of these conditions will be found in different cases either important aids or essentials for the production of sleep. To ensure the first of these conditions, it may be needful to prohibit all study for some hours before retiring to rest. An evening walk, so as to induce a certain amount of bodily fatigue, is, where it can be had recourse to, often beneficial; while in other cases a warm bath at bedtime, followed by friction of the skin, may greatly facilitate sleep. Sometimes a mere hot foot-bath, with or without mustard, will prove beneficial. A cup of warm beef-tea, gruel, or some weak stimulant (such as hot whisky and water or a glass of stout) just before going to bed may also have a salutary influence, and the gruel may be repeated, or taken preferentially, during the night. Monotonous sensorial impressions (sounds or gentle frictions); or a monotonous dwelling of the mind upon certain uninteresting imaginary sights or verbal repetitions are, again, sometimes found to act as provocatives of sleep, though in other cases they completely fail.

In debilitated or neurasthenic conditions of the system, a patient's ability to sleep may often be greatly improved by the administration of such nerve tonics as arsenic and strychnine in combination with digitalis or *sumbul*; and some patients suffering from worry or overwork have derived great benefit in the way of improved sleep by taking spirits of turpentine (m 30) in capsules at bedtime.

Where the preceding measures are unavailing, recourse must be had to hypnotics and sedatives, such as bromide of potassium, chloral hydrate, opium in one or other of its forms, morphine, Indian hemp, amorphous hyoscyamine, hyoscyne, &c., in doses appropriate to the age and condition of the patient. In the more urgent cases the doses of such hypnotics may have to be repeated till sleep is procured; but in many of these urgent conditions the sedative influence of packing in the wet sheet must not be forgotten. In all cases of insomnia apart from drug-treatment it is important, till a better habit is established, that the patient should abstain from tea or coffee, or take them only weak and in small quantity.

Several other most useful remedies of this class have been in use during recent years, the most important of which are sulphonal, trional, paraldehyde, chloralamid, chloralose, and chloretone. Of these, sulphonal (gr. 15–30) often acts well, and produces less depressing effects than chloral hydrate. It has, however, of late years been to a considerable extent superseded by trional (given in the same doses), because of its more rapid action and more speedy elimination from the system. Paraldehyde (m 40–120) is a very safe hypnotic to give where such a drug is required in patients suffering from heart- or lung-disease, but the great objection to it is its very nauseous taste and odour. Chloralamid (gr. 20–45), given in a slightly acidulated solution, is free from these objections, and is equally safe, though perhaps less reliable. Chloralose may be given in cachets or tabloids (gr. 6–8), as also may chloretone, though in larger doses (gr. 8–18). The writer has found them both safe and reliable hypnotics, capable, in suitable cases, of producing six or seven hours of sound sleep. For occasional use in time of need they are undoubtedly of great value. Such remedies, however, ought never to

be taken except under the orders and directions of a medical man, who alone would be able to judge as to the most suitable drug, the proper dose, and the mode of its administration. With some of these drugs, a dose on alternate nights is found to be sufficient; and in all cases it is of the greatest importance to obtain the desired result with the minimum quantity that will prove effective. Again, wherever hypnotics are had recourse to, it is of great importance to see that their use is not continued after the need for them has passed. It not infrequently happens, for instance, that much of a patient's insomnia may be due to a bad habit of the system, which yields after it has been broken in upon by the use of hypnotics for a short period. Abrupt discontinuance is generally most inadvisable; there should rather be a gradual diminution of the dose, with or without the knowledge of the patient. See HYPNOTICS; and SULPHONALISM.

III. Sleep Unnatural in Character.—Under this head we have to do with various unnatural conditions, in which the abeyance of the cerebral functions that occurs during sleep is more partial than that which normally exists. In disturbed sleep the physiological condition pertaining to and provocative of sleep is generally less profound than it should be, just as in other cases of unusually deep sleep (akin to stupor) such a condition is generally more profound than natural. In the cases to which we now refer, however, the brain-condition productive of sleep is partial in its area: portions of the brain that are usually involved in the physiological condition peculiar to sleep remain exempt, so that the sleeper exhibits powers which sleep usually annuls. Hence we may have *somniloquy* or *sleep-talking*; *somnambulism* or *sleep-walking*, or what are known as *night-terrors*.

In those who exhibit the first of these phenomena, dream-thoughts are capable of evoking correlative acts of speech, and such persons will sometimes allow a listener to hold a sort of conversation with them, of which in the waking state they recollect nothing. This dream-conversation may be more or less coherent. Dreams themselves, too, vary much in their coherency in different individuals. In some persons, whose sleep is to that extent unnatural, powers are displayed during this condition which even surpass those of the waking state. Mathematical problems have been solved during such sleep; poems and music have been composed and written out, which have altogether surprised the same person when awake. In all these states we have to do with a morbid condition of sleep, partial in its area, in which there is the further peculiarity that certain faculties are in a condition of exalted activity. The alliances here are intimate with the conditions that are now studied under the name of 'hypnotism,' but which were formerly included under the term 'animal magnetism.' See MAGNETISM, ANIMAL.

Many of the above remarks apply to somnambulism also. Here the morbid sleeper possesses an unwonted power of calling his muscles generally into activity in response to his dream-thoughts. Sight in relation to the dream may be good, though unrelated visual impressions are not taken cognisance of. Muscular sense-impressions also are freely acted upon; but the sleep-walker may be quite deaf to all ordinary auditory impressions.

TREATMENT.—These are to be regarded as distinctly morbid conditions, and the persons manifesting them may often be cured by attention to the

general health, and the use of remedies calculated to give tone to, and allay the irritability of, the nervous system. A line of treatment, in fact, not very dissimilar from that to which one would have resort in convulsions or epilepsy will often suffice to cure these minor manifestations of nervous disorder.

Finally, sleep may be disturbed by certain phenomena occurring to the person while he is actually in this condition, which, though scarcely to be spoken of as disorders of sleep, ought at least to be mentioned in this article. One of minor significance is snoring, which at times may be so loud as to awaken the sleeper; but another of far greater significance is the occurrence of convulsive or epileptic attacks, which in some patients occur only during sleep.

H. CHARLTON BASTIAN.

SLEEPING SICKNESS.—See NEGRO-LETHARGY.

SLOUGH (Sax. *slog*, a foul hole or hollow).—A mass of dead material occurring among living tissues. A slough may be in the form of a large mass; or in shreds, as in ulcers and septic wounds. See GANGRENE; ULCER and ULCERATION.

SMALL-POX.—SYNON.: *Variola*; Fr. *La petite vérole*; Ger. *Blattern*.

ÆTIOLOGY.—Except in the case of those protected by vaccination, immunity is rare. One attack does not invariably protect for life. The writer has observed 92 cases of recurrent small-pox out of some 12,000. (See IMMUNITY, p. 722.) Dark-coloured races seem especially liable to the disease.

Seasonal prevalence. See PERIODICITY IN DISEASE, p. 1190, fig. 2.

Age.—No age exempts from attack, apart from protection by recent vaccination. The younger the child the greater the risk of a fatal issue. The fetus is sometimes attacked *in utero*. Some infants resist vaccination and exposure to small-pox, and some are born bearing vesicles or scars, showing that they have suffered from the disease during uterine life.

SEX.—In early life sex appears to cause no difference in susceptibility. After puberty more males than females are attacked.

NATURE OF VIRUS.—The *contagium* of small-pox has not, up to the present, been isolated. Practically the only micro-organisms discovered are such as belong to suppurative processes, but thus far the bacteriological study is very incomplete. The virus of small-pox exists in the secretions and excretions, and is given off freely from the lungs and the skin. It is said to be most active at the period when the clear contents of the pocks begin to turn cloudy, but whether the disease can be communicated before the eruption appears is doubtful; opinion inclines to the affirmative. The disease may be communicated after death. A fine desquamation occurs during convalescence and may be a source of infection.

MORBID ANATOMY.—The skin and those portions of mucous membrane that are in direct contact with the external air, viz. the lining of the mouth, pharynx and trachea, are sometimes found softened, congested, and covered with inflammatory exudation. Such internal parts as may have been inflamed exhibit evidence of such change. The pleural cavity, for instance, may be filled with serum, but as a rule the viscera are found free from

every appearance of special disease. Among very many *post-mortem* examinations made, in no case had the disease extended to the intestinal mucous membrane, but pustules were found in the nose and mouth, on the tongue, tonsils, soft palate and pharynx, also in the trachea and bronchi, the upper part of the œsophagus, and in the lowest part of the rectum, in the vagina and on the vulva; they are never found in the bladder, and only in the urethra near the meatus. The spleen is enlarged and soft, and of a lighter colour than natural. Renal changes are not common. In the hæmorrhagic type there may be found hæmorrhages of various sizes scattered over the serous covering of different viscera, in the connective tissue, into the muscles, and beneath the capsule of the kidneys; also throughout all the mucous membranes, from mouth to rectum, and in the uterus and Fallopian tubes, the ovary and testicles, the pelvis and calices of the kidneys, and the ureters. In the later stages of the disease the corpuscles have a tendency to form irregular clumps instead of *rouleaux*.

SYMPTOMS.—There are five well-marked stages of small-pox: (1) Incubative; (2) Prodromal; (3) Eruptive; (4) Suppurative; (5) Desiccative.

1. *Incubative.*—The incubation-period occasionally varies a little, but is almost invariably twelve days. See INCUBATION, and p. 727.

2. *The Prodromal* or initial stage is ushered in with frontal headache and sickness, which are severe, particularly in young children. Backache, which in the case of older patients awakes suspicion, is absent in children. The position of the pain is said to be sometimes indicative of the type of case: thus, if in the lumbar region, the attack will be very severe; in the dorsal less so; while if it be located entirely in the cervical, a very mild form may be anticipated. The combination of headache, sickness and backache is so significant that if these are alone present, precautionary measures may with advantage be adopted. The temperature rises rapidly and may reach 104° F. or 106° F. by the end of twenty-four hours, the pulse is frequent, and the tongue is creamy or dry. The premature appearance of the menses is also a frequent event, said to be due to a direct action of the variolar poison upon the genital functions. Not infrequently there is coma, preceded by convulsions in children, and in adults delirium. Albuminuria may be present. The chlorides in the urine are diminished, but the other solid constituents remain proportionally undisturbed.

Prodromal rashes.—In this stage peculiar initial rashes are by no means uncommon, and from a prognostic and diagnostic point of view very important. According to McNeill they may be divided into (1) the *Erythematous*; (2) the *Petechial*; and (3) the *Petechio-erythematous rashes*.

(1) *The Erythematous rash*, when fully developed, is of a bright red colour, which disappears momentarily on pressure. In some cases the redness is uniform, like erysipelas; in others it is punctate like scarlet fever; and in others again it occurs in patches and crescents like measles. The sites chosen by this rash when any part of the body is specially affected are the extensor surfaces of the arms and legs. In some cases the redness is smooth and uniform for some inches round the arms above the wrists, and the legs above the ankles, although mottled and scanty elsewhere. In other cases it covers the whole body.

(2) *The Petechial rash* is of a brownish-red colour when discrete. If thickly set it has a blue or purple tinge. The site chosen by this rash is very characteristic. It almost invariably selects the lower part of the abdomen and the groins to about an inch or two below Poupart's ligament. The lower margin runs from a point near the pubes in front of the thighs in an oblique line upwards, outwards and backwards, parallel to Poupart's ligament, to about an inch above the great trochanter, and then upwards to near the middle of the crest of the ilium. In rare cases the rash extends higher in the abdomen, and sometimes covers the flanks up to the axillæ, and the chest to the edge of the pectoral muscles. As a rule it does not reach further back than the edge of the latissimus dorsi. In very exceptional cases is any part of the body affected by this rash while the groin remains free.

(3) *The Petechio-erythematous rash* in the height of its development is redder than the petechial. This redness is dark, with a tinge of purple, and sometimes is almost blue in the groins. The erythematous rash covers a wider area than the petechial, and the colour varies, according as the erythema is more or less mixed with petechiæ. The erythema fades, but the petechiæ are persistent on pressure. The site chosen by this rash is not so well defined as in the case of the petechial. The parts in which the petechiæ are seen in the redness are as a rule similar to those parts affected by the petechial rash. Sometimes, however, there are no petechiæ in the groin, while they are present on the sides of the chest, on the inner surfaces of the upper arms, and in the axillæ. The rash reaches lower down on the thighs and further up on the chest than the petechial rash. It sometimes surrounds the body, leaving the back above the spines of the scapulæ free and the buttocks below the line of the trochanters.

The duration of the initial rashes varies. The erythematous rash remains bright but for a short time; it simply fades to light red and disappears without leaving any pigmentation. The petechial and petechio-erythematous rashes begin to fade slowly one or two days after their first appearance, leaving considerable pigmentation and mottling of the skin, which disappears after periods varying from three to twenty days in different cases.

The prognostic value of the Initial rashes may be summarised as follows:—

(i) If the patient has a purely erythematous rash he is more likely to have a slight attack of small-pox than if he have any other initial rash or none at all.

(ii) If the rash is petechial the case is about twice as likely to be a confluent or semi-confluent attack, but the ultimate result is likely to be almost as favourable as in general cases.

(iii) If the rash is petechio-erythematous the case is almost three times more likely to be severe than in general cases, and the termination is more likely to be unfavourable. The darker the redness, and the more persistent it is on pressure, the more likely is the case to be severe. If a purely petechial rash is on one part of the body and a purely erythematous rash on another, the prognosis is more favourable. In forming an opinion, other circumstances besides the initial rash must be considered and weighed. These rashes appear with great irregularity—some epidemics affording numerous instances, others very few; hence the scanty reference to them in the records of older epidemics.

3. *The Eruptive Stage*.—The peculiar eruption invariably appears after the completion of forty-eight hours of initial fever, and it should be remembered that the statements made by patients as to its accession put it, as a rule, later than it really occurs, the spots being so minute that they often at first escape observation. The forehead and hairy scalp are by far the most common sites for the first appearance of the rash. After these come, in order, the backs of the wrists, the trunk and arms, and finally the legs. With the advent of the rash comes a marked fall of temperature, the normal not infrequently being reached by the time the exanthem is fully out. At the same time the mucous membranes become affected, the eruption appearing in the mouth, on the pharynx, cheeks, lips, tonsils, œsophagus, vulva, vagina, anus, and extreme end of the urethral canal. The papules are at first slightly red, so minute that they may be easily overlooked, but yet conveying a distinct sense of irregularity to the finger as it is passed over the surface, as though millet-seed or small shot were embedded in the skin; if the patient, however, be cold, with contracted facial capillaries, the eruption may not be so easily detected. More slowly, usually some hours later, after the primary papules have appeared on the face, those on the legs develop, and last of all on the feet. The full efflorescence is reached usually in from 48 to 72 hours, and portions of skin upon which mechanical irritation or pressure has existed as from bands of petticoats, garters, collars) will reveal very closely congregated papules, strikingly in contrast with other parts; further, although the eruption may be considerable on the back, breast, arms, and trunk, it is always very sparse on the abdomen. On the third day of the rash, vesicles are formed filled with clear fluid; these enlarge until the fifth day, by which time they have attained the size of a pea, and are semiglobular and umbilicated, in a greater or less number.

4. *The Suppurative Stage*.—About the eighth or ninth day of the eruption, the contents of the vesicles become purulent, the areola seen at first surrounding the pocks is more extended and of a deeper colour, the umbilication is lost and the pustules have a flattened top, appearing of a greyish-yellow colour. These changes are first noticed on the face and follow the order in which the eruption appeared. If the eruption is discrete, the temperature of maturation does not as a rule rise, except for a few hours, and convalescence is not therefore retarded. If there be a plentiful crop of pustules there is generally a considerable degree of swelling of the face which also extends to the scalp, often involving the eyelids in such a manner that the eyes are completely closed. This subsides about the tenth or twelfth day, by which time the hands and feet are seen to have participated. Some pain in the throat with dysphagia is common when the swelling of the face arises, and at the same period an amount of viscid saliva dribbles from the mouth.

5. *The Desiccative Stage* begins about the eleventh or twelfth day, sometimes earlier; the facial pustules first commence to dry up and rapidly proceed to form crusts or scabs, which fall off after a variable time. Some of the pustules are always liable to be prematurely broken by accident or the patient's interference, and these will consequently crust over earlier than they otherwise would have done. So that in fixing the period of desiccation, those pustules only must be regarded of which the natural

progress has not been interfered with. Red spots are always left which are somewhat elevated as long as the skin remains swollen, but after a time either disappear, without leaving a trace, or else change to depressions varying with the amount of damage done to the true skin by ulceration. Those with long-adherent crusts invariably leave deep cicatrices with inverted edges, and a punctated seamed base; such are particularly observable about the *alae nasi*.

VARIETIES.—A slight innovation on the usual nomenclature of the various kinds of the disease is ventured upon, as it is difficult to classify one or two under the usual divisions employed.

They may be described under eight headings: (1) Discrete; (2) Confluent; (3) Semi-confluent; (4) Hæmorrhagic or Malignant; (5) Hæmorrhagic pustular; (6) Modified (Varioloid); (7) Variola Aquosa; (8) Corymbosæ.

1. The *Discrete* form may be taken as the standard for descriptive purposes, as the number of such cases forms by far the larger proportion of those attacked and has already been considered in the foregoing paragraph.

2. The *Confluent* form commences like the discrete, but the initial symptoms are invariably more grave and pronounced; indeed, it may be said that the intensity of the symptoms in the prodromal stage is in direct proportion to the subsequent eruption, and that high temperature and severe disturbances usually (but not invariably) indicate confluent small-pox. The eruption appears earlier and spreads more rapidly than in the milder forms. The papules are always discrete at first, but subsequently coalesce; but however numerous they may be on the face, hands, and feet, they will always, as in the discrete form, be found less scanty on the extremities, and very sparse indeed on the abdomen. The temperature falls but little on the advent of the rash, remaining persistently high from the onset; occasionally, however, there is so marked a reduction of fever that the patient fancies he is progressing satisfactorily. By the eighth or ninth day, the pocks having attained their maximum pustular size, and the bluntness of their summits giving way to a hemispherical shape, there is a recrudescence of temperature, which perhaps reaches 104° or 105° . The pulse is very rapid, there is marked throbbing of the carotids, and great restlessness and insomnia are present. About this time the peculiar characteristic constant greasy odour becomes accentuated, and violent delirium appears—demanding constant nursing. The writer has seen this derangement assume both a grave homicidal and suicidal tendency. Salivation in adults is often profuse, the cervical and inguinal glands enlarge, and great tumefaction of the head and face appears—so pronounced is this general swelling that the patient cannot see, hear, or smell. The presence of the eruption on the mucous membrane renders swallowing, breathing, and micturition almost impossible, and makes up a sum total of misery perhaps unequalled by any other disease. In fatal cases by the tenth or eleventh day a typhoid condition ensues. In other instances the maturation of the pustules goes on for a day or two satisfactorily, then suddenly the pulse falters, the pustules collapse, the extremities become cold, and the patient dies. A fatal termination occurs as a rule on the eleventh day in vaccinated subjects, on the ninth in the unvaccinated. In favourable cases, about the eleventh day the secondary fever abates.

Between the Confluent and the Discrete forms there is necessarily constructed a third class, or :—

3. *The Semi-confluent* cases, in which some of the pustules stand distinct, others coalesce, the confluent patches being more or less numerous. There is in consequence a very appreciable gradation of risk to life, as when the confluent patches are many and extensive the form may be divided by a fine line only from that of the true confluent; indeed, this class furnishes a large mortality—in some epidemics reaching as high as 16 or 18 per cent.

4. *Hæmorrhagic* or *Malignant* form (Synon. : *Variola Nigra*; *Variola Hæmorrhagica*; *Black Small-pox*; *Purpura Variolosa*).—The initial symptoms are very pronounced; there is great pain in the lumbar and præcordial regions, and almost constant vomiting; the rash appears after forty-eight hours of high fever, but it is only on careful inspection that a few scattered papules are discovered in the usual situations, while the intervening skin is of a dark brick-dust colour. About the third or fourth day the greater part of the body is ecchymotic, emitting an almost intolerable odour, in which the breath participates. The face is not only somewhat swollen, but dark purplish in colour, the conjunctivæ are swollen and black, hæmorrhage having taken place beneath them, and the corneæ appear as if sunk in dark-red pits, from which blood often trickles down the cheeks. Hæmorrhage also occurs from the mucous surfaces, from the bowels, stomach, lungs, kidneys, and bladder, and in women from the vagina—occasionally from all combined. If the patient lives until the third or fourth day, a few vesicles may be seen; these are, however, invariably scanty and abortive, and to the inexperienced add little to aid in the diagnosis of the disease. The temperature is very variable, sometimes high, sometimes sub-normal, and the mental faculties are invariably painfully lucid up to the moment of dissolution. Young and strong persons, with dark eyes, hair, and complexion, are more frequently the victims of hæmorrhagic small-pox.

5. *Hæmorrhagic pustular* form.—This form of the disease, from which recovery often takes place, presents certain common features and peculiarities. It is so named from the fact that the contents of the pustules become black-centred, caused by a complete stasis of the blood in a cluster of engorged capillaries. The hæmorrhage occurs during the change from vesicle to pustule, the eruption then aborting and convalescence being soon established. In this mild form there is rarely hæmorrhage from mucous surfaces and the constitutional symptoms are not more marked than in an ordinary case of moderate severity. The blood-containing pocks are also formed on the lower extremities from mechanical causes, as by running about when in a state of delirium, or after much handling by attendants. When with this condition hæmorrhage into the skin, beneath the vesicles or pustules and from the mucous membranes, occurs, the cases prove fatal in the great majority of instances, death generally taking place as soon as the pustular stage is reached or even sooner.

6. *Modified small-pox* is that which occurs subsequent to a more or less successful vaccination, and is seen in the bulk of patients admitted into small-pox hospitals. This was shown by the writer in an analysis of 10,403 cases, of which 6,939 were beyond question vaccinated in some form or the other. The initial symptoms of such

may be severe, but are not usually so; and the influence of the vaccination being still retained, renders the course of the disorder less dangerous and diminishes the intensity of the primary fever. When the eruption appears the difference between variola and varioloid becomes apparent: the rash is sometimes exceedingly scanty; owing, however, to the bad quality of the primary vaccination or to the exhaustion of its protective power, cases are seen in which the eruption is very copious and exceptionally confluent. These cases seldom, however, in early life fail to follow a very different course from that of true variola. On the fifth day the papules become vesicles, which in a day or two dry up, while the almost complete absence of secondary fever is both its constitutional peculiarity and the main source of the patient's safety.

7. *Variola Aquosa* is a very fatal form in which the eruption never becomes pustular. It is characterised by large, watery vesicles, tending to form patches; the skin of the hands and knees looks as if it had been macerated for a long time in water, the epidermis completely separating from the cutis on pressure. The eruption in such cases is scarcely elevated above the surface of the skin of the face and body; it is flattened and without definition of form. The temperature is generally low, there is marked depression of the vital powers from an early stage, the extremities are generally cold and the patient very uneasy and restless.

8. *Corymbosæ* small-pox is a very rare form of the disease, the peculiarity being that the eruption is arranged in clusters like berries. The mortality it causes is quite out of proportion to the amount of rash. Vaccinated persons are more frequently attacked than the unvaccinated, and there is a great tendency to the formation of symmetrical patches. Some capital has been made by anti-vaccinators in reference to this class of case by pointing out that in Marson's patients, as in others, they occurred more frequently in the vaccinated. This was owing only to the small number of this curious form of small-pox being observed by him and others.

DIAGNOSIS.—In a well-marked instance the diagnosis is very easy. In the less severe cases reliance must be placed, not on a single sign or symptom, but on the collection and comparison of all. During the initial stage the difficulty may be great, yet an error at this stage may be followed by disastrous results, not only to the patient but to others, to whom the disease may be inadvertently communicated. A character peculiar to small-pox is the suddenness of the invasion, accompanied by a peculiar and generally persistent state of præcordial trouble, and one of the almost constant precursors is backache; these, combined with frontal headache, high temperature, rapid pulse, and a general feeling of severe illness, are symptoms of marked importance. Still, they are not sufficiently definite to warrant a reliable diagnosis of small-pox until the appearance of the characteristic eruption. Measles is the disease with which variola is most frequently confounded, and the appearance of the skin during the early stage of eruption is certainly very like it, but the maculæ in the former are developed simultaneously on the face, trunk, and extremities, and are accompanied by running at the eyes and nose, and a harsh, dry cough; the exanthem also appears on the *fourth* day, while that of small-pox follows on the *third* day, or after forty-eight hours' illness.

In measles, again, the papules are not so elevated, and therefore are not so distinctly felt as in small-pox. Very important, too, is the degree of fever in variola in the initial stage; although it may at first reach 105° or 106° F. the temperature falls soon after the eruption appears, while in measles it continues the same or even rises.

Varicella often leads to difficulty in diagnosis. See CHICKEN-POX, p. 279.

In the form of syphilitic eruption which looks like small-pox, the rash is scattered symmetrically over the face, limbs, and trunk; it may be discrete or confluent; the papules are hard and shotty at first; they have depressed centres; they form adherent scabs, and they leave scars. The eruption differs from variola in the slowness of its evolution, in its long persistence and its very slow decline. It is only in its early stages that mistakes in diagnosis are likely to occur.

In *Glanders* the initial symptoms somewhat resemble small-pox, and the rash consists of hard papules, which, however, speedily become ulcers (see p. 579). Like *varicella*, this rash appears in successive crops; and there is no defined period (forty-eight hours) of prodromal fever as in variola. Certain *drug-rashes*—*copaiba* and iodide of potassium—are like small-pox, while vaccination with calf-lymph may develop an erythematous rash known as *Roseola vaccinosa* appearing from the 8th–12th day, which has been mistaken for the eruption of variola.

Erysipelas simulates small-pox by causing redness, swelling, and fever, but all the other symptoms are wanting; and other diseases associated with pain in the back have given rise to errors in diagnosis. See LUMBAGO.

PROGNOSIS.—The factor of the highest importance is the presence or absence of one or more typical vaccine-scars. Unmodified small-pox is an exceedingly fatal disease (see MORTALITY, p. 1028). The disease is more fatal at the beginning and during the height of an epidemic than at its close; periods of the year also appear to exercise some influence on the mortality; therefore, in the consideration of the probable result of any given case, several circumstances must be kept in view, as: (1) The character and amount of vaccination. (2) *Age*.—Very few infants under one year recover, and from birth to five years the disorder is very fatal. In old age the chances of recovery are slight. (3) *Pregnancy*.—The mortality in pregnant women is greater than in non-pregnant women, and gestation probably tends to impart the hæmorrhagic character to the disease (see PREGNANCY, Disorders of). (4) *Eruption*.—The quantity and character of the rash must be regarded; if scanty the disease rarely proves fatal. Confluence, on the other hand, is of the utmost gravity. Flattened pustules, lack of acuminations, pasty-white eruption without swelling, and all forms of hæmorrhagic spots render recovery improbable. (5) *Delirium* is a comparatively harmless symptom. In confluent cases patients die from exhaustion and septicæmia; rapidity, dicrotism and feebleness of pulse are critical signs, as also low muttering delirium, restlessness, insomnia, diarrhœa, absence of perspiration, and refusal of nourishment.

COMPLICATIONS.—*Bronchitis*, sometimes associated with *Pneumonia*, is generally present. *Pleurisy*, often purulent, is a tolerably frequent and dangerous complication. *Diphtheria* is an accredited complication. The writer has seen many

laryngeal disorders in small-pox, but never anything resembling characteristic diphtheritic membrane. *Glossitis* arises during the secondary fever; the tongue becomes enormously swollen, causing dyspnoea and dysphagia. Few of those so attacked recover. *Inflammation of the larynx*, leading to ulceration of the mucous membrane and necrosis of the cartilages, is now and then seen; in such the epiglottis and aryteno-epiglottidean folds are oedematous, with the cartilages necrosed and surrounded by pus; this generally occurs during convalescence, and may terminate in either dysphonia or aphonia.

Otorrhœa and its results are not infrequent; but *mastoid abscess* is a very rare complication.

Ulceration of the Cornea is a common complication, and often leads to complete destruction of one or both eyes. It begins at various stages of the disease—the second week is, however, the most common—and runs a very rapid course. Starting as a conjunctivitis with itching and photophobia, it extends in perhaps a few hours only to the covering of the eyeball: the swelling rapidly increases, and at the same time a copious purulent discharge occurs. On examination, a small spot of ulceration can be seen near the margin of the cornea; this spreads with marvellous rapidity, destroying the several layers, and giving rise to hypopyon and panophthalmitis. It is very doubtful if, as stated by some, pocks form on the eyeball. The most favourable result is an interstitial keratitis.

The *abdominal viscera* are rarely affected, but occasionally diarrhœa is very persistent. *Edema of the legs*, due to weakness and exhaustion, is sometimes seen; it may also be due to chronic nephritis, but the latter is a very rare sequela of small-pox. *Permanent psychical disturbance* is the result occasionally of the delirium, and occurs in both mild and severe cases. *Dementia* occasionally results. See INSANITY IN SPECIAL DISEASES, p. 770.

Boils are the most common of all the sequelæ of small-pox. They are very numerous and painful, and protract the convalescence.

Gangrene, usually of penis and scrotum, and *erysipelas* of scalp and face are sometimes met with, and almost invariably after confluent small-pox, at the end of the second week.

Orchitis is an occurrence of considerable frequency, especially in severe cases; it is occasionally met with in lads, but more often in adults, and appears and develops with the eruption. Resolution is the usual termination.

Baldness of a permanent character may result from small-pox, also loss of beard and whiskers.

TREATMENT.—There is no drug capable of exerting an influence over the course of the disease after the manifestation of the symptoms peculiar to small-pox, but at certain stages vaccination can prevent or modify it: for example, if the operation were performed within forty-eight hours after a person had been exposed to, and contracted the disease, his safety would be secured; if delayed for seventy-two hours the attack would be modified; done later, however, it would be absolutely ineffectual, and serve only to bring vaccination into disrepute. The only two drugs that have justified a trial are salol and sulphite of sodium. The ordinary rules for nursing infectious patients must be carried out; the nurses should be protected by vaccination (see NURSING THE SICK; FEVER, p. 535). If the rash come out thickly it will be wise to remove as much of the hair off the head and face

as possible. The diet should be light and nutritious; for ordinary drink fresh-made lemonade is acceptable, and for children cold or iced water. Stimulants with eggs may be required; the diffusible stimulants, as ammonia and ether, may be needed. Constipation should be relieved. Daily tepid sponging of the whole body must be insisted upon, and as it is common for boys and men who have long prepuces to suffer from retention of urine from phimosis, this should be attended to, as also the state of the genital organs of women; indeed the utmost cleanliness cannot be too strongly enforced.

During the stages of suppuration and desiccation prolonged warm baths are appreciated, by which the local inflammation is often much reduced. In France the patient is sometimes completely washed two or three times a day in a solution of perchloride of mercury (1 in 1,000). The use of a dark chamber is said to have modified the eruption; the same results are perhaps obtained by excluding the ultra-violet rays, which have strong chemical action, by means of red window-glass and red curtains. The early convulsions of children are best met with bromide of potassium and henbane, while sleep in adults is obtained either by morphine or the administration of liquor opii sedativus. Chloral hydrate is an untrustworthy narcotic, and by no means devoid of danger. Care should also be taken not to push narcotics too freely, otherwise coma may ensue and a fatal collapse. For the throat-trouble, ice constantly sucked, a gargle of carbolic acid and glycerine, or a solution of chlorate of potassium affords relief. Spraying with glycerine and tannin or alum is sometimes useful. In the violent delirium, so often associated with small-pox, mechanical restraint is often demanded to obviate unexpected results, and although alcohol too often plays an important part in the causation, no doubt it is partly occasioned by the intensity of the fever. Reduction of temperature usually resists the measures employed. Antipyretics avail but little, and are not devoid of danger; even the cold bath is not efficacious, except for very short periods. In the stages of pustulation and scabbing intolerable itching is often complained of, and for its relief vaseline and carbolised oil, or some other greasy material is the most favoured. The result of considerable experience teaches that anti-pruritic remedies are useless, and tend to promote rather than prevent both the pitting and the great irritation that occurs. Lead-lotion, to which has been added liq. carbonis detergens, applied warm, very frequently answers better. In young children nothing avails if this symptom is much in evidence, and it portends an almost certainly fatal result. Gregory's remark that 'the masks and ointments formerly in use for that purpose (the prevention of pits and scars) are in reality more hurtful than beneficial' is as true now as when he made it.

Pain in the feet—sometimes very intense—is best relieved by a hot linseed poultice.

Complications must be treated according to their nature. The most satisfactory procedure as regards the terrible affection of the eyes is the application of the yellow oxide of mercury to the ulcer itself as soon as discovered, supplemented by the frequent and free use of a lotion made of extract of belladonna (gr. x ad ʒj), applied as warm as possible; this keeps the pupil well dilated, diminishes swelling, and reduces the pain, which, however, is as often absent as present.

Small-pox patients convalesce quickly and require few if any so-called tonics; their large appetites are notorious. Warm antiseptic baths should be taken every second or third night during the stage of convalescence, and no patient should be permitted to mix with the healthy until every scab has fallen off and the skin is in a normal condition. Scabs are often found under the nails of both feet and hands, which sometimes are cast off.

The disposal of the dead claims attention, and certain precautions are imperative. Delay in burial should be most strenuously opposed, and cremation by all means carried out if possible. See PUBLIC HEALTH: Disposal of the Dead, p. 1346.

For the disinfection of the room occupied by a small-pox patient, see article DISINFECTION, pp. 412-415; and PUBLIC HEALTH, p. 1345.

W. GAYTON.

SMELL, Disorders of.—See NOSE, Diseases of; and OLFACTORY SENSE.

SNAKE-POISONS.—See VENOM, Effects of; VENOMOUS ANIMALS.

SNEEZING, Paroxysmal.—SYNON.: Fr. *Coryza Spasmodique*; Ger. *Niesekrampf*.

DEFINITION.—An affection characterised by frequent and uncontrollable attacks of sneezing, out of proportion to any nasal secretion.

ÆTIOLOGY.—The causes of excessive sneezing may be broadly classified as *extrinsic* and *intrinsic*. *Extrinsic* causes include especially various vegetable substances in the form of powder, of which tobacco-snuff is the type, and the pollen of certain plants the most frequent example (see HAY FEVER). The *intrinsic* conditions in connection with which the affection occurs vary considerably. In some cases it is associated with whooping-cough or asthma, and it is especially common in young persons. Paroxysmal sneezing, especially in the early morning, is occasionally associated with epilepsy. It has been met with in pregnancy, and even during more than one pregnancy in the same person, ceasing in the intervals, and has been supposed to replace morning-sickness (Barnes). In some persons a bright light or intense colour is sufficient to determine an attack of sneezing, apparently by some abnormal sensory association.

SYMPTOMS.—The morbid sneezing has no special characters. It is distinctly a reflex act, being usually excited by some slight impression on the fifth nerve. A catarrhal condition of the nasal mucous membrane is common. The secretion has been thought to be, in some cases, of a special character, but its nature is unknown.

TREATMENT.—The attack itself may usually be cut short by a strong impression on some branch of the fifth nerve; when this fails, a mustard poultice to the back of the neck, or an emetic, may be employed, if the attack is sufficiently severe. Atomised astringent nasal inhalations, or the vapours of creosote or iodine, are useful, but the most effectual agent is the application to the nasal mucous membrane of a solution of hydrochloride of cocaine by a nasal douche. The general health should be put right, and a course of bromide of potassium is often useful, combined with iron, quinine, or arsenic. See CATARRH; and HAY-FEVER.

W. R. GOWERS.

SNUFFLES.—A popular term for the condition in which a nasal discharge exists in children suffering from congenital syphilis. See *SYPHILIS*.

SODEN, in Taunus, Germany.—Common salt waters. See *MINERAL WATERS*.

SOFTENING.—*SYNON.* : Fr. *Ramollissement*; Ger. *Erweichung*. See *BRAIN*, Softening of; *SPINAL CORD*, Softening of; *FATTY DEGENERATIONS*; *THROMBOSIS*; and *EMBOLISM*.

SOMNAMBULISM.—Sleep-walking. See *SLEEP*, Disorders of.

SOMNILOQUY.—Sleep-talking. See *SLEEP*, Disorders of.

SOMNOLENCE.—An unnatural drowsiness or disposition to sleep. See *SLEEP*, Disorders of.

SONOROUS RHONCHUS.—A variety of dry *râle* or rhonchus, of a low-pitched character, resembling snoring and similar sounds, and produced in the larger air-tubes. See *PHYSICAL EXAMINATION*; and *RHONCHUS*.

SOPOR (Lat.).—An unnatural deep sleep, from which the patient can only be roused with difficulty. See *CONSCIOUSNESS*, Disorders of.

SOPORIFICS (*sopor*, heavy sleep).—*SYNON.* : Fr. *Soporifiques*; *Soporatives*; Ger. *Einschlâfernde Mittel*.—Agents that promote sleep. See *NARCOTICS*; and *SLEEP*, Disorders of.

SORDES (Lat. : filth).—*DEFINITION.*—Crusts which form upon the lips and teeth of persons suffering from extreme exhaustion.

DESCRIPTION.—Sordes occur commonly in what is called the typhoid state, whether this be due to typhoid fever or to the intoxication produced by the poisons of any of the pathogenic organisms which multiply in the body. Sordes appear first as thin, light-yellowish crusts upon the prolabia, generally in close proximity to the teeth; gradually increase in thickness and in area; and, changing their colour to brown, or even black, at length extend to the adjacent surfaces of the teeth. They seldom or never cover those portions of the teeth which are hidden by the lips, but spread over their exposed surfaces; so that, as the patient lies with slightly parted lips, they bridge over the interval in the form of a narrow band upon the middle of the incisors of the upper jaw. When the lips are more widely separated, the sordes do not extend, except in conditions of extreme exhaustion, over the whole of the exposed surfaces of the teeth, but form two ridges, corresponding with the margins of the upper and lower lips.

PATHOLOGY.—Sordes are composed of various schizomycetes, mingled with *débris* of food and epithelium. Micrococci of various forms, and often diplococci, with bacteria and bacilli, occur almost constantly; *Bacillus subtilis* frequently; and one of the writers has found, each in a single instance, *Sarcina ventriculi* and *Spirochaeta plicatilis*.

TREATMENT.—These organisms, which are of constant occurrence on the papillary surface of the healthy tongue, are easily dislodged from the smooth lips and teeth. But in conditions of great prostration, especially when the prostration is associated with delirium, the slight frictions necessary for their

removal are not made. There is often a marked absence of saliva due to its deficient secretion; hence they obtain so firm a hold that they can only be removed by careful and repeated cleansing. Such cleansing may with advantage be performed with a piece of soft rag, or a brush, dipped in a weak solution of Condyl's fluid, or in the glycerine of boric acid. A spoonful of iced water repeated frequently will be a great comfort. So, too, is a small piece of ice allowed to dissolve in the mouth, or lemonade, or weak black tea without milk, slightly acidulated with a slice of lemon.

HENRY T. BUTLIN.
D'ARCY POWER.

SORE-THROAT.—A popular name for various affections of the pharynx, larynx, and tonsils. See *LARYNX*, Diseases of; *PHARYNX*, Diseases of; and *TONSILS*, Diseases of.

SOUFFLE (Fr.).—A soft, blowing sound. The term is applied either to the respiratory murmur heard over the lungs; or to certain murmurs heard in connection with the heart or blood-vessels. See *PHYSICAL EXAMINATION*.

SOULZMATT, in Alsatia.—Alkaline table-waters. See *MINERAL WATERS*.

SOUTH AFRICA.—No description of this country in its present condition (November, 1901) can be of any medical interest.

SPA, in Belgium.—Iron or chalybeate waters. See *MINERAL WATERS*.

SPAIN, Southern.—See *MALAGA*; and *CLIMATE*, Treatment of Disease by.

SPANÆMIA (*σπανός*, rare; and *αἷμα*, blood).—A condition of blood, in which the proportion of its solid constituents is below the normal, the blood thus appearing thin. See *ANÆMIA*; and *BLOOD*, Morbid Conditions of.

SPAS.—See *MINERAL WATERS*.

SPASM.—*SYNON.* : Fr. *Spasme*; Ger. *Krampf*. *DEFINITION.*—A name given to abnormal contraction, occurring either in muscular organs, in single muscles, or in groups of muscles.

I. Spasm of muscular organs.—We may cite as instances those spasms which occur in the pharynx in hydrophobia; the contractions of the œsophagus in œsophagismus and in some cases of hysteria; the painful contractions of the intestine constituting intestinal colic; of the lower end of the rectum in tenesmus; of the bladder or of the urethra in certain cases of inflammation with irritability; of the vagina in vaginismus; of the uterus in rare cases of sudden abortion resulting from shock; possibly of the heart in certain diseases of that organ; of the vessels in various regions of the body, and on various occasions, from overaction of vaso-motor nerves; of the bronchial tubes in certain cases of asthma and hay-fever; of the glottis in laryngismus stridulus, and in pertussis; as well as of the gall-ducts or ureter under conditions of irritation, either direct or reflex. All are due to excessive nervous stimuli, maintaining conditions of muscular contraction which are unusual both in degree and in duration. These spasms are, therefore, tonic in type, and in almost all the cases cited involuntary muscular

fibres are those involved. See COLIC; and the various articles on the special organs involved.

2. *Spasm of single muscles or of groups of muscles.* This is divisible into two main categories, that is, into *tonic spasms*, in which the contractions are continuous, and *clonic spasms*, in which contractions and relaxations occur in quick succession; the former being typified by cramps, and the latter by convulsions.

Under *tonic spasms*, we may have cramps of brief duration, affecting a single muscle, such as the diaphragm in hiccough; or of prolonged duration, as in the sternomastoid in certain cases of wry-neck. The tonic contraction may affect several muscles at the same time, as in lock-jaw, or the painful cramps which occasionally occur in the calves of the legs, or in other parts of the body. Such local spasms occur also in the condition known as tetany, in conjugate deviation of the eyes, and in writer's cramp; likewise in spasmodic spinal paralysis, in hysterical paralysis, and under various conditions of irritative organic disease implicating motor nerves, or motor centres or tracts either in the spinal cord or in the brain. More general tonic spasms occur in cataplexy, in tetanus, and in strychnine-poisoning.

This whole class of tonic spasms is supposed to be due to irritation, mechanical or chemical (nutritive), operating *directly*, either upon motor centres or upon the fibres conveying motor incitations in some part of their course between the brain and the muscles. In other cases, however, tonic spasms are of *reflex* origin, and the cause of irritation operates in or upon sensory surfaces, nerves, or centres.

Clonic spasms are also of various kinds. They may be limited to single muscles, such as the orbicularis palpebrarum; or they may affect particular groups of muscles, such as those of one side of the face, or the muscles of the lower jaw on both sides, or certain of the abdominal muscles, or some of the foot-muscles, as in ankle-clonus. In other cases clonic spasms may be more general, taking the form of unilateral or of bilateral convulsions. The latter also may be irregular or of coördinated type.

Where clonic spasms are much slighter in degree and in range, affecting some muscular fibres and that to a small extent, rather than entire muscles in a more marked manner, we have the production of *tremors*, which may be either fine or coarse, local or general.

Transitional conditions also exist, connecting all these various manifestations more or less closely with one another. See STRYCHNINE, Poisoning by; TETANY; WRITER'S CRAMP.

H. CHARLTON BASTIAN.

SPASMODIC.—SYNON.: Fr. *Spasmodique*; Ger. *Krampfhaft*.—A descriptive epithet applied or applicable to conditions or diseases in which spasms, and mostly those of the tonic class, are met with as prominent or essential constituents; for example, *spasmodic croup*, *spasmodic asthma*, *spasmodic stricture*. See SPASM.

SPASMUS NUTANS.—See HEAD-NODDING OF INFANTS (p. 630).

SPECIFIC.—When applied to a disease, the word 'specific' signifies that such disease is produced by a cause different from that of any other disease, and that it has distinctive characters; for example, syphilis and the eruptive fevers. When

applied to a remedy, it implies that the substance has a distinct and definite effect in the cure of a certain disease, such as mercury in syphilis, or quinine in ague; or that it acts upon a particular organ, as ergot upon the uterus.

SPECTACLES, Uses of.—See STRABISMUS; and VISION, Disorders of.

SPECTROSCOPE IN MEDICINE.—INTRODUCTION.—Defining a prism in optics, as a solid angle bounded by two planes, it may be stated generally, that a spectroscope consists essentially of a prism and a slit. A diffraction-grating may replace the prism, but for medical purposes no advantage is gained by its use.

According to the kind of spectroscope, other accessories are required; thus, there are two kinds of spectroscope used for medical purposes—*chemical spectroscopes* and *micro-spectroscopes*. In the former the slit is set at one end of a tube, known technically as the collimator, at the other end of which, and having the slit in its focus, is a lens which makes the rays admitted through the slit parallel before entering the prism. The prism refracts and disperses (when they can be dispersed) the rays passing through it, and, if they be rays of white light, they emerge from the second face of the prism as a coloured image of the slit, red at one end, violet at the other, passing from red into orange, yellow, green, blue, and violet. This rainbow-band is the continuous spectrum of the light-source. If, on the other hand, a light-source be used containing not compound rays, but those of one colour only—for example, such as are yielded by a colourless flame into which a salt of sodium is introduced—then the rays emerge from the prism as a yellow line, a yellow image of the slit. The prism should be set at the minimum angle of deviation for the sodium-line. (For the meaning of this term, and the method of setting the prism, the reader may consult Glazebrook's *Physical Optics*.) The spectrum is then magnified in a telescope, which is a small astronomical refractor, moving round the table of the spectroscope, and capable of being focussed.

In *direct-vision* spectroscopes, to which the micro-spectroscope belongs, a compound prism is used; by this means the slit and the prism can be placed in the same straight tube.

In the *micro-spectroscope*, which is a combination of a microscopic eye-piece and a direct-vision spectroscope, a lens collects the rays. Passing up in the optic axis of the tube of the microscope, they then fall on the slit and are made parallel by another lens placed between the slit and the compound prism. This compound prism is composed generally of three prisms of crown-glass and two of flint-glass, united to each other by Canada balsam. By such a combination deviation is eliminated, while sufficient dispersion is retained to make the spectrum long enough. A right-angled reflecting prism covers half the slit, so that a second spectrum can be compared with that of the substance beneath the objective of the microscope; a side-stage being adapted to the side of the micro-spectroscope, perforated with a square hole, and provided with spring clips to hold tubes, &c., the light being reflected into the hole by means of a plane mirror suitably mounted. The slit can be widened and narrowed by means of a screw and springs bearing on the

jaws of the slit, which should be made to move away from each other equally, as this prevents displacement of the centre of a band or line when the slit is widened.

It is advisable to work with both these instruments; but if one only is desired, then the micro-spectroscope is to be recommended. Useful observations may be made, however, with a pocket spectroscope, procurable at a trifling cost.

DIFFERENT KINDS OF SPECTRA.—When light from various sources is examined with the spectro-scope, the appearances observed may be classed under three heads: (1) Spectra consisting of bright lines or striæ; (2) Continuous spectra; (3) Absorption-spectra.

(1) *Bright-line spectra* consist of bright lines on a dark background, occurring singly or in groups, placed in the same or different parts of the spectrum. Glowing gases or glowing vapours yield such spectra when their combinations are heated in the Bunsen flame; the heavy metals require to be volatilised at a much higher temperature by means of the electric spark.

Metallic poisons may be detected by their bright-line spectra; and the elements, sodium, potassium, calcium, and others, can be similarly detected in the ashes of calculi, and elsewhere. The late Dr. Bence-Jones, in his study of the 'chemical circulation,' used the spectroscope to determine the rapidity of the distribution of lithium-salts to distant parts of the body, such as the crystalline lens and the hip-joint.

(2) *Continuous spectra* are yielded by incandescent solids and fluids. Gas-light, candle-light, the electric and lime-lights, incandescent platinum, &c., yield a continuous spectrum—the band of colours referred to above, red, orange, yellow, green, blue and violet—one colour passing gradually into the next without break.

(3) *Absorption-spectra* are of two kinds: (a) those consisting of black lines occurring in a continuous spectrum; and (b) those consisting of broad black spaces, or shadings of varying degrees of darkness, in a continuous spectrum. The spectrum of the sun, and of many of the stars, are examples of the former, and the latter are those with which medical spectroscopy has to do. These black lines, bands, or shadings are spaces of darkness in the spectrum due to the absence of certain rays. Those in the solar spectrum, which were discovered by, and named after, Fraunhofer, are caused by the presence of vapour in the sun's atmosphere. Every gas and every vapour when in a comparatively cool state absorbs the same rays that it emits in the incandescent state. If no vapour existed around the sun, then we should have thousands of bright lines belonging to the elements burning in the sun. Some of the solar lines are, however, telluric, i.e. of earthly origin, and are due to absorption in the earth's atmosphere. The most prominent Fraunhofer lines, beginning from the red end of the spectrum, have been called A, a, B, C, D, E, b, F, G, and H.

Solutions of animal and vegetable colouring-matters have the property of arresting certain rays of light passing through them; and corresponding to the rays stopped, or enfeebled, we have spaces of darkness in the spectrum—the *absorption-bands*. Solid pigments may do the same, even when the light analysed (by the prism) is reflected from their

surface. Absorption may, however, be general, that is, one or the other end of the spectrum may be absorbed.

THE STUDY OF ABSORPTION-SPECTRA.—Two pigments may give the same spectrum, and yet not be identical; to prove identity their respective spectra must be changed in the same way by reagents. In studying such spectra the first thing to be done is to map the principal lines in the solar spectrum. By consulting a map of the solar spectrum, and then examining the spectrum of diffused daylight, concentrated, if necessary, by a condenser on the slit, it is easy to identify the most prominent Fraunhofer lines referred to above. Of these A, a, and H are not easy to see. Next they should be mapped on a piece of smooth drawing-paper. Both the chemical spectroscope and the micro-spectroscope should be provided with *photographed scales*; angular measurements for the former are only indispensable for certain measurements, such as the calculation of refractive indices. These scales can in both instruments be illuminated by a mirror at the end of the scale-tube. By means of a millimetre-scale a map is easily made from the readings obtained from the Fraunhofer lines. The scale of this instrument is to be set so that D shall stand at a convenient number; for the chemical spectroscope it is generally set at 50.

In mapping an absorption-spectrum we begin by setting the scale. A flame coloured by a sodium-salt is brought before the slit of the chemical spectroscope, or reflected up by means of the microscope-mirror on to the slit of the micro-spectroscope; then the scale is adjusted until the sodium-line stands at the same number on the scale that the D line stood at. The slit is then illuminated by means of artificial light, say an Argand gas-burner, the light being condensed on the slit by a bull's-eye condenser in the case of the chemical spectroscope. The fluid to be examined is then placed in a vessel, such as a test-tube, held in a suitable holder, before the slit of the chemical spectroscope, or in a small flat-bottomed tube let into a thin slab of wood, for the micro-spectroscope. If the solution be too darkly coloured to transmit the spectrum, either a thinner layer or a more dilute solution must be used. Hermann's hæmatoscope is frequently used for this purpose, as by means of a screw-adjustment any depth of fluid can be examined; it is only applicable to the chemical spectroscope. The slit must not be too wide, and the focus should not be altered after the sodium-line has once been focussed. A black cloth, to exclude extraneous light, should be used to cover the chemical spectroscope. Bands in the red end of the spectrum are best seen by artificial light, in the violet by daylight. For examining portions of organs or tissues a compressorium is very useful, as various degrees of thickness can then be examined.

When publishing results it is necessary to give the measurements of absorption-bands in terms of a universal scale. Now, no two arbitrary scales agree, so that all measurements should be reduced to wave-lengths, denoted by the sign $\lambda\lambda$. Zeiss's micro-spectroscope is provided with a wave-length scale, but the readings of any spectroscope may be reduced to wave-lengths by means of an *interpolation curve*. A sheet of logarithm-paper has the arbitrary numbers of the scale of the spectroscope written out along the top line, each tenth of an inch corresponding to one division of the scale. Along the

side-line, at right angles to this, the wave-lengths are written, each tenth of an inch here being made to correspond to two millionths of a millimetre. It is convenient to begin at the top of this line with 410 millionths of a millimetre, then the next *inch* division has 430 placed opposite to it, and so on down to 730. On referring to Angström's numbers, the wave-lengths of the principal Fraunhofer's lines are found to be as follows in millionths of a millimetre: A = 760, a = 718, B = 686, C = 656, D = 589, E = 526, b = 516, F = 486, G = 430. Their value on the arbitrary scale of our spectroscope has been determined by actual measurement. By means of these data their positions on the paper are denoted by small crosses; through the centres of these crosses a curve is drawn. When now we want to know the value in $\lambda\lambda$ of any number of the scale of the spectroscope, we can find it by running the eye along the perpendicular line joining the top line with the curve, thence to the right-hand side line, where its wave-length is given. In other words, the abscissæ are the arbitrary numbers of the scale, the ordinates the wave-lengths.¹

USES OF THE SPECTROSCOPE IN MEDICINE.—It is not necessary to describe in detail the various pigments and their spectra which have been discovered in the animal body. It will suffice to point out briefly some of the applications of the spectroscope to medicine, especially as a full account of most of these pigments is given in Professor Kendrick's *Text-book of Physiology*, vol. i., and in Professor Halliburton's *Text-book of Chemical Physiology and Pathology*.

In medical jurisprudence the spectroscope is indispensable for the detection of blood-stains on clothing, knife-blades, &c. In poisoning by carbonic oxide from the inhalation of coal-gas, charcoal-fumes, &c., the spectrum of the blood is peculiar, and reduction, by means of sulphide of ammonium, cannot be brought about. Other poisonous gases have been found to enter into peculiar combinations with hæmoglobin, such as nitric oxide, &c.; doubtless research will reveal the existence of many such combinations.

To the physician the instrument is useful in enabling him to detect blood and its decomposition-products, and also bile-pigments and their decomposition-products, in urine and various pathological fluids, under diseased conditions, and from the administration of drugs. In the detection of various pigments, which cannot be recognised by other methods, microscopic or chemical, as well as in enabling us to form an idea as to the extent and nature of the metabolic changes taking place under the influence of disease, the spectroscope promises to be a helpful guide. In fact, pigments have already been found in the urine which can be produced artificially from hæmoglobin and hæmatin, &c., by certain chemical methods, by means of which we have found out how they are produced in the body. These pigments serve as finger-posts to point out the various steps of the abnormal processes by which not only they, but the substances with which they are associated, are originated. The pigment known as uro-hæmatoporphyrin may be given as an example. This can only be produced in the labo-

ratory by the action of very energetic *reducing* agents on hæmoglobin or hæmatin, yet it occurs in many diseased conditions, in which, until recently, it was supposed that increased oxidation took place; but we now know that exactly the opposite occurs, and the spectroscope confirms this. Again, the rapidity of the reduction of oxyhæmoglobin to reduced hæmoglobin may be measured by the spectroscope, as Hénocque has shown. Observing the ungual phalanx of the thumb, at the root of the nail, by means of a direct-vision spectroscope, he finds, if a ligature be quickly applied, that in health reduction takes place in seventy seconds, whereas in anæmic states it may happen in from thirty to forty seconds, being dependent on the amount of hæmoglobin, the amount of hæmoglobin reduced in one second being 0.2 per cent. under normal conditions.

Wertheimer has also made use of the spectroscope in a novel and ingenious manner. He injected sheep-bile into the femoral and mesenteric veins of dogs, and detected the presence of the writer's cholo-hæmatin in the bile of the dog within ten minutes after its injection into the femoral, and five after its injection into a mesenteric vein, showing, as he remarks, that the liver has the power of picking the constituents of bile out of the circulating blood.

Instead of repeating what is already known about the pigments and their spectra, attention is called to the accompanying chart (*coloured*), where the most important spectra are figured. In this, sp. 1 represents the spectrum of oxyhæmoglobin. That of the compounds of carbonic oxide and of nitric oxide, respectively, with hæmoglobin resembles this, except that the bands are nearer the violet. 2 is the spectrum of reduced hæmoglobin, got by adding sulphide of ammonium to a solution of oxyhæmoglobin. 3 is the spectrum of methæmoglobin, a substance intermediate between hæmoglobin and hæmatin, in which the oxygen is more firmly combined than in oxyhæmoglobin. It occurs on the edges of healing wounds, in old blood-stains, in various exudations, &c., and may be produced artificially by treating a solution of blood with a great number of reagents, which are not energetic enough to split the hæmoglobin into hæmatin and a proteid. 4 is the spectrum of alkaline methæmoglobin, *which is very often mistaken for oxyhæmoglobin in alkaline urine*. It may be obtained by adding a little ammonia to a solution of methæmoglobin. 5 is the spectrum of acid hæmatin in ether; and 6, that of alkaline hæmatin in rectified spirit. 7 is that of reduced hæmatin, got by adding a reducing agent, such as ammonium sulphide, to a solution of alkaline hæmatin. Hæmochromogen is another name for this pigment. This is a very important spectrum, as by its means blood can be detected with great certainty when present in minute traces. Sometimes blood may be present in urine, adhering to the sediment; if this be filtered off, digested in rectified spirit containing ammonia, filtered, and the filtrate treated with ammonium sulphide, this spectrum is obtained. Again, in detecting blood-stains on clothing, knife-blades, &c., the bit of cloth, or blade, is treated with the same reagents, with a similar result. 8 is the spectrum of acid hæmatoporphyrin, got by dissolving hæmoglobin in strong sulphuric acid and filtering through asbestos; and 9, that of alkaline hæmatoporphyrin, obtained by dissolving hæmatoporphyrin in alcohol and ammonia. These two spectra, and 14 and 15, should be carefully studied, as a condition known as hæmatopor-

¹ By using the *reciprocals* of the numbers expressing the wave-lengths, the curve becomes nearly a straight line. The reciprocal of a fraction is obtained by making the numerator and the denominator change places. Thus, the reciprocal of $\frac{1}{2}$ is 2, the reciprocal of $\frac{1}{5}$ is 5, and of $\frac{1}{3}$ is 3, i.e. 5.

Plate representing the Spectra of the most important Pigments.

pyrurina has lately been described, first by the writer, since then by others. In many of these cases it seems to have been caused by the administration of sulphonal or trional, but not in all. The urine is a deep Burgundy-red colour, and decomposes very slowly; a specimen may remain for years unchanged. 10 is the spectrum of normal, and 12 that of 'pathological,'¹ urobilin, in rectified spirit and sulphuric acid; that of stercobilin is almost identical with the latter. 11 and 13 are the spectra of normal and pathological urobilin respectively, treated in a spirit-solution with zinc chloride and ammonia, which develops a green fluorescence. 14 and 15 are the spectra of acid and alkaline urohæmatoporphyrin. This pigment can be obtained by treating hæmatin with energetic reducing agents, aided by heat, such as sodium-amalgam, zinc and sulphuric acid, &c.; and an early stage hæmatoporphyrin is produced, then this pigment.² It occurs as such, as the writer has discovered, in the urine of acute rheumatism, and of many other diseases, including Addison's disease. A. E. Garrod finds that its presence is independent of blood-destruction in rheumatism, and must probably depend upon a failure of those organs, in which it should be metabolised to other pigments, to effect such change. See p. 614.

Bilirubin and biliverdin, the colouring-matters of human bile, give only a *general* absorption of the spectrum; but either of them when treated with nitric acid gives 16, that of Gmelin's reaction, when the spectrum of the violet stage is examined. 17 is the spectrum of Pettenkofer's reaction; and 18, that of indigo-blue and indigo-red from *normal* urine, obtained by heating with hydrochloric acid to which a little nitric acid has been added, then, when cold, agitating with chloroform. This test succeeds when affe's fails.

The above are the most important spectra from a purely medical point of view. There are, of course, other pigments in the human body present under normal conditions, such as myohæmatin and the histohæmatins (discovered by the writer), the porphyrins or fat-pigments, formerly known as steins, and the black pigments included under the name of melanins. The last show no absorption-bands, and probably arise somehow in connection with the lipochromes, although in cases of melæuria associated with melanotic sarcomata a chromogen, or colourless mother-substance, is present which on oxidation changes into melanin. At all events, the origin of a melanin from hæmoglobin seems doubtful.

Many attempts have been made to explain the bronzing of the skin in Addison's disease, but as yet physiologists are not disposed to accept any of the hypotheses offered. The writer finds, however, that the suprarenal bodies of many mammals contain a chromogen, pointing to the indisputable fact that these organs are concerned in the downward metabolism of effete hæmoglobin; this, taken in connection with the presence of urohæmatoporphyrin in the urine, would seem to point out that, if the suprarenal bodies are diseased, then effete blood-colouring matter must be present in excess in the blood, and produce staining of skin and mucous membranes.

The writer thinks it right to add that his reasons

for supposing that there are at least two kinds of urobilin, viz. normal and pathological, and that urohæmatoporphyrin is not identical with ordinary hæmatoporphyrin, are based on the fact that similar substances are obtained by reducing hæmatin *outside* of the body. These pigments correspond with those found in urine, and whether they are mixtures or not, represent various stages of metabolism.

CHARLES A. MAC MUNN.

SPECULUM (Lat.).—SYNON.: Fr. *Speculum*; *Miroir*; Ger. *Speculum*; *Spiegel*.

DEFINITION.—An instrument adapted for exploring the several channels and deeper-seated parts of the human body. The chief of these are the ear, the eye, the nose, the mouth, the throat, the rectum, and the vagina. For each of these there are specially adapted instruments.

DESCRIPTION.—Specula are made of various materials, and in a variety of shapes. The speculum is intended not only to permit and facilitate inspection, but also to dilate the canals and to expose parts, in order that they may be treated surgically, or have medicaments applied to them. For this reason a cylindrical speculum will not always answer the purpose; we have, therefore, bivalve and trivalve specula, and many other forms. On account of the friability of glass, other material has not infrequently to be used, such as white polished metal, celluloid, or wood; the last is objectionable, as it has no reflecting power; but when it becomes necessary to apply the actual cautery through a speculum, a substance must be employed that is a non-conductor of heat and non-friable, such as wood.

VARIETIES.—**Aural specula.**—Some have a trumpet-shaped opening, which facilitates the introduction of light, and greatly increases the illuminating and reflecting power. There are also bivalve aural specula with a screw lever, and others with handles attached so as to separate the blades. See EAR, Diseases of.

Eye specula.—These are known by the name of *eyelid retractors* and *ophthalmoscopes*, both of which are really specula for examining the eye, though not generally classified as such. See OPHTHALMOSCOPE.

Nasal specula.—There are several forms of these, the great purpose they have to serve being that of dilating. One, known as Elsberg's, is three-bladed. See NOSE, Clinical Examination of.

Throat specula.—Specula for examination of the throat are generally called *laryngoscopes*. See LARYNX, Clinical Examination of.

Rectal specula.—These are cylindrical, bivalve, or trivalve. The cylindrical are made on the principle of Fergusson's vaginal speculum, but with an opening so as to expose the wall of the rectum at the part to which it is adapted. The valvular forms are made of white metal.

Vaginal specula.—Of these there are many kinds. Perhaps the most useful is that known as Fergusson's, which is cylindrical and made of glass, with a coating of mercury behind it, so as to give it reflecting power, and backed by vulcanised indiarubber. An improved variety of this is of a tapering form, so as to admit more light (see UTERUS, Diseases of). Sims' duckbill speculum is of great use in retracting the perineum and dilating the vagina, when space is required for operation, as in vesico-vaginal fistula. Then there are bivalve and trivalve metallic specula. Wooden

¹ According to some authors pathological urobilin is a mixture of normal urobilin and hæmatoporphyrin.

² Urohæmatoporphyrin is said by certain observers to be ordinary hæmatoporphyrin.

cylindrical specula are always used when the actual cautery is applied, for reasons already mentioned. For the ordinary purposes glass is the preferable material, as it is unaffected by caustics.

The uses of specula will be found described in connection with the diseases of the several organs to which they have reference.

It is worthy of record that many varieties of specula have been discovered among the ruins of Pompeii, and that recently a quadrivalve vaginal speculum has been unearthed there.

CLEMENT GODSON.

SPEECH, Disorders of.—**SYNON.** : *Troubles du Langage*; Ger. *Störungen der Sprache*.—Defects of speech are very various in their nature, degree, and mode of causation.

ÆTIOLOGY AND PATHOLOGY.—Disorders of speech may depend upon (1) *congenital*, or (2) *acquired* defects of the brain, or of certain of its nerves and sense-organs.

1. *Congenital defects.*—The most frequent and important of these defects is *deafness*, which entails mutism, so that the individuals thus afflicted are known as ‘deaf-mutes.’ It must, however, be borne in mind that this condition of mutism or dumbness may also be brought about by absolute deafness occurring from any cause after birth, but before the child begins to talk; or even after it has learned to talk, up to the fifth or seventh year. In cases of the latter type, the child, when without the accustomed guidance derived through the sense of hearing, soon forgets how to speak and becomes dumb. In addition to this class of cases, there are those of congenital idiocy without deafness, in which the child never learns to talk or articulate in the proper sense of the term (see **IDIOCY**). There are also other cases allied to the last, in which, owing to some intracranial lesion occurring either before, during, or soon after birth, the child’s subsequent mental condition is greatly impaired, as well as its motor power. In these most deplorable cases the child may never be able to speak in any distinct or articulate fashion, it may not be able to walk or even stand, or it may only be able to accomplish these latter acts imperfectly. In some of these children there is evidence of the existence of a hemiplegic condition, with arrest of growth of the paralysed limbs. Such patients are also frequently subject to one-sided fits; but it is not certain whether in such cases the inability to speak is especially prone to occur in those who are congenitally paralysed on the right side. In some of the less severe examples of this latter type which have come under the writer’s observation, speech has been merely deferred—the child has not commenced to speak till the fourth, fifth, or even the sixth year. See **DUMBNESS**; and **CEREBRAL DIPLEGIA**.

Hadden described several curious cases of speech-defect met with in children, to which the term ‘*idioglossia*’ has been applied. These persons have to a certain extent a language of their own; so that when asked to repeat phrases, they make use of sounds of their own instead of those proper to the words that should be employed. The sounds which they substitute are said to be always the same for the same words. Some of these patients at least seem to be capable of writing correctly from dictation. They may also show a fair amount of intelligence generally.

2. *Acquired defects.*—Among acquired defects of speech we have troubles of various degrees and kinds, which may come on at any period between infancy and old age, and which, as regards duration, may be temporary or permanent. The great variation in the extent and nature of these defects is due to the fact that the impeding condition or lesion may act (1) upon parts of the brain concerned with the genesis of thought, and of the will to speak; (2) upon some part of the nervous channels or centres concerned with the actuation of speech; or (3) upon the peripheral nerves and organs concerned with articulation and vocalisation. Thus it happens that acquired defects of speech may, in one set of cases, be associated with the most marked alterations in the intelligence or previous mental condition of the patient, while in others they may be represented by mere defective articulation or vocalisation. In briefly referring to the principal varieties, it will be convenient to pass from the simple to the more complex types.

Proper vocalisation is essential for the production of normal speech; where it alone is defective we have to do with various kinds of aphonia, which may be due to very different causes (see **VOICE, Disorders of**). Again, articulation as a mere motor act may be interfered with or perverted in diverse modes. Where speech-movements are inco-ordinate, we have such common defects as stuttering or stammering (see **STAMMERING**); or else those less marked perversions of speech-movements which are met with in some cases of chorea. Again, where the movements concerned in speech are more simply defective, we have that indistinctness of articulation and blurred utterance which, in various degrees, is so commonly associated with different forms of paralysis due to cerebral disease. To this kind of defect the name ‘*Aphemia*’ is now commonly applied. It presents itself under many various conditions, and with different degrees of completeness. It may show itself in its most extreme form in ‘*labio-glosso-laryngeal paralysis*,’ or in other forms of bulbar disease. This blurred or difficult articulation is also one of the signs met with in general paralysis of the insane, and in disseminated cerebrospinal sclerosis. Again, it occurs in association with hemiplegia caused by different lesions in various parts of the brain, between the bulb below and the cerebral cortex above. As a rule, it is most marked and most persistent in hemiplegia due to disease of the pons Varolii, while in lesions higher up it is apt to be slight and more transitory, especially where such lesions exist on the right side of the brain. It is evident, indeed, that this kind of defect is specially prone to occur where there is damage to the first parts of the outgoing tract leading from the kinæsthetic centres in the left third frontal convolution, or in any lower parts of the same tract, or when there is damage to the actual motor centres for articulation situated in the bulb. Damage to the third left frontal convolution itself gives rise to a form of speech-defect which is commonly known as *motor aphasia* (see **APHASIA**). Related to speech-disorders of this type are the other more complex and extremely varied defects of speech classed under the head of *amnesia*.

Finally, in this relation, reference should be made to certain forms of speechlessness occasionally met with in hysterical females, or in the insane of both sexes, in which there may be a deficiency of will to speak, dependent upon perverted cerebral action,

either without or with a discoverable basis of actual morbid changes. In such cases patients may remain dumb for months or for years; there may be no apparent motive, or the speechless condition may, in the insane, stand in direct or indirect relation to certain delusions.

PROGNOSIS AND TREATMENT.—The treatment of these various defects of speech will, of course, depend upon their nature, causes, and associated conditions. Reference must, therefore, be made to the several special articles in which the different forms of such defects are considered. It may be said here, however, that most of the forms of speech-disorder dependent upon congenital defects are comparatively little amenable to treatment. Those due to brain-lesions occurring later in life are oftener mere temporary defects, diminishing after longer or shorter periods, as the effects of the original lesions become lessened by time and treatment. Some of the marked cases of aphemia, moreover, are capable of being cured or greatly improved by careful daily drilling in the articulation of vowel-sounds and short words, provided this exercise be persistently and methodically carried out.

H. CHARLTON BASTIAN.

SPERMATIC CONCRETIONS.—See CONCRETIONS.

SPERMATORRHOEA (σπέρμα, seed; and ῥέω, I flow).—SYNON.: Fr. *Spermatorrhée*; Ger. *Samenfluss*.

DEFINITION.—A real or apparent discharge of seminal fluid, occurring without voluntary sexual excitement.

Two varieties may be recognised: (1) *True spermatorrhœa* is the discharge of spermatozoa from the urethra, or with the urine, at periods other than during sexual excitement. (2) *False spermatorrhœa*, or *prostatorrhœa*, is the discharge of the seminal-like fluid, destitute of spermatozoa.

ÆTIOLOGY.—Local irritation, whether from masturbation or from some diseased or disordered condition of the genital organs, is the cause of spermatorrhœa in the first instance. General or local morbid conditions, such as balanitis, phimosis, a long prepuce, urethral catarrh, irritability of the prostate, a tender spot in the urethra, varicocele, spasmodic contraction of the levator ani from rectal irritation, worms in the intestinal canal, constipation, and changes in the nerves or nerve-centres supplying the genito-urinary tract, inducing either hyperæsthesia or anæsthesia, may occasion or be the result of masturbation and subsequent spermatorrhœa. Sugar in the urine and involuntary emissions of semen at night are frequently associated in young men. When ætiological factors persist, slight mental or local stimuli are sufficient to perpetuate the discharge.

SYMPTOMS.—The first symptom that alarms the subject of spermatorrhœa is the occurrence of frequent nocturnal emissions, at first with, and afterwards without, erotic sensation. These reduce his strength, render him weak and irritable, and gradually prey upon his mind; and if, as frequently happens, masturbation be practised, they induce a condition of extreme mental depression. When the patient reaches this state, the mere reference to sexual matters, the sight of anything lewd, the act of defæcation, or a chance irritation of the penis during walking, riding, or driving, is often suffi-

cient to cause an abortive or, it may be, a complete emission. The discharge may, in advanced cases, find its way into the bladder and be voided with the urine. The discharge may be the ordinary seminal fluid; or it may be less in quantity, clearer, tenacious, more like synovial fluid in appearance and consistence. In the latter case it seldom contains spermatozoa, but it is usually only the fore-runner of the other more serious state, or it may alternate with it. A tender spot in the lumbar region of the spine is frequently complained of. These conditions combine to render the patient for the time being physically and mentally a wreck, sleepless, listless, nervous, anæmic, and with an old and insipidly anxious look upon his muddy or pimpled face. Intercourse becomes well nigh impracticable, the discharge of semen occurring before the introduction of the organ; or erection may be impossible or imperfect. Men in middle life, owing to weakness of the genital organs, are not infrequently affected by imperfect erections and by false spermatorrhœa.

DIAGNOSIS.—In the diagnosis of the cause of spermatorrhœa, the condition of the external genitals must first be determined. The presence of a tender spot, of hyperæsthesia, anæsthesia, or stricture, in the urethra, can be made out by passing a catheter. Pressure on the perinæum and inspection by aid of the urethroscope may assist in the diagnosis. The urine must be tested for sugar and for albumen. The discharge itself must be found and examined microscopically, the presence of spermatozoa establishing true spermatorrhœa. Glairy fluids, like that of prostatorrhœa, occur in the urethra during the last stages of a gleet, straining at stool, and also in stricture. The history of the case, and catheterism, readily clear up the cause of the discharge.

PROGNOSIS.—In the generality of instances the patient gets quite well, either by ordinary care on his own part, or by medical treatment. In other cases, however, the development of some inherited disease manifests itself simply from the weak condition to which the patient is reduced. In some instances dementia or melancholia is induced, and the patient continues his impure habits even while under watch and ward in a lunatic asylum.

TREATMENT.—Should any local irritation appear sufficient to cause spermatorrhœa, it ought to be treated and removed if possible. A long prepuce should be cut off, balanitis cured, a varicocele treated, or rectal irritation removed. To prevent masturbation many plans have been tried, such as the application of iodine to the penis, or touching the parts with caustics, which, by the pain they cause, prevent the patient meddling with the organ. These measures, or such as these, combined with encouragement from the medical attendant, and resolution on the part of the patient, will help towards a cure. Local tenderness in the urethra may be relieved by counter-irritation to the perinæum, or by applying caustics directly to the tender surface, either in substance or in solution. The solution chiefly used is one of nitrate of silver, varying in strength from five to sixty grains to the ounce, and it is best applied by the silver syringe-catheter, the flexible tube, or through the urethroscope. The patient's digestion and impaired physical and mental condition must be looked after. Stomachic and nervine tonics, such as gentian, strychnine, phosphates, and iron, are the most useful,

and must be given for some time. To allay irritability of the genital organs, the bromides and belladonna may be given, separately or in combination. For hyperæsthesia the extract of belladonna, in half-grain doses morning and evening, is especially useful; it may be given with the tonics recommended above. Should anæsthesia of the urethra and genitals exist, galvanism has been tried and has proved successful. The patient should sleep on a hard bed, and get up the moment he wakes. A separate bedroom should be disallowed. Cold hip-baths morning and evening, rectal injections of cold water, walking exercise, and mixing in company as much as possible, are useful adjuvants to treatment.

SPHYGMOGRAPH, The (σφυγμός, the pulse; and γράφω, I write).—An instrument devised to record the character of the pulsations in an artery.

The tracing is called a *pulse-tracing* or *sphygmogram*, and consists of a series of curves, varying in number and form according to the frequency and the characters of the pulse. See PULSE.

The tracing is generally taken from the radial artery. The wrist is over-extended, and fixed steadily, while a small pad is applied accurately over the artery as it passes by the styloid process. The up-and-down movements of the pad are recorded on an enlarged scale by a style on a smoked paper, which is made to travel uniformly by clock-work. There are two forms in use, Marey's, which is superior but is cumbersome, and Dudgeon's, which is handy, but has the disadvantage that the needle is so light that it allows an excessive oscillation with a sudden pulse. The pad is kept applied over the surface of the artery by means of a spring; and the pressure is varied until the tracing with the greatest amplitude is obtained, when the clock-work is started. It is important to choose the right pressure, although, taken in this manner, it does not correspond to the arterial pressure. It is unfortunate that the sphygmograph has fallen out of use, as, within certain limits, it has great value. It enables the variations in the pulse to be recorded from time to time, and it allows the character to be recorded and discussed at leisure. Tracings taken with different varieties of instruments are not comparable, as the impulse-wave, due to the sudden impact of the wave on the pad, varies with the construction of the instrument. It is necessary, therefore, to be familiar with the sort of impulse-wave different pulses produce before discussing a tracing. In a Dudgeon's instrument the impulse-wave, in proportion to the tidal, is higher than with Marey's.

The next difficulty is that the tracing is the result of the combined movements of the artery and the venæ comites, and hence, when there is forced expiration, the height of the tracing is markedly increased, and the amplitude diminished, while with forced inspiration there will be a great fall in the height of the tracing, especially if forced expiration precede this. If these three facts be borne in mind much of the criticism as to the uselessness of the sphygmograph disappears. There is much to be learnt from studying sphygmograms which cannot be apprehended otherwise.

In taking a tracing it is necessary to keep the arm and the instrument still; to have the pad exactly on the centre of the vessel, or the up-stroke will be oblique, the top rounded, and the height deficient; and to choose such pressure as will give the tracing with the maximum amplitude. The papers should be well enamelled, and may be smoked by burning camphor; and when the tracing has been taken, and the necessary details, including the pressure applied, scratched on with a pin, it can be varnished by passing it through gum benzoin or Burgundy pitch (1 in 8) or through tincture of tolu.

A pulse-tracing shows at a glance the rate, rhythm and quality of the pulse, which can be studied at leisure. Irregularities, and especially inequalities, that escape the finger are registered, and indications as to the strength of the cardiac action and condition of the vessel-walls, which are most important for prognosis and treatment, are put on record. Both finger and sphygmograph detect sudden changes; but they both fail to appreciate the minor changes in tension and size, which are constantly going on with the various actions of daily life. These were unrecorded and unsuspected until other means of diagnosis were used (see PULSE). A recorded tracing differs from what can be felt with the finger, in the presence of the impulse-wave. This is produced by the suddenness with which the lever is tossed up. When this lever is light it is carried up higher than the pad by which it is started, and hence the fall in the trace, down again to the tidal wave.

The *tidal wave*, or *predicrotic*, or *first secondary wave*, as it is also called, is due to the impulsive tension in the arteries, following the increased pressure in the aorta and great vessels, from the reception of the ventricular contents. The *dicrotic*, or *great secondary wave*, is an oscillation of the blood-column, mainly, if not wholly, produced by the rebound of the blood from the closed aortic valves under the pressure of the aortic recoil. See DICROTISM.

A pulse-tracing (fig. 1) consists then in a *line of ascent*, *a* to *b*, which ends in the *impulse-wave*, *b*, and its size depends on the form of the instrument and on the suddenness of the pulse; from the impulse-wave the tracing falls slightly, till it is again raised by the *tidal wave*, *c*. After the tidal wave a more marked descent occurs, called the *aortic notch*, *e*, and the line again rises, into the *dicrotic wave*, *d*. The *line of descent*, *b* to *a'*, is thus broken by two waves and two notches. The two waves have already been described; of the two notches one precedes the tidal wave; while the aortic notch, preceding the dicrotic wave, marks the fall of pressure in the arteries antecedent to the closure of the aortic valves. The moment these valves are closed the line of descent rises again. It is the bottom of this notch, marking as

it does the closure of the aortic valves, which points out the termination of the ventricular systole. The remainder of the line of descent corresponds with

FIG. 1.—Typical Pulse-tracing.—*a* to *b*, line of ascent; *b* to *a'*, line of descent; *b*, impulse-wave; *c*, tidal wave; *d*, dicrotic wave; *e*, aortic wave.

the diastole of the ventricle, and is sometimes broken by smaller waves.

The pulse-tracing is modified in its chief features by the state of arterial fulness or tension. When the tension is high (fig. 2) the line of ascent is less

FIG. 2.—Tracing of Pulse of High Tension.

lofty; the tidal wave is large, nearer to, and sometimes blended with the small impulse-wave; the aortic notch is shallow, and high in the line of descent; the dicrotic is not much developed; and the line of descent is gradual. When the tension is low (fig. 3), the line of ascent is lofty; the

FIG. 3.—Tracing of Pulse of Low Tension.

summit-wave distinct; the tidal wave small; the aortic notch deep and low; the dicrotic highly developed; and the line of descent sudden. These modifications are interfered with if the normal elasticity of the arteries be lost, as in arterial degeneration.

INDICATIONS.—The evidence yielded by the sphygmograph mainly concerns: (1) The mode of the heart's contraction. (2) The condition of the peripheral circulation. (3) The state of the arteries and their coats. (4) Valvular diseases of the heart.

1. The Mode of the Heart's Contraction.—The sphygmographic tracing shows this by the line of ascent. When the heart-muscle acts suddenly and vigorously, the line is vertical and lofty, and terminates in a pointed impulse-wave. Unless the vessels are over-full of blood, there follow well-marked tidal and dicrotic waves. On the other hand, when the heart's contraction is feeble the line of ascent is less vertical and lofty; the impulse-wave is less distinct; the tidal and dicrotic waves are smaller, or the former is blended with the summit wave. The pulse, moreover, unlike the pulse of a vigorous ventricle, is easily

obliterated by pressure. A note of the pressure at which the largest trace is obtained should always be made, as it enables the observer to compare results at different times.

2. The Condition of the Peripheral Circulation.—The easy or difficult passage of the blood through the arterioles, causing a low or high pulse-tension, is roughly estimated by the pressure required to develop or to obliterate the tidal and dicrotic waves. Obstructed peripheral circulation is manifested by increase of the tidal wave, diminution of dicrotic, and lessened height of line of ascent (fig. 4). The heart, apart from febrile or nervous

FIG. 4.

excitement, empties less suddenly under these conditions. On the other hand, in easy and quick peripheral circulation, such as occurs in fevers, the sudden heart-contraction causes a more vertical and higher line of ascent, the summit-wave is exaggerated, the tidal wave lessened, and the

FIG. 5.

FIG. 6.

dicrotic fully developed (fig. 5). In such conditions the fully dicrotic and hyperdicrotic waves are recorded (fig. 6). The rapid onflow of blood is, moreover, shown by the more sudden fall of the line of descent. It is by the comparative study of the waves, and the pressure required to record them best, that we obtain valuable indications as to heart-strength and pulse-tension in acute diseases, and in the earliest stages of some chronic affections.

3. The State of the Arteries.—There are three chief conditions of the arteries that modify the pulse: (a) The state of the muscular coat; (b) degenerative conditions of the arterial walls; and (c) the presence of aneurysm.

(a) When the muscular coat is contracted the artery imparts to the finger a hard, wiry sensation,

FIG. 7

which shows in the tracing by a short line of ascent, and the blending of the summit and tidal waves in an oblique line of descent, scarcely broken by dicrotism (fig. 7). In the opposite condition of relaxed arterial coats the dicrotic and summit-waves are enlarged and the tidal waves lessened.

These changes can be experimentally illustrated by the application of cold and heat to the surface of the body. The cold and hot stages of ague also show the two states.

(b) When the walls of the vessels have degenerated they become more or less rigid, so that the modifying influence of their elasticity on the blood-pressure is lost. The impulse-wave in the radial artery consequently approaches more to that imparted by the heart's systole. In these conditions the pulse often beats visibly, so that we are prepared for the amplitude of the tracing. The tidal wave is large, nearer to, and often blended with the impulse-wave, while the dicrotic is badly marked. The presence of these peculiarities often

FIG. 8.

leads to the early diagnosis of unsuspected atheroma of the great vessels (fig. 8).

(c) When the sac of an *aneurysm* is seated on a main trunk after its origin from the aorta, it acts as a diverticulum, and so modifies the pulse-form by rendering the line of ascent oblique, diminishing or abolishing the impulse-wave, modifying the dicrotic, and more or less converting the down-tracing into a sloping line. The finger recognises these changes as a slow feeble pulse. Such peculiarities in the left radial artery are produced by an aneurysm of the left subclavian, or in the right radial by innominate aneurysm. When the aneurysm is connected with the thoracic aorta in its ascending portion, there is frequently a dissimilarity between the two radial pulse-traces, which is persistent, one being smaller than the other, more vibratory, or more easily obliterated by increased pressure. The pulse usually more affected is the right, as the aneurysm tends to implicate the innominate artery. In aneurysm of the transverse portion of the arch the left pulse is more commonly diminished in force and amplitude, and is also retarded (figs. 9 and 10). In aneurysms of the

FIG. 9.—Right Radial Tracing.

FIG. 10.—Left Radial Tracing.

descending thoracic and abdominal aorta, the dicrotic wave is often much increased in both pulses, while the right radial yields usually the more normally developed trace.

These signs may be more or less simulated by the pressure of tumours on the arterial trunks, or by their partial obstruction by clots. The sphygmographic signs of aneurysm, therefore, require to be confirmed by the use of the ordinary means of

diagnosis. In some cases, however, the pulse-tracings alone suffice to indicate the lesion and its seat.

4. Valvular Diseases of the Heart.—Valvular diseases of the heart generally influence the pulse-tracing. In *aortic regurgitation* this is strikingly seen (fig. 11). The strong, dilated ventricle discharges suddenly an increased charge of blood into a lax aorta, and consequently there is a lofty line of ascent, ending in a pointed impulse-wave. The tidal wave is small in proportion; and the dicrotic, which occurs lower than normal in the line of descent, is generally much diminished, on account of the leakage into the ventricle interfering with the rebound of the blood-column from the closed valves. The dicrotic wave, thus starved, is followed by a rapid fall in the tracing, showing the quick emptying of the artery. It is this contrast between the height of the summit-wave and the rapid fall of the tracing, unbroken by any *sustaining* wave, that gives the pulse its splashing and collapsing character. These features, the small dicrotism and the rapid fall, indicate the amount of regurgitation. In some cases of this valve-lesion the tracing shows a well-marked tidal wave and a fairly developed dicrotic wave; and increased pressure by the spring of the sphygmograph, instead of obliterating the tracing as usual, shows that there is a fair amount of tension. Such features commonly occur in older persons, in whom the valve-defect is small and due to atheroma, and not to rheumatism, and the pulse-form is modified by the addition of the characters of the pulse of degenerated arteries. When such features are observed in rheumatic cases, and the tracing nearly resembles the normal form, they point to perfect compensation and small valve-defect. The characters are much accentuated when the arm is raised.

FIG. 11.

In *aortic stenosis* the tracing will indicate the amount of the lesion. When the narrowing is extreme the impulse-wave is lost, the line of ascent becomes oblique and gradual, and the pulse is felt to be slow, i.e. the vessel distends slowly. More commonly a break in the line of ascent marks the position of the impulse-wave, while above it rises the large tidal wave, due to the feeble impulse (fig. 12). In cases in which the obstruction is less in degree, the summit of the tracing may be forked by a sharp division between the impulse- and tidal waves. The dicrotic wave is lessened. A small impulse-wave, followed by an exaggerated tidal wave, arising from a strong and often dilated ventricle, pushing a large blood-wave gradually into the arteries through the narrowed aortic orifice, are the characteristics of this lesion when pure. When it is associated with aortic regurgitation, the large tidal wave is still pronounced.

FIG. 12.

Mitral-valve lesions, which are less immediately connected with the arterial blood-movement, present less decided characteristics. In *mitral regurgitation* the tracing is often of the normal outline, when the compensation is fairly perfect. In some cases, in addition to great rapidity, the pulse is small and flabby, in striking contrast

the vigour of the impulse (fig. 13). The line of descent is sloping, and the tidal and dicrotic waves are only defined. In some cases, where compensation has failed, great irregularity is the chief feature of the tracing, a series of small, ill-developed pulsations being succeeded by large and well-formed pulsations. On analysis, the series of small, ineffectual pulsations correspond to inspiration, and the smaller and more vigorous ones to the respiratory pause. In other conditions similar irregularities are produced by the same influences. Burdon Sanderson, who first referred these irregularities to their cause, says: 'The mechanical effect of inspiration

FIG. 13.

to augment the quantity of blood contained in the pulmonary circulation, and hence to increase the frequency of the contractions of the heart. This increased frequency depends on the distended state of the auricles, in consequence of which the ventricles contract more rapidly during their period of relaxation. In this way the length of the diastolic pause is diminished, and the hurried action of the heart is satisfactorily accounted for; but the question still arises, Why are the rapid beats which occur in inspiration also ineffectual? It is due to the tracing being formed by the combined movements of artery and vein. With inspiration the veins empty and the pulse-trace falls in consequence.

Similar peculiarities are noticeable in tricuspid regurgitation and dilated heart.

In *mitral stenosis* the sphygmographic evidence is very important. The pulse-tracing shows irregularity in the line of descent, which often is greatly prolonged through a missed pulsation—a true intermission in the beat, and sometimes broken by the interpolation of a small, abortive pulsation (fig. 14)—

FIG. 14.

In the former, when the auricle has failed to contract, the latter when the ventricle fails, although the auricle has done so. The effect of an excess of digitalis in cases of mitral stenosis is often to produce a *pulsus bigeminus* in which only every second beat reaches the wrist. The abortive pulsations are due to over-distension of the auricle, causing premature auricular contractions, which propagate themselves to the ventricle, and so produce a ventricular contraction on a small charge of blood. They mostly occur during inspiration, from the causes above mentioned. The rhythmical relations between the contractions of the auricle and the ventricle are thus disturbed, and hence the features just described.

These are the special characters of the pulse of mitral stenosis. In some cases, where the stenosis is not great and the compensation perfect, the pulse is regular in time and form, or nearly so; but in these cases characteristic irregularities can often be produced by vigorous exertion.

Finally, in therapeutical investigations the sphygmograph is indispensable as a means of discovering the influence exerted by a drug on the state of the vessels, on the condition of the peripheral circulation, and on the vigour of the heart. The modifications in the form of the pulse-tracing above described enable the investigator to estimate these effects.

G. NEWTON PITT.

SPINA BIFIDA (*spina*, the spine; and *bifida*, cleft).—SYNON.: Fr. *Hydrorhachis congénitale*; Ger. *Rückenspalte*.

DEFINITION.—A congenital malformation, in which there is a sac-like protrusion of the spinal membranes through a cleft in the neural arches of one or more of the vertebrae.

ETIOLOGY.—The malformation is due to an arrest of development of the spinal cord and vertebral canal, whereby the laminae fail to unite to form the spinous processes.

ANATOMY.—Spina bifida may occur in any part of the vertebral column, but is most frequent in the lumbo-sacral region, where the laminae are latest to unite.

Three chief forms are described: Spinal meningocele, Meningo-myelocele, and Syringo-myelocele.

1. The *spinal meningocele* consists of a protrusion of the dura mater and arachnoid blended together and contains cerebro-spinal fluid. The cord and nerve-roots remain in the spinal canal. This is a rare form.

2. The *meningo-myelocele*, the most common form, consists also of the dura mater and arachnoid, but contains, in addition to cerebro-spinal fluid, the spinal cord and nerve-roots. The cord can be traced as a thin band over the posterior part of the wall of the sac, some of the large nerve-roots given off from the cord running across the interior of the sac to re-enter the spinal canal, and thence passing out of the intervertebral foramina in the normal manner.

3. The *syringo-myelocele* is the most rare form. The central canal of the cord is greatly distended with fluid, the expanded cord being thus spread out as a lining to the sac, with which it is intimately blended. The nerve-roots in this form pass through the walls of the sac to their destination.

The coverings of the sac may be healthy skin, but more commonly normal skin is found only at the sides, the central portion consisting of thin bluish or bluish-white congested membrane. At the lower part of the sac, in the case of a syringo-myelocele, a slight depression is sometimes seen at the spot where the spinal cord terminates. At the bottom of this depression, which is known as the umbilicus, a minute foramen, through which cerebro-spinal fluid may ooze, at times communicates with the central canal of the cord. In some cases of spina bifida there is no protrusion, but the skin, membranes, and cord blended together, and covered by a tuft of hair, form a slight depression between the cleft spinous processes. This is known as *spina bifida occulta*, and is not infrequently associated with paraplegia, contractures, or deformities of the feet.

CLINICAL CHARACTERS.—The common form of spina bifida gives rise to a swelling of globular or ovoid shape, with its long axis vertical, and varies in size from a walnut to the foetal head. It is situated in the middle line of the back, and nearly

always in the lumbo-sacral region. It may be covered with healthy skin, but more commonly the central portion of the tumour consists of a bluish-white translucent membrane. The swelling becomes tense when the child is made to sit up or cries, or when pressure is made on the anterior fontanelle; but can be made less tense by direct pressure on the sac, and when the child is held up by the legs or placed in the prone position. The gap between the laminae can generally be distinctly felt. In the infant the anterior fontanelle protrudes when pressure is made on the tumour.

DIAGNOSIS.—The congenital origin of spina bifida will serve to distinguish it from a new-growth developed subsequently to birth. From other congenital tumours it may be known by its translucency, increase of tension on straining, situation in the middle line, and, when this can be felt, by the gap between the laminae. The diagnosis of the various forms from one another is not always easy. A syringo-myelocoele can hardly be diagnosed from a meningo-myelocoele; but opacity in the middle line at the situation of the spinal cord and nerve-roots, a dimple where the end of the cord is attached to the sac, the existence of a vertical furrow and the presence of paralysis, contracture or deformity of the lower limb, and want of control over the bladder and rectum will help to distinguish these forms from a simple meningocele, which is usually translucent all over, of a smooth contour, and unattended by paralytic symptoms.

COMPLICATIONS.—Spina bifida may be associated with hydrocephalus, meningocele or encephalocoele, club-foot, paralysis or contracture of the lower extremities, paralysis of the bladder and rectum, and imperforate anus. In rare instances the whole spinal canal may remain partially or completely unclosed; or there may be other congenital malformations incompatible with life. See **MONSTROSITIES**.

COURSE AND TERMINATIONS.—The majority of cases of spina bifida terminate fatally, often within a few days or weeks of birth; the child dying from marasmus, or from spinal meningitis and convulsions, frequently preceded by rupture of the sac and the escape of the contained cerebro-spinal fluid. When the fluid only oozes away gradually, spontaneous and complete cure may rarely occur; the tumour contracting to a small nodule, and the aperture in the canal closing more or less completely. When the cutaneous covering is thick and normal, the tumour may gradually decrease in size as age advances, or it may increase in size without material inconvenience up to the adult period of life, attaining the size of a child's head, or even larger dimensions.

PROGNOSIS.—This is unfavourable when the tumour is of large size at birth, and is covered only by a thin membrane, or has a broad base; and this is more especially the case when the spinal cord and large nerve-roots are contained in the sac, and the lower extremities and bladder and rectum are paralysed. When the base of the tumour is narrow, and its cutaneous covering thick and normal, the prognosis is more favourable, especially if the malformation be situated over the sacrum.

TREATMENT.—Whatever the variety of spina bifida, where the sac is covered by a thick pad of skin and shows no tendency to increase, it is advisable simply to protect it with a suitable bandage and shield, since it will probably give rise to no in-

convenience and possibly shrink with age. Where the sac is of large size, merely covered by a thin membrane, and contains in its walls the expanded spinal cord; where the cerebro-spinal fluid is oozing away, or where there is extensive marasmus, or paralysis of the lower limbs, bladder, or rectum, no treatment is of any avail, and the child will probably die in a few days. Suspension of the patient by the legs in an obliquely prone position will stop the leakage, and if the sac is kept aseptic the child may survive for some weeks or even in rare cases recover, the closure of the leak being followed by shrinkage of the sac. The treatment by pressure, tapping, and injections is not satisfactory, though up till recently injection with Morton's iodo-glycerine solution was perhaps the favourite procedure, and was attended with the best results. Now, however, in all suitable cases most surgeons excise the sac since a radical cure is in this way obtained. An elliptical incision is made on either side of the sac through the healthy skin, the two skin-flaps raised, and the sac with its central membranous covering excised, and the neck ligatured or sutured in such a manner that the line of skin-sutures does not correspond to the ligatures or sutures of the neck. In the meningo-myelocoele, after the skin-flaps have been raised, the cord and nerve-trunks are carefully dissected from the sac-wall and replaced in the spinal canal; or, if very adherent to the sac, strips of the sac-wall are left attached and replaced with the cord and nerves. The membranes at the neck of the sac are now drawn together by delicate silk sutures, and the skin-flaps united in the way described above. During the operation the patient should be in the prone position, with the pelvis well raised on pillows so as to avoid as much as possible the draining away of the cerebro-spinal fluid. The strictest antiseptic precautions should of course be taken. Excision, as a rule, should be delayed till the child is a few weeks old.

W. J. WALSHAM.

SPINAL ACCESSORY NERVE, Diseases of.—The upper medullary fibres of the spinal accessory nerve emerge from the surface of the medulla oblongata below the pneumogastric. They arise from a column of nerve-cells adjacent to the nucleus of the hypoglossal, and continuous with the nucleus of the pneumogastric. Their fibres join the latter nerve and innervate the movements of the palate and larynx. Their share in the nerve-supply to the pharynx is undecided, but it is certain that the levator palati is supplied by them. Paralysis of the vocal cord, tongue, and palate is occasionally due to disease at the surface of the medulla in this region, and the fact that stimulation of the roots of this nerve causes movement of the palate has been proved experimentally by Horsley and Beever. The lower, spinal fibres of the nerve emerge from the side of the cord as low as the sixth or seventh cervical nerves, having passed through the substance of the lateral columns, and arising from the anterior cornua, in common with the motor fibres of the upper cervical nerves, which supply muscles associated with those to which this nerve goes. The spinal part ascends through the foramen magnum, and is connected with the bulbar portion for a short distance; the two parts then separate, the latter joining the pneumogastric, the former passing to the neck, and supplying the sternomastoid and the upper part of the trapezius. The double relation

of the nerve is thus correctly expressed in its name. The bulbar fibres alone are 'accessory' to the pneumogastric; the 'spinal' fibres are strictly part of the motor cervical roots.

1. **Paralysis.**—**ÆTIOLOGY.**—The nucleus of origin of the nerve may be diseased owing to slow degeneration of the motor cells, as in progressive muscular atrophy and chronic bulbar paralysis, and also in syringomyelia and central growths that spread from the cervical region to the medulla. The nucleus of origin of the bulbar portion may be damaged by acute processes, especially softening (acute bulbar paralysis); and the grey substance from which the spinal fibres arise may be involved in acute poliomyelitis (infantile spinal paralysis). The roots of the nerve are sometimes damaged by injuries, such as fracture or dislocation of the upper cervical vertebrae; by narrowing of the foramen magnum; by tumours external to the cord; and especially by meningitis, syphilitic or simple, in this region. The spinal part of the nerve, from its long course, is especially liable to suffer. The nerve is rarely injured in fractures of the skull. The causes of paralysis of the vagal portion, after its junction with the pneumogastric, have been considered in the article on diseases of that nerve. The spinal part, in its course to the muscles, may suffer in rare cases from rheumatic inflammation, or from injury; may be compressed by enlarged glands; or implicated in abscesses in its neighbourhood.

SYMPTOMS.—Paralysis of the spinal accessory may be complete, when the disease involves the nerve where both parts are united, but is much more commonly partial, on account of the extensive origin of the spinal portion, and the early separation of the two divisions. The symptoms indicating disease of the accessory part of the nerve, as loss of movement of the vocal cords, are described in the articles on the pneumogastric nerve and on diseases of the larynx. The paralysis of the palate, which is so often associated, is recognised by the defective movement in phonation. See PALATE, Paralysis of.

The loss of function of the spinal portion of the nerve is shown by paralysis of the muscles which it supplies—the sternomastoid and trapezius. Unilateral palsy of these muscles does not affect the normal posture of the head, but when behind the vertical position it cannot be rotated to the opposite side. Paralysis of the trapezius, which may occur alone if the disease of the nerve is behind the sternomastoid, is almost confined to the upper part of the muscle, that proceeding from the occipital bone to the clavicle. The middle part of the muscle receives a sufficient nerve-supply from the cervical nerves to prevent conspicuous paralysis or wasting, although the fibres of the spinal accessory can be traced almost to its lower border. The loss of the upper part alters the contour of the neck, and the shoulder is not raised in deep inspiration. The shoulder can, however, still be elevated voluntarily, this movement being effected by the upper and middle part of the muscle. Abduction of the arm by the deltoid is interfered with, on account of the loss of the support afforded by the upper part of the trapezius; and the supplemental action of other muscles causes a slight rotation of the scapula. If the nerve or its origin is damaged by an acute process, the paralysed muscles undergo wasting, which is usually rapid, and is accompanied by the reactions which characterise nerve-degeneration.

PROGNOSIS AND TREATMENT.—The prognosis and treatment of paralysis of the spinal accessory nerve are those of the morbid process causing the paralysis (see especially PROGRESSIVE MUSCULAR ATROPHY; LABIO-GLOSSO-LARYNGEAL PARALYSIS; and PNEUMOGASTRIC NERVE, Diseases of). In all cases, if the muscles waste and present loss of faradic irritability, voltaic electricity should be applied.

2. **Spasm.**—The muscles supplied by the spinal accessory nerve are frequently the seat of spasm, causing 'torticollis,' or 'wry-neck.' The spasm is due to an affection of the centres, probably in some cases those in the medulla, in others those in the cortex of the brain. This affection is described in a special article. See WRY-NECK.

W. R. GOWERS.

SPINAL CORD, Diseases of.—**SYNON.**: Fr. *Maladies de la Moelle Epinière*; Ger. *Krankheiten des Rückenmarkes*.—Though the spinal cord is commonly regarded as a single organ, yet it is one which is very composite in structure, and still more so in function. It is in part (1) a mere aggregate of connecting fibres between the body generally and the brain—that is, an accumulation of channels of conduction for sensory impressions of all kinds, both superficial and deep, on their way to the brain; and also for outgoing motor incitations from the brain to all the voluntary muscles of the body, as well as to those pertaining to the viscera and their ducts, and to blood-vessels. In part, however, the cord also consists (2) of a serial aggregation of more or less fused ganglia having to do with the execution of voluntary and all sorts of reflex actions; with the functional activity of organs; and with the nutrition of tissues.

Before the diseases of the spinal cord are dealt with seriatim, the following functions will be briefly considered:

Channels of Conduction, p. 1519.

Spinal Reflexes, p. 1520.

General Ætiology and Pathology, p. 1521.

Regional Diagnosis, p. 1526.

Channels of Conduction.—Although it is impossible within the space allotted to this article to enter in detail into the functions of the cord, it may be briefly stated that, with regard to the channels of conduction, both the direct cerebellar and the antero-lateral ascending tract convey impressions to the cerebellum; the former has been supposed to convey impressions of the muscular-sense order, and the latter, if it does not convey impressions of the same kind, may give passage to impressions of common sensibility serving as additional incitations to some of the complex reflex actions regulated by the cerebellum. On the other hand, the columns of Goll are also commonly supposed to transmit muscular-sense impressions, though the ultimate destination of these may be to the cortex in the Rolandic areas of the cerebrum. The evidence derived from syringomyelia makes it highly probable that painful and thermal impressions reach the cerebrum by way of the central grey matter, in accordance with the views of Schiff. As to impressions of touch and pressure nothing definite is known; the paths for these impressions may lie partly through the columns of Burdach, and partly through the grey matter of the posterior horns (Tooth), as the only other ascending tracts seem to be a series of short commissural fibres running

through the lateral columns, and serving to connect the nerve-cells at various levels of the posterior cornua with one another.

In addition to the crossed and the direct pyramidal tracts, there are two other columns seeming to contain outgoing fibres in each half of the spinal cord. The most important is known as the ‘antero-lateral descending cerebellar tract,’ which consists of fibres

is known that the posterior roots of the spinal nerves divide on their entrance into the cord into two main longitudinal branches, ascending and descending. Of these the ascending branch has been hitherto principally referred to, but the descending branch ought also to undergo degeneration. But the only descending degeneration in the posterior columns occurs in a small tract which is known (from its shape) as the ‘comma-tract.’ Mott has found that this degeneration occurs not only in sections of the cord, but also after section of the posterior nerve-roots, and that on each occasion it extends downwards for a limited distance only (half to three-quarters of an inch). It seems, therefore, most probable that this degeneration of the comma-tract represents the degeneration of the fibres belonging to the descending branches of the posterior roots.

Spinal Reflexes.—The reflexes of purely spinal mechanism which are of importance (by their presence, absence, or alteration) as indications of disease of the spinal cord in different longitudinal regions have been divided into (a) the superficial or skin-reflexes, and (b) the deep or so-called ‘tendon-reflexes.’

(a) *Skin-reflexes.*—The most important of these are tabulated below. The designation of the parts of the cord upon which they severally depend is based upon a very useful table published by Gowers.

These skin-reflexes vary much in different indi-

FIG. 1.—Sections showing the ‘Descending Cerebellar Tract’ in the Spinal Cord of the Dog, following upon extirpation of the left half of the cerebellum (Schäfer after Marchi); A, Lumbar Cord; B, Cervical Cord. The degeneration is in the antero-lateral column of the same side as the lesion, except in B, where there is a little degeneration on the opposite side.

that are connected with cells in the cerebellar cortex of the same side, and which undergo degeneration on removal of the corresponding half of the cerebellum (Marchi). These fibres form an extensive

Name of Reflex	Mode of Excitation	Nature of Result	Level of Cord upon which Reflex depends
Plantar reflex	Tickling sole of foot	Movements of toes; of these and foot; or of these and leg	1st, 2nd, and 3rd sacral nerves (lower part of lumbar enlargement)
Gluteal reflex	Irritation of skin of buttock	Contraction of glutæi	4th and 5th lumbar nerves
Cremasteric reflex	Irritation of skin of upper and inner part of thigh	Drawing up of testicle	1st and 2nd lumbar nerves
Abdominal reflex	Irritation of skin of abdomen along edge of ribs, and above Poupart's ligament	Contraction of upper or of lower part of abdominal muscles	8th to 12th dorsal nerves
Epigastric reflex	Strokeing side of chest over 6th and 5th intercostal spaces	A dimpling of corresponding side of epigastric region (contraction of highest fibres of rectus abdominis)	4th to 6th or 7th dorsal nerves
Scapular reflex	Irritation of skin in interscapular region	Contraction of posterior axillary fold (teres), or of several of scapular muscles	6th or 7th cervical to 2nd or 3rd dorsal nerves

circumferential tract in the anterior three-fourths of the antero-lateral column, spreading inwards in front of the crossed pyramidal tract to reach the intermedio-lateral tract of the grey matter. The tract which is thus marked out is most extensive in the upper regions, and gradually lessens in the lower part of the cord, but can be traced almost to its termination. It embraces in the dog the part of the anterior column which in man is occupied by the direct pyramidal tract, and also the whole region of the tract of Gowers, the fibres of these two tracts being intermingled. Some of the fibres of the anterior roots also exhibit degeneration after removal of the cerebellar hemisphere, and are therefore probably directly continued from fibres of this tract. The same holds good for nearly all the efferent cranial nerves (Marchi). These degenerated fibres are numerous on the same side as the lesion, but a few occur in the opposite nerves.

The other tract formerly thought to contain outgoing fibres is now believed, with more probability, to belong really to the afferent system of fibres. It

viduals, as regards the facility with which they may be obtained. They are often more marked in children and in women than in men; though when the latter are of an irritable or nervous temperament, some or all of the skin-reflexes may in them be well marked even in conditions of health. It must be borne in mind, also, that the superficial reflexes are always distinctly exaggerated, when the corresponding regions of the skin are tender in association with related visceral disease (Head).

In cases where extensive transverse lesions exist, situated higher up in the cord than the nerves upon which any of these reflexes depend, such reflexes are commonly supposed to be exaggerated in intensity. This, however, is not the case where we have to do with total transverse lesions. The fact that this or that reflex exists shows not only that the afferent and efferent nerves, but that the path through the spinal cord at the corresponding level, is practically undamaged. It is not, however, necessarily true that absence of any of the reflexes is an indication of disease at the corresponding level

SECTIONS OF SPINAL CORD IN LOWER CERVICAL, MID-DORSAL, AND MID-LUMBAR REGIONS (SCALE 1:1).
ON THE RIGHT SIDE OF EACH SECTION THE CONDUCTING TRACTS ARE INDICATED.
COLUMN OF ANTERIOR HORN — (a) Mesial group of nerve-cells; (b) Lateral or ventro-lateral; (c) dorsal or dorso-lateral; (d) central group; (e) Lateral cell-column; (f) Middle cell-column; (g) Cells of posterior horn.

the spinal cord. It may be so; but it may also be that the disappearance of the reflex is dependent upon disease in some part of the afferent or of the efferent nerves, leaving the cord itself intact. Or it may also happen that the particular reflex is simply not to be obtained in the individual under examination. Or, again, with a complete transverse lesion of the lower cervical or in the upper or middle dorsal regions of the spinal cord in man all reflexes dependent upon lower portions of the cord, excepting perhaps the plantar, will (though this is contrary to usual belief) be found to be abolished. See SPINAL CORD, Special Diseases of: 9. Softening of.

Further, it must be borne in mind that in certain cases of hemiplegia (even where hemianesthesia does not co-exist) these skin-reflexes are often notably diminished or even abolished on the paralyzed side of the body; though the reverse condition of things will probably obtain in regard to the deep or 'tendon-reflexes' next to be considered. It will probably be found, hereafter, that this reversing effect upon the skin-reflexes is associated with the existence of lesions in special parts of the brain, and not with lesions in other localities, though such special sites are at present very imperfectly known.

Recently a modification of the plantar reflex in

reflex is often the earliest to appear in disease of the pyramidal tract. See BABINSKI'S SIGN.

(b) '*Tendon-reflexes*.'—Much discussion has taken place as to whether these are 'reflexes' at all, in the proper sense of the term. Into this question we do not propose to enter. The phenomena themselves, to which alone reference will be made, are chiefly two in number, namely, *ankle-clonus*, and that variously known as the *knee-phenomenon*, *patellar tendon-reflex*, *knee-reflex*, or *knee-jerk*. Corresponding phenomena are met with in the upper extremities in the form of 'wrist-jerk' (produced by a slight blow over the radial side of the wrist), and 'elbow-jerk' (from a blow upon the triceps tendon). These phenomena are increased or diminished under the influence of the same kind of conditions that cause increase or diminution of the 'knee-jerk,' so that no further special reference will be made to them.

There is a distinct difference in regard to the importance of the presence of the 'knee-jerk' and 'ankle-clonus' respectively. The 'knee-jerk' occurs in health, so that it is its absence, as well as its increase, which is of principal significance in certain diseases. 'Ankle-clonus,' on the contrary, is a phenomenon not to be obtained in a state of health, so that its presence was formerly thought by some to be a positive sign of disease of the spinal

Name of Reflex	Mode of Excitation	Nature of Result	Level of Cord upon which Reflex depends
<i>Knee-jerk</i> . . .	By striking patellar tendon with edge of hand or with percussion-hammer, while leg hangs loosely over fellow, or over forearm of operator. Also by striking quadriceps tendon, above patella	A single upward jerk of the leg and foot, slight or distinct	2nd and 3rd lumbar nerves
<i>Ankle-clonus</i> . . .	With knee extended or very slightly flexed, by pressing quickly and firmly against anterior part of sole of foot (so as to stretch calf-muscles) and then keeping up the pressure	A series of clonic contractions at the ankle-joint, continuing as long as the pressure is maintained, and instantly ceasing when it is relaxed If the condition is very highly marked it may spread to the whole limb, or even to that of the opposite side	1st to 3rd sacral nerves (lower part of lumbar enlargement)

association with disease of the pyramidal tract made known in 1896 by Babinski (and now often spoken of as 'Babinski's sign,' or 'Babinski's reflex?') has received much attention. The normal plantar reflex to slight irritation in healthy adults, and in children after learning to walk, is by *flexion* of the toes, whereas Babinski pointed out that in all such persons with lesions of the pyramidal tracts the corresponding response is by *extension* of the toes, especially of the great toe. An extensive investigation as to this sign upon a very large number of individuals by Walton and Paul (*Journ. of Nerv. and Ment. Dis.*, June 1900) has led them to the following, among other, conclusions: (a) in early infancy no constant or characteristic movement of the toes occurs, though extension is rather more frequent than flexion; (b) the Babinski reflex obtains in about 70 per cent. of hemiplegics and epileptics, and in approximately the same proportion of cases with disease involving the pyramidal tract in the spinal cord; (c) it is never present in health, and there is reason for doubting its existence in either functional or organic nervous or other disease not implicating the pyramidal tract; (d) this

cord. But this is a view which requires limitations—and limitations of such a kind as to deprive the manifestation of ankle-clonus of much of its diagnostic significance. It may exist, for instance, after one-sided fits dependent upon disease of the cerebral cortex; and, again, it may exist to a well-marked extent where the antero-lateral columns of the cord are pressed upon at a certain level, even though (as in the condition above referred to) no lateral sclerosis of the cord has been developed.

General Ætiology and Pathology.—The spinal cord itself may be damaged by disease invading it *from without*—that is, taking origin either in the bony canal or in the enveloping membranes; or it may be the seat of *intrinsic* pathological changes. As the former conditions may and do constantly produce functional derangements or actual structural changes of a secondary order in the cord itself, we must take cognisance of them here, so that the various peculiarities as to their occurrence may be made known and considered side by side with those pertaining to the different causes of disease of intrinsic origin,

from which they have to be distinguished at the bedside.

(a) **Extrinsic Causes.**

(1) *Stabs or bullet-wounds* may involve limited regions and parts of the spinal cord.

(2) *Fracture with dislocation of some of the vertebræ* (as results of severe falls or other mechanical violence) exists as an occasional cause of an associated paraplegia, produced by the crushing of, or pressure upon, the spinal cord. This is most apt to occur in the cervical region, though the dorsal and lumbar regions are, to a less extent, liable to similar accidents.

(3) *Tubercular caries of the vertebræ* may exist in any of the regions, and may or may not be associated with *angular curvature* in a corresponding portion of the spine. The paraplegia, or other result of interference with the functions of the cord, in the majority of cases of this disease, is not due so much to its compression by diseased bone, as to the irritation and subsequent compression of the cord by inflammatory products.

(4) *Cancer of the vertebræ* occurs either as a primary or as a secondary affection. Such a new growth may involve the dura mater or not, and as it grows it may at first irritate and subsequently compress the spinal cord itself.

Other diseases of the spine are rare as causes of disease of the spinal cord. Still aneurysmal erosion of the vertebræ with subsequent pressure upon the cord must not be forgotten, and very rarely an aneurysm bursts into the spinal canal. Exostoses and enchondromatous growths from the bones may also quite rarely compress the cord.

(5) *Cancer of the spinal meninges, or new-growths of other kinds* (see 21, SPINAL CORD, Tumours of), may also involve irritation, and subsequently compression, of the anterior or posterior nerve-roots, or of the spinal cord itself in one or other region. *Hydatids*, again, should be remembered as possible causes of spinal disease, especially where their existence has already been detected in the body, in other situations.

(6) *Hæmorrhage into or upon the meninges.*—See MENINGES, SPINAL, Diseases of.

The foregoing groups of causes of disease of the spinal cord give rise to sets of symptoms having a generic resemblance, because in each case *compression* acts upon the cord, or upon the spinal roots and cord, from without, in one or other direction.

(b) **Intrinsic Causes.**

(7) *Hæmorrhage* occurs with extreme rarity into the spinal cord. This is due, in the main, to the firmer texture of the cord, and to the greater abundance of supporting connective tissue around its blood-vessels, as compared with that surrounding the vessels of the brain. When hæmorrhage, of idiopathic origin, does take place into the spinal cord, it almost invariably occurs in the softest portion of the organ, namely, its central core of grey matter—and in this region it may extend for some distance upwards and downwards. As a result of falls or blows, also, hæmorrhage into the substance of the cord is a rare event; still, under these conditions, it occurs occasionally—mostly in association with laceration of the substance of the cord. Of this latter kind of lesion, resulting from a fall from a height of about twenty-five feet, the writer has recorded a remarkable instance, in which, although the cord was severely lacerated, there was

no external wound and no fracture or dislocation of vertebræ.

(8) *Embolism* occurs with great rarity in the spinal cord, and is still more seldom recognised when it does occur. This is due to the fact of the small size of the arteries of the cord, and, as compared with the frequency of embolism in the brain, to the absence among them of any large trunk, like the middle cerebral, coming off more or less directly from one of the great vessels arising from the arch of the aorta. Emboli are known to reach the brain much more rarely by way of the vertebral than by way of the carotid arteries; and the principal arteries of the spinal cord are either direct offsets from the vertebral (anterior spinal), or indirect branches from the same (posterior spinal)—the latter arising from the inferior cerebellar, which are twigs from the termination of the basilar artery. Apart from these vessels, the blood-supply of the cord comes from still smaller twigs, derived from the intercostal and lumbar arteries, which anastomose with and reinforce the anterior and posterior vessels, at intervals, along the whole length of the cord. All the principal vessels, small though they are, seem to anastomose freely with one another. Thus, even if embolism of the spinal arteries should occur, as it probably does very rarely, its effects would be diminished in importance, and obscured clinically as well as *post mortem*, by reason of the very small size of the vessels, and also by the fact of their not being 'end' arteries.

(9) *Thrombosis* would, however, be capable of occurring in diseased spinal arteries, as well as in those of other parts of the body. Subsequent observations may perhaps show that degenerative changes or endarteritis are particularly common in the spinal arteries, so that the occurrence of thrombosis in them would thereby be rendered all the more easy and likely to occur. Once set up, the process of thrombosis might easily spread in this network of small spinal vessels, and yet be very difficult to recognise in them except by the effects that would be produced upon the tissue of the spinal cord—namely, the production of softening. A similar process may also take place in the peculiarly tortuous network of *veins* which surrounds the spinal cord on all sides—perhaps even with more facility than in the veins of other parts—when general and other local conditions favour its occurrence. Ollivier, in fact, called attention to the probably natural slowness of the blood-current through the spinal veins, and to the multiplicity of causes which (owing to their influence upon respiration and cardiac action) tend still further to retard it—such as violent emotions or efforts, and all such diseases as greatly interfere with respiration or with the force and regularity of the heart's action. Ollivier adds that he has often seen in elderly persons fibrinous clots filling the veins of the cord, as well as those which are to be found on its nerve-roots.

Thus one of the common causes of ordinary degenerative softening, as it occurs in the encephalon, would also be operative in the cord.

(10) *White softening* of the spinal cord is, in fact, very common; often implicating its whole transverse area for a variable extent. It differs in no respect in its naked-eye or microscopical appearances from the process as it is met with in the encephalon. It is altogether unreasonable to assume, in accordance with current nomenclature, that this condition

is mostly a result of inflammation, and therefore to be spoken of as a *myelitis*, when the pathologists of our time have declared that the similar process in the cerebrum and cerebellum is mostly of degenerative origin.

(11) *Myelitis*.—The writer is, of course, far from denying that primary inflammation may involve areas of the cord, and entail 'softening' of its substance. He believes, however, that 'acute myelitis' is far more likely to occur as a secondary process, in connection with pressure upon and consequent irritation of some part of the cord, encroached upon by fractures or dislocations of the vertebrae, or otherwise wounded; also as an occasional sequela of tubercular vertebral caries, of the direct pressure made upon the cord by some meningeal tumour, or of hæmorrhage into its substance. The question rather is as to the causation of primary or idiopathic softening—whether this is, in accordance with common phraseology, to be ascribed to inflammation, or whether it is non-inflammatory and of thrombotic origin, as the writer believes. Yet he is also far from believing that *all* the secondary softenings met with in the spinal cord are necessarily of inflammatory origin. Many of these also are probably due to degenerative changes from pressure and thrombosis, rather than to inflammatory causes.

Processes of degenerative 'softening' are mostly brought about quickly, so that they would from a clinical point of view, in the main, correspond with what is commonly spoken of as 'acute myelitis.' As for 'chronic myelitis' (in the commonly understood sense of chronic softening), the writer believes that no such disease should be any longer described. Many 'softenings' are in a certain sense chronic, as, though they may be more or less abrupt in their onset, they tend to last long rather than to kill quickly. Again, other maladies which the older physicians would have ascribed to 'chronic myelitis' or 'chronic softening,' are now known to partake more of the nature of chronic indurations, and to have as their bases various processes of sclerosis.

(12) Processes of *sclerosis* are extremely common in the spinal cord. In nature they are overgrowths of the connective tissue of this organ, altogether similar to those occurring in other organs and tissues, under the name of 'fibroid substitutions' or 'non-inflammatory hyperplasias of connective tissue' (see FIBROSIS). Sclerosis occurs under various forms, and constitutes the basis of several distinct diseases, which are in all cases gradual and more or less slow in their onset, as well as in their progress. It may occur (a) as a *diffuse* general overgrowth (after the manner of a cirrhosis in other organs); (b) in the form of *fasciculi* or bands limited to particular columns of the cord (especially the posterior and the lateral); or (c) in an *insular* manner, so as to form islets of sclerosis, scattered altogether irregularly through the cord at different levels, as in 'disseminated sclerosis.' Sometimes overgrowth of the connective tissue is the primary event, in other cases it is sequential to an atrophy occurring in the nerve-elements themselves.

(13) Tissue-changes allied to these in their results or later stages, though they have a peculiar history and course of their own at the commencement, are the so-called '*secondary degenerations*' which occur in certain regions of the cord, as a result either of

some previous damage or injury to this organ itself, or as a sequel of brain-disease.

These 'secondary degenerations' illustrate facts originally made known by Waller, to the effect that when nerve-fibres are severed from the ganglion-cells from which they are outgrowths, the white substance of Schwann gradually breaks up in the course of seven to fourteen days, and undergoes a process of fatty degeneration, by which it is ultimately resolved into a multitude of fine granules and fat-particles. The white columns of the cord are composed of aggregations of nerve-fibres running parallel with one another, so that when one of these columns is cut across, or when the continuity of its fibres is interrupted by some severe lesion occurring in their midst, a process of 'secondary degeneration' manifests itself simultaneously in all the fibres thus damaged, extending upwards or downwards from the lesion according as the fibres cut across have afferent or efferent functions. Thus the result appears as one or more band-like tracts of degeneration, running upwards or downwards according to the extent and situation of the transverse area of the cord affected.

In order to deal as briefly with this subject as possible, it may be said that experience has hitherto shown that such band-like tracts of 'secondary degeneration' occur especially in each lateral half of the cord, in three situations, namely, (1) in the lateral columns; (2) in the inner portions of the anterior columns; and (3) in the posterior columns. The degenerations in the anterior columns, and in the posterior and median portions of the lateral columns, take place in a direction downwards from the site of section or lesion of the fibres, at whatever level the damage may chance to exist; while those in the posterior columns and in the superficial portions of the lateral columns take place in an upward direction, starting from the section or seat of destructive lesion by which these columns may be invaded.

The fibres that undergo the *descending degeneration* in the lateral columns (constituting the 'crossed pyramidal tract') are generally believed to be those which transmit volitional stimuli to the various voluntary muscles of the body, and which come into relation with motor cells in the anterior cornua at different levels. These different fibres are supposed to enter the lateral columns at the commencement of the spinal cord, passing into them, in fact, as a result of the 'decussation of the pyramids.' Thus, the motor tract continued downwards through the 'internal capsule' from one Rolandic area of the cortex, let us say the *left*, continues along the crus and through the pons on the same side; thence passing into the bulb a considerable proportion of its fibres decussate with their fellows, and thereby reach the right lateral column of the cord, down which they proceed as a compact group in the manner indicated. The remainder of the fibres of the left motor tract (those which do not decussate) pass down also in a compact body (the 'direct pyramidal tract') and occupy most of the inner half of the left anterior column.¹ Thus, if the whole of the left motor tract be seriously damaged or cut across in the internal capsule or at any point above

¹ Though this is the rule, yet it would appear from the observations of Flechsig that developmental anomalies are apt to occur, so that the relative proportion between the decussating and the non-decussating fibres is subject to much variation in different individuals.

the 'decussation of the pyramids,' we should have a small band of degeneration in the anterior column on the same side, and also a larger band of degeneration in the opposite (or right) lateral column (fig. 2, H)—that is, we should have the form of secondary degeneration associated with many cases of hemiplegia. But if there be complete section of or destructive disease involving the antero-lateral columns of one side of the cord itself, then we should have a band of degeneration in the anterior, as well as in the lateral, column of

FIG. 2.—P. Showing descending areas of degeneration: *a*, in inner part of anterior columns; *l*, in lateral columns (mid-dorsal region). Case of *paraplegia*, from complete transverse softening in upper dorsal region.

H. Showing descending degenerations in case of *right hemiplegia*, from extensive softening of left 'internal capsule.' (Twice natural size.)

the same half of the cord. Or if either column be cut or damaged singly, then in such column a band of degeneration would be found extending downwards from the seat of lesion. Or if, as so frequently happens, we have to do with a total transverse lesion, represented, for instance, by a focus of softening extending through the whole thickness of the cord in the upper dorsal or in some other region (so that the patient suffers from complete paraplegia), we should then find large areas of secondary degeneration in each lateral column below, as well as smaller areas in the inner part of each anterior column (fig. 2, P). The areas in both situations become less extensive as they descend, and gradually wear themselves out in the lower part of the lumbar swelling. It was stated by Bouchard, and has been commonly repeated by succeeding writers, that the areas in the anterior columns do not appear beyond the mid-dorsal region; but this mode of termination, as the writer pointed out in 1867, is certainly not invariable.

FIG. 3.—P. Showing ascending areas of degeneration: *g*, in columns of Goll; and *l*, along outer border of lateral columns, in middle of cervical swelling (corresponding with direct 'cerebellar tract' and the 'tract of Gowers'). Case of *paraplegia*, from complete transverse softening in upper dorsal region.

In such a case as that last cited, namely, one of paraplegia due to a total transverse lesion in the upper dorsal region, there would be found above the seat of lesion certain *ascending degenerations*—the principal of which would be situated in the posterior columns, though others, smaller and more recently recognised, are to be met with in the outer

part of the lateral columns (fig. 3). The ascending degenerations in the posterior columns are often strictly limited to the so-called 'columns of Goll.' Situated on each side of the posterior median fissure, they together constitute a median wedge-shaped patch, whose apex extends forwards to the commissure, and whose base is at the posterior surface of the cord. This band of degeneration

FIG. 4.—Peculiar areas of ascending degeneration, met with in a concussion-lesion of the Spinal Cord.

A, transverse section of the Spinal Cord, near the middle of the cervical region; B, transverse section through the cervical region of the cord, near lower border of medulla; C, section through lower part of medulla oblongata; D, section through medulla about $\frac{1}{4}$ " below the *Calamus scriptorius*.

The areas in the posterior columns (*a*, *a'*, *b*, *b'*) have a very peculiar disposition. The areas in the lateral columns in A are very unsymmetrical; that of the right side, anterior to *c'*, represents the lateral sensory tract.

reaches upwards to the bulb, where its fibres seem to terminate in the nucleus gracilis.

It seems clear, however, that, under certain conditions, the areas of ascending degeneration in the posterior columns may be differently arranged, and not completely limited to the 'columns of Goll,' since in a case with a lesion of some kind in the mid-cervical region (the nature of which is not known, because, unfortunately, this part of the cord was not preserved) the writer long ago found such areas as are represented in fig. 4 in the upper cervical region and in the medulla. The ascending areas of degeneration occupying the superficial portions of the lateral columns were traced by the writer upwards into the restiform bodies. These are areas which we now know to correspond with the subsequently described 'direct cerebellar tract'; while the 'tract of Gowers'—corresponding with the part of the areas anterior to *c'* in fig. 4, A and B—which has still more recently been described, also contains afferent fibres for the cerebellum, though they reach it by a different route. According to Schäfer, they can be traced upwards into the bulb and pons Varolii, while they eventually enter the cerebellum as part of the superior peduncle, passing mainly to the vermis. The fibres of this latter tract are intermingled with those of a part of the descending cerebellar tract (fig. 1), which is the only other long tract of degeneration existing in the spinal cord that has not hitherto been mentioned.

In these areas of degeneration, in addition to the changes already mentioned as occurring in the nerves themselves, other processes take place. There is, for instance, a very distinct but secondary over-

growth of the connective tissue throughout the diseased area, as well as an abundant development of large 'granulation-corpuses,' precisely similar to those met with in ordinary foci of softened nerve-tissue. The granulation-corpuses are closely packed among the meshes of the connective-tissue overgrowth and the atrophied nerve-fibres. In preparations which have been immersed in bichromates or in chromic acid, these corpuses do not become stained to nearly the same extent as the healthy nerve-tissues; hence the areas containing them remain pale, and are consequently to be traced with the greatest ease in spinal cords which have been immersed for a week or two in these fluids, though when they were in the fresh state no such areas may have been detectable, even on the most careful examination, by the naked eye. On the other hand, when sections through such degenerated areas of spinal cord are mounted in the ordinary way in Canada balsam, the granulation-corpuses become invisible, so that Tooth and other recent writers make no mention of the existence of granulation-corpuses in the areas of degeneration—the most obvious change then being the overgrowth of connective tissue, leaving, as Tooth says, 'loculi filled with homogeneous material not staining by Weigert hæmatoxylin.' This 'homogeneous material' in the loculi represents, as the writer believes, granulation-corpuses altered by the preparation of the specimens.

(14) *New-growths* in the substance of the spinal cord itself are not very common, nor, on account of the limitations of space within the spinal canal, do they ever attain a very large size, so long as they take the form of circumscribed growths. For this situation a growth equalling a hazel-nut in bulk would be esteemed large. In regard to the nature of the growth, this is, of course, a matter of purely pathological interest, since the clinical signs and symptoms which a growth in the spinal cord is capable of causing would not vary with its nature, but would be wholly dependent upon its situation, and its rate and manner of increase. *Cancer* occurs within the spinal cord almost solely as a secondary extension from a similar growth pre-existing in the dura mater or in the vertebræ, or possibly in more distant parts. In altogether exceptional cases it may occur primarily in the spinal cord. *Gliomata*, *sarcomata*, and *myxomata* may also occasionally be met with, either in pure or in blended types; and in the case of the former we may have infiltrating growths occupying a wide area in the central and posterior regions of the cord more especially, through a considerable portion of its length, such as occurs in syringo-myelia. *Tubercular* nodules are also apt to occur, either alone or in combination with a tubercular meningitis. *Syphilitic gummata* may likewise be found in the substance of the cord, though their presence in this situation is not so frequent as it is in association with the spinal meninges.

(15) *Atrophy with degeneration of ganglion-cells* is apt to occur as a secondary process with extreme frequency in portions of the grey matter of the cord which happen to be more or less implicated in other contiguous pathological changes. But in two or three distinct diseases the ganglion-cells or the anterior cornua in different parts of the cord are prone to be suddenly overtaken by an ætiologically obscure failure of nutrition, commonly supposed to be of an inflammatory nature, which speedily entails

an atrophy of the particular cells affected. This, for instance, occurs as the anatomical basis of 'infantile paralysis,' and of the similar form of paralysis now known to occur (though more rarely) in adults. In these diseases whole groups of contiguous and functionally related cells are affected simultaneously, and as the atrophy of the ganglion-cells progresses there is generally evidence of a secondary overgrowth of the surrounding neuroglia in the anterior cornua. To assume that this process is inflammatory in type, as the terms 'cornual myelitis' or 'acute anterior polio-myelitis' imply, seems to the writer somewhat questionable. Inflammation does not commonly limit itself to individual tissue-elements, and the slight overgrowth of the contiguous neuroglia may well be a secondary process of simple hyperplasia. This latter process is indeed less evident where, as in 'progressive muscular atrophy,' the initial and mysterious atrophy of individual ganglion-cells occurs more slowly and more sparsely. Cells, here and there, in particular anatomical groups, undergo in this affection the atrophic process, leaving others around them for a time as healthy as ever. Yet, as the disease progresses, the ranks of the healthy cells become gradually thinned in an altogether irregular manner; and this atrophy of nerve-cells, as it occurs, speedily entails, for reasons to be set forth in the next section, a corresponding atrophy of functionally related muscular fibres.

Trophic Relations between different Tissues and different Parts of the Spinal Cord.—Irritation of the posterior cornua, or of the posterior roots of the spinal nerves, may give rise to various pustular or vesicular eruptions in related portions of the skin, often associated with neuralgic pains in these same regions. In other cases, with lesions in some parts of the grey matter, ulceration or actual sloughing of certain related tracts of skin is easily determined—especially under the combined influence of continued external pressure and frequent irritation from urine or fæces, as in some cases of paraplegia. See p. 685.

Degeneration or destruction in any way of the great ganglion-cells of the anterior cornua, or of the anterior roots of the spinal nerves (either within or outside the cord), gives rise, in the course of two or three weeks, to atrophy of the muscle-fibres with which such atrophied cells or nerve-roots are in relation. We thus get an atrophic paralysis, associated with the electrical 'reaction of degeneration.'

Certain diseases affecting the grey matter of the cord (in ways and sites which cannot be precisely defined) are also commonly supposed to be associated with chronic diseases of the joints; it seems, however, to the writer that these articular changes may be due rather to a co-existing peripheral neuritis involving certain nerves proceeding to the joints. Sometimes comparatively unimportant, these joint-changes lead in other instances to great atrophy of the articular ends of the bones, and possibly to dislocation with utter destruction of the joint, as in some cases of locomotor ataxy. Atrophy, with brittleness of bones, may also be met with in the same or in allied cases.

The fact of the existence of these trophic troubles in association with such lesions may be admitted wholly irrespective of the explanation of their pathogenesis. Whether they are due to defective or altered influences transmitted by ordinary motor and

sensory nerves in relation with such tissues, or to altered influences through certain purely hypothetical 'trophic nerves,' lies altogether outside the fact of the mere co-existence of the several trophic troubles with the several lesions—which is the point of more immediate interest for the practitioner of medicine.

Regional Diagnosis.—We already possess a number of valuable clinical data available for throwing light upon the regional side of the problem of diagnosis. It must be borne in mind, however, that the regional diagnosis of diseases of the spinal cord is itself a twofold problem. It involves a consideration: (a) of the *transverse area* involved; and (b) of the *longitudinal situation and extent* of the disease in such areas.

(a) **DIAGNOSIS OF THE TRANSVERSE AREA INVOLVED.**—The facts to be tabulated under this head may be set down in the order of their relation to different component parts or regions of the spinal cord.

(1) *Anterior roots of spinal nerves.*—Irritation of these may give rise to various forms of twitching or to tonic spasms in related muscles. Great pressure upon or destruction of the anterior roots will give rise to local complete or partial paralysis in the related muscles, followed in the course of a week or two by marked atrophy, and the establishment of the electrical 'reaction of degeneration' (see PARALYSIS). There will also be an abolition of reflex excitability of these muscles in response to skin-irritation, or to blows upon or stretchings of their tendons.

(2) *Antero-lateral columns.*—Increasing pressure upon or disease of these columns gives rise to paresis, gradually deepening into motor paralysis of parts deriving their nerve-supply at or below the seat of lesion.

When the disease occurs in the lateral column more especially, there may be twitchings or startings in the muscles below, or well-marked spasms, and possibly painful cramps. There may also be great exaltation of the superficial and deep reflexes, if the manifestation of the latter is not hindered by pre-existing spasms. The plantar reflex shows itself in the form of *extension* of the toes, especially of the great toe—'Babinski's sign' (see p. 121). Motor paralysis exists to some extent, but without any appreciable impairment of sensibility. No marked wasting of muscles, or diminution in electrical reactions, usually occurs.

(3) *Grey matter.*—(a) *Of anterior cornua.*—Disease of these parts causes motor paralysis, with atrophy, loss of faradic excitability and of reflex excitability in related muscles—as in cases of disease of the anterior roots of spinal nerves.

(b) *Of posterior cornua and central parts.*—Damage of these regions of grey matter will, according to its completeness in transverse extent, cause more or less delay or defect in the transmission of painful and thermic impressions, and perhaps interfere also with other modes of sensibility. Some trophic lesions in skin and joints may also be met with.

At different levels in the cord special centres (represented in both anterior and posterior regions of grey matter) in connection with definite functions may be interfered with by morbid conditions implicating the grey matter.

(4) *Posterior columns.*—The results of disease confined to this situation (more especially to the

'root-zones') will be—ataxy or signs of inco-ordination of movements; interference with impressions of touch, pressure, temperature, and of 'muscular sense'; abolition of knee-reflex; and diminution or loss of sexual desire.

(5) *Posterior roots of spinal nerves.*—From irritating lesions there will arise lancinating or other pains in the skin and deeper textures of related portions of the limbs, and possibly trophic skin-lesions. Pressure or destructive lesions will give rise to loss, in various degrees, of different modes of sensibility, superficial and deep; and diminution or abolition of the superficial and deep reflexes in related regions of the body.

It has been shown by Sherrington and others that there is considerable overlapping of the skin-areas supplied by contiguous posterior roots, and this has recently been well exemplified in one of the writer's cases of spinal caries operated upon by V. Horsley. In the course of the operation a single posterior nerve-root in the mid-dorsal region was divided on the right side, while two nerve-roots were divided on the left side. Around this latter half of the body a narrow band of anaesthesia was produced, only one inch wide; while on the right side there was no anaesthesia, this being obviated apparently by the overlapping above referred to. No such overlapping exists, however, in connection with the territories of the nerves concerned with the appreciation of heat and cold, or of painful impressions (Head).

(b) **DIAGNOSIS OF THE LONGITUDINAL SITUATION AND EXTENT OF THE LESION.**—This is a consideration distinctly secondary to the other, since, at whatever longitudinal level the disease may be situated, its clinical characters will always be qualified by the part or parts of the transverse extent of the cord that may be involved. Here we are accustomed to obtain information of a general kind from the fact (1) that *special centres* in connection with different viscera and functions, situated at different longitudinal levels in the cord, may be more or less deranged. But we have to depend in the main (2) upon the signs indicative of the *implication of particular sensory and motor nerves*, whose exact relations with different portions of the spinal cord are known. Such signs may consist of some excess or defect of *sensibility*, of *motility*, or of *reflex activity*. Again, where disease or injury of the vertebrae exists in association with disease of the spinal cord, we may be guided by the known relations of the different vertebral spines to the different nerve-roots and segments of the cord.

Evidence from perverted activity of Spinal Centres.

(1) The lateral columns in the upper cervical region contain the motor paths for the muscles of respiration, so that section or disease of these columns at a lower level may interfere with the movements of respiration on the same side of the chest (thoracic muscles); while if the lesion reaches as high as the fourth and third cervical nerves (the origin of the phrenic) the diaphragm itself also becomes paralysed, and the movements of respiration must therefore almost cease.

(2) Again, the upper cervical region of the cord, though it does not contain actual centres connected with the excitation of the heart's action, is traversed by the augmentor and accelerator nerves, whose point of exit from the cord, as white *rami*

viscerales, is with the second, third, and other upper dorsal anterior roots. These nerves ascend to the stellate ganglion, and thence proceed to the heart.

Thus different lesions in this upper cervical region of the cord may, according to their nature and extent, greatly interfere with the heart's action, as well as with the respiratory movements. The frequency of the pulse may be either notably accelerated or retarded; while the respiratory movements may be slower or much quicker than natural, and also extremely irregular and perverted in rhythm.

(3) The lower cervical and upper dorsal regions of the cord also contain the so-called 'cilio-spinal centre.' The fibres emanating from it pass outwards with the fibres of the anterior roots in the first, second, and third dorsal nerves, but especially in the second, and thence into the cervical sympathetic. Irritation of them causes dilatation of the pupil on the same side, together with widening of the palpebral fissure, while section or other destructive lesion of these parts causes contraction of the pupil.

(4) The vaso-motor nerves for the side of the head and neck, and the pinna of the ear, together with those for the lateral lobe and half the isthmus of the thyroid body, arise in similar regions of the cord, and also leave it similarly. Irritation of them produces contraction of the blood-vessels and a lowering of temperature of the side of the face and head, together with diminution of sensibility, an absence of perspiration, and (should the irritation continue) a tendency to slight atrophy of the corresponding side of the face. Destructive lesions, on the other hand, operating upon these vaso-motor fibres, tend to produce a reverse set of conditions. See SYMPATHETIC SYSTEM, Disorders of.

Sometimes there may be signs of paralysis of oculo-pupillary fibres co-existing with signs of irritation of the vaso-motor fibres, or *vice versâ*.

(5) Gaskell has shown that all the *vaso-motor nerves* of the body leave the spinal cord in the anterior roots of the spinal nerves, from the second dorsal to the second lumbar inclusive, passing thence into the lateral ganglia of the sympathetic, in which these vaso-motor fibres lose their medullary sheaths. He adds: 'This chain might, therefore, most appropriately be called the chain of vaso-motor ganglia instead of its present meaningless title of main sympathetic chain.' Gaskell also thinks, and in this he is supported by Sherrington, that the vaso-motor nerves, as well as certain visceral motor nerves, are connected with ganglion-cells in the lateral regions of the grey matter. (See PLATE XVII., p. 1520.)

Generally it may be said that section of one half of the cord or destruction of it for any extent longitudinally, causes at first paralysis of blood-vessels in the lower parts of the body on the same side—this vaso-motor paralysis carrying with it in the same parts an increase of temperature and an exaltation of sensibility. In a short time, however, the vaso-motor paralysis (and with it the increase of heat and sensibility) passes away, owing to the vaso-motor centres in parts of the spinal cord below, and to the peripheral vaso-motor centres, adapting themselves to act independently of those in higher parts of the cord, and of the supreme regulating centre in the medulla ob-

longata. (As a rule, the higher vaso-motor centres control those lower down, but after temporary paralysis even the peripheral vaso-motor centres seem to resume control over related blood-vessels.)

(6) The movements and secretions of the stomach and intestines generally are certainly influenced by the cord in different regions, so that in various cases, owing to perversions of this normal spinal influence, we may get vomiting, diarrhoea, or obstinate constipation—as direct results, that is, of morbid changes in certain parts of the cord in which intestinal sympathetic fibres have their roots. It seems, however, that through the greater portion of the alimentary canal the circular muscles are innervated by motor fibres distributed with the vagus. Thus peristaltic contractions of the oesophagus, stomach, and intestines can be excited by vagus-stimulation, whether the stimulus be applied to the roots of the nerves as they leave the bulb, or to the main trunk of the vagus in any part of its cervical or thoracic course. On the other hand, the circular fibres of the rectum and of the descending colon are supplied by the lower abdominal splanchnic nerves, which leave the cord with the thoracic and not with the sacral outflow of visceral nerves (Gaskell).

In the grey matter of the lumbar swelling of the cord there are aggregated a number of *centres* having to do with important functions, which may be variously interfered with by disease. These centres are those which regulate—(7) the evacuation of the rectum; (8) the evacuation of the bladder; (9) erection, and ejaculatio seminis; and (10) the contractions of the uterus.

In each case the spinal centre constitutes an independent reflex centre, provided with its afferent and efferent nerves, but in each case also there is more or less of connection between the spinal centre and others in the cerebral hemispheres. There must therefore be double sets of fibres for each centre traversing the whole length of the spinal cord and medulla; partly (commissural) for the transference of afferent impressions from each spinal centre to the brain, and partly (internuncial) for the conduction of efferent impressions from cerebral kinæsthetic to spinal motor centres.

In the case of the uterine centre these cerebral connections are of comparatively slight importance; since, with a complete transverse lesion in the cervical or even in the upper dorsal region, the process of parturition may still be successfully accomplished. So long as the spinal mechanism is complete and perfect, parturition may take place without the need of cerebral co-operation. Our subsequent remarks will, therefore, refer principally to the other three lumbar centres.

Complete transverse lesions occurring in any part of the dorsal or cervical regions will, of course, entirely cut off all the above-mentioned lumbar spinal centres from connection with, and therefore from any voluntary control by, the cerebral hemispheres. But various limited local lesions in particular transverse areas of the cord (though the locality of such areas cannot at present be definitely specified) may produce similar results, so far as the cerebral control of any one or two of the lumbar centres is concerned. According as the severance of these lumbar spinal centres from cerebral correlation and control is complete or partial, one or other of the following results would be produced:—

Name of Centre	Complete Severance from Cerebrum	Incomplete Severance from Cerebrum	
	Afferent and Efferent Fibres	Afferent Commissural Fibres only	Efferent Internuncial Fibres only
<i>Rectal centre</i>	Unconsciousness of need, and inability to prevent evacuation <i>Result.</i> —Constipation, with incontinence of feces after an aperient	Unconsciousness of need, and therefore no attempt to restrain evacuation	Consciousness of need to evacuate, with no ability to restrain the act
<i>Vesical centre</i>	Unconsciousness of need, and inability to prevent micturition <i>Result.</i> —Reflex evacuation in gushes at intervals	Unconsciousness of need, and therefore no attempt to restrain micturition	Consciousness of need, but inability to restrain micturition
<i>Sexual centre</i>	Diminution or absence of sexual desire. Erections and emissions, if they occur, wholly dependent upon the spinal reflex mechanism	With simple destruction of fibres, nearly same results as set down in previous column; but with <i>irritation</i> of afferent fibres there might be great increase of desire (satyriasis or nymphomania)	Feelings of desire, but no erection in response Erection and emissions, if present, purely through spinal reflex But with <i>irritation</i> of efferent fibres there may be persistent erections, mostly without desire

The *rectal* and the *vesical spinal centres* are each composed of two parts, with their separate afferent and efferent nerves—one set in relation with a sphincter muscle, and the other in relation with detrusor or expulsive muscles in functional opposition to the former. The several nerve-fibres, both afferent and efferent, in connection with these centres have been shown by Sherrington to be contained in the first four sacral nerves, and in the case of the bladder also in the third, fourth, and fifth lumbar nerves (though none are contained in the intervening sixth and seventh lumbar). Thus, as Sherrington says: 'If, as one may suppose, the position of the outflow of the efferents fairly indicates the position of the nucleus whence they come, then we may suppose that a long nucleus for the bladder exists in the lumbo-sacral region, which has, however, a gap in its continuity. . . . The outflow from the anterior roots above the gap is into the sympathetic system; from the anterior roots below the gap it is direct by the sacral nerves.' Destruction or irritation of either of these sets of fibres, or of one of the centres, will necessarily interfere to some extent with the working of this particular centre, so that its functions may be interfered with in several different ways. There may be various degrees of irritability of the bladder or rectum, or various degrees of paralysis of these organs.

In cases of paralysis of the bladder, especially when they are due to lesions implicating its spinal centre, the urine is apt soon to become fetid and alkaline, and inflammation (alone or with ulceration) is most prone to be set up in its mucous membrane.

The details as to the modes of disturbance of the *genital function*, where disease implicates its lumbar centre or the afferent and efferent nerves in connection therewith, are less known than where it involves the communicating fibres between this centre and the cerebrum. The *nervi erigentes* have been shown to pass out with the second and third sacral nerves, so that the sexual like the rectal centre is contained in the posterior part of the lumbar swelling. In the female the uterine centre has been shown to be similarly situated.

Evidence from implication of particular Sensory or Motor Nerves.

The more precise indications concerning the

longitudinal implication of the spinal cord are, as already stated, derivable from the level at which alterations in sensibility or in motility (either voluntary or reflex) are to be detected. The more closely the lesion approaches to what is called a 'total transverse lesion,' the more distinctly will signs of this order reveal themselves. It is important, too, to recollect that the fibres of different sensory roots are to some extent dispersed through cutaneous surfaces overlying the muscles supplied by the corresponding motor roots. There are, however, many exceptions to this.

In regard to *sensibility*, the upper limit at which the trunk is affected is often sharply defined by the presence of a feeling of constriction, of pain, or of numbness ('girdle sensation') encircling the body. This sensation is generally supposed to be due to irritation of the roots of the nerves as they traverse the posterior columns (or perhaps outside them) at the upper level of the lesion. This symptom may of course be absent, but in some cases of paraplegia it is well marked, especially where the upper level of the lesion lies anywhere between the third and the twelfth dorsal nerve-roots.

Our knowledge has of late been greatly increased concerning the extent and distribution of the cutaneous areas ('segmental skin-fields') pertaining to each sensory spinal nerve, owing to the labours of Ross, Allen Starr, James Mackenzie, Head, and Sherrington. As the last investigator says: 'Although in a plexus each posterior spinal root gives separate contributions to several nerve-trunks, the cutaneous distribution of the root is composed not of patches which are disjointed, but of patches which are so joined that the distribution of the entire root forms one continuous field. . . . Each segmental skin-field spreads, to a certain extent, across neighbouring segmental skin-fields. . . . The *fore-lap* and the *after-lap* are, throughout the body, very great, and each region of skin appears to be supplied by at least two sensory roots. . . . The shape of a segmental skin-field is, where simplest—e.g. in the trunk and neck—band-like, wrapping transversely round one lateral half of the body; it has fairly parallel edges, but is somewhat broader near its ventral than at its dorsal end. In the limb the segmental skin-fields are *distorted* from the simple band-like type; and they are also seemingly

dislocated from their attachments to the mid-dorsal and mid-ventral lines of the trunk. This peculiar distribution Sherrington explains by supposing that the mid-dorsal as well as the mid-ventral line of the body extends outwards in the position of the limb as a side-branch or secondary axis. 'Upon these dorsal and ventral side lines, as upon secondary

FIG. 5.—To show the presumed distribution of the areas supplied from the 2nd lumbar to the 1st sacral segments. (After Head.)

The area marked in *cross lines* represents L 2.

The area marked in *vertical lines* represents L 3.

The area marked with *circles* represents L 4.

The area marked with *dots* represents L 5.

The area left plain below represents S 1.

dorsal and ventral axes, the cutaneous segments of the limb are ranged, as though upon folded portions of the axial lines of the trunk itself.'

Now, as already stated (p. 1526, (5)), this overlapping of the segmental skin-fields exists, especially for tactile sensations, owing probably to the related tracts of grey matter in the spinal cord each extending into the spinal segments above and below its own, and consequently being represented in the corresponding posterior spinal nerve-roots. The researches of Head, however, seem to show that no such overlapping of segmental skin-fields or extension of related grey matter into adjacent spinal segments exists for painful impressions, or for those of heat and cold. Consequently, to determine the exact boundaries of a cutaneous area of defective sensibility, whether due to a lesion in the cord or of one or more posterior spinal roots, we shall get much more accurate results if we seek to map out the areas in which the patient may be insensitive to painful impressions, or to those of heat and cold, rather than those areas in which he is insensitive to ordinary tactile impressions. These different areas in relation with the several posterior roots have been definitely mapped out by Head. A supplemental figure, showing the probable skin-fields from the second lumbar to the first sacral inclusive, has been reproduced above (fig. 5). For the rest the plates given by Head must be consulted. See p. 1138.

Efforts were also formerly made to define the muscles that were paralysed, in any given case, with a view to determine the upper limit of the lesion in the cord. It was thought that a reference to the

anterior roots by which such muscles are innervated ought to enable us to fix upon the particular segment of the cord from which their nerves proceed, and thus to determine with precision the upper level of the lesion in the *motor regions* of the cord. This is a matter, however, by no means so simple as might be supposed, because the majority of limb- and trunk-muscles receive fibres from more than one motor root, as Preyer and Krause and others showed long ago. The same conclusion has been arrived at by Eckhardt, and later by Sherrington. The former says: 'A great number of muscles in the limb obtain nerve-fibres each of them from several nerve-roots. Most of the thigh-muscles always, some of the leg-muscles frequently, are supplied by three, the latter more often by two, nerve-roots.' According to Sherrington, when a muscle is supplied by three nerve-roots it is noticeable that the middle root of the three usually causes the most powerful contraction. However this may be, it is obvious that the fibres going to each muscle must take their origin 'over a certain considerable longitudinal region of the cord.'

This fact, that muscles receive their nerve-supply from two or three different nerve-roots, was formerly thought to be due to the circumstance that the same muscle is called into play in different co-ordinated movements. And the view of E. Remak, that functionally related or synergic muscles are represented together in the anterior horns of the spinal cord, was supposed to have been confirmed and extended by Ferrier and Yeo by their experimental observations on the functions of the anterior roots. They say that stimulation of the individual roots of the brachial and crural plexuses results, not in mere unrelated contractions of various muscles, but in highly co-ordinated synergic contractions, leading to definite movements. But as the 'muscles thrown into action by each root are innervated in most cases by several nerve-trunks,' the result 'of section of each motor root would therefore be paralysis of the corresponding combination, not necessarily, however, of the individual muscles involved . . . while *weakened*, they might yet act in other combinations in so far as they were supplied by other roots.' The different combined movements which they thought to be dependent upon particular motor roots are cited by the authors in this paper.

This important subject has been re-investigated of late by Sherrington, who comes to an opposite conclusion. He says: 'Contrary to Panizza's doctrine, revived and ably reappointed by Remak and by Ferrier and Yeo, and followed since by Bert, Marcacci, and others, I believe John Müller to have been right in attributing to the arrangement of the motor roots of the limb-plexus an anatomical significance, based on metamerism, rather than a teleological significance dependent upon supposed demands of functional co-ordination.' He considers that in the great majority of cases muscles innervated by the same nerve-root lie adjacent one to another; but 'that the loss of some particular co-ordinated movement results, from the severance of one of the motor roots of the limb-plexus,' he says, 'I have been unable to detect, and seen no evidence to support.' His own investigations lead him to believe that the section of some two, three, or even more anterior roots going to the upper or lower limb-plexus leads to a weakened condition of many movements. He adds: 'The helplessness, at first very apparent,

rapidly diminished up to a certain point. The diminution seemed to be largely due to the over-coming in course of time of an unwillingness to attempt movements with the injured limb.⁷ His experiments with monkeys convinced him that the execution of a co-ordinated movement was still possible when one motor root only of the plexus remained open as a channel from the cord.

All this shows that the upper level of a lesion in the cord can only be fixed approximately by reference to the motor paralysis existing in limbs or in the trunk of the body.

The integrity of those *reflex* actions which can be elicited either in health or in disease depends, of course, upon the integrity of the entire nervous arcs concerned (that is, upon the integrity of incoming fibres, centres, and outgoing fibres). Thus, though the impairment of a reflex may not necessarily be due to central causes, its presence, on the other hand, clearly shows that the grey matter and other regions of the cord which must be traversed by its stimuli are not impassable; while its exaltation will indicate the probable existence of some congestion by which the grey matter in question is rendered more excitable, or else some central change by which it is cut off from cerebral inhibitory influences. In § 4 will be found all the needful indications referable to the presence or absence of reflexes which can be used for the determination of the upper level of a lesion existing in the spinal cord. The lower level of a lesion in this organ is always extremely difficult to determine; and if it is to be made out at all, it must be done by reference to the existence of particular muscular atrophies, rather than from the presence or absence of certain reflexes.

Other data in regard to the longitudinal situation of a lesion in the spinal cord are of a more precise order, and are dependent upon the *relations of the vertebral spines to different anterior nerve-roots*. These data are available in cases where the spinal cord becomes implicated in connection with primary disease or injury of the vertebræ. To obtain such data, it is needful to know the exact relations subsisting between the bodies of the different vertebræ, their spines, and the origins of the different nerve-roots.

Only the highest cervical nerves arise from the cord opposite the place at which they leave the spinal canal. As we descend, the distance between these two points gradually increases, and it attains its maximum when we come to the nerves of the cauda equina. What nerve-origins correspond, therefore, to a given vertebral level can only be decided by careful anatomical investigation.

A further complication is introduced into this question, seeing that the vertebral spines, which we are compelled to deal with as localising guides, have different relations in different parts of the spinal column to the bodies of their respective vertebræ—e.g. they incline downwards in the dorsal region more especially, to a less extent in the cervical, and scarcely at all in the lumbar region.

Some of the principal facts in reference to these two points, namely (1) the relations of spinous processes to bodies of vertebræ, and (2) the relations of vertebral spines to origins of nerve-roots, will be found to be embodied in the next section.

SUMMARY.—For practical purposes it will be well here to group together the various indications

as to longitudinal localisation to which we have referred—classifying them as they are related to one or other of four regions of the spinal cord.

(a) **Cervical Region of the Cord.**—*This corresponds externally with the space between the occiput and the upper border of the seventh cervical spine (eighth cervical nerve).*

The first, second, and third cervical spinous processes are respectively opposite the origins of the third, fourth, and fifth cervical nerves. The phrenic nerve (motor nerve of the diaphragm) arises from the fourth, or from the third and the fourth cervical nerves. Opposite the third cervical spine (level of fifth cervical nerve) the cervical swelling of the cord begins; while it ends opposite the seventh cervical spine (level of the first dorsal nerve).

Disease of this region may involve interference with respiration, and possibly weakness of voice; interference with the heart's action—pulse very frequent, or the reverse; flushing or pallor of the head and neck; continued priapism (with crushing lesions); augmentation of temperature in the body generally (hyperpyrexia); and marked contraction or dilatation of the pupil.

The innervation of the shoulder-, arm-, and hand-muscles is derived from spinal nerves between the sixth cervical and first dorsal inclusive; those supplying the ulnar side of the hand and forearm arising from the lower level, that is, from the upper part of the next region. The upper extremities may, therefore, be more or less paralysed, as well as the trunk and lower extremities.

(b) **Upper Half of the Dorsal Region of the Cord.**—*This corresponds externally with the space between the seventh cervical spine (first dorsal nerve) and the fourth dorsal spine (sixth dorsal nerve).*

The results of disease here are apt to be these: The 'scapular reflex' may be abolished, calling into activity as it does the last two or three cervical and the first two or three dorsal nerves; the intercostal muscles are paralysed at different levels; a 'girdle sensation' is felt at different levels; there may be prominence of certain vertebral spines, and possibly tenderness on pressure or on tapping over them; the 'epigastric reflex' may be abolished, depending as it does upon the spinal cord at the level of the fourth to the sixth or seventh pairs of dorsal nerves; and priapism (with crushing lesions) may occasionally be met with. We may have, therefore, some or all of these signs together with more or less complete paralysis of the lower part of the trunk and of the lower extremities.

(c) **Lower Half of the Dorsal Region of the Cord.**—*This corresponds externally with the space between the upper border of the fifth dorsal spine (seventh dorsal nerve) and the lower border of the tenth dorsal spine (space below twelfth dorsal nerve).*

Disease here may give rise to the following symptoms: The 'abdominal reflex' may be abolished, depending as it does upon the integrity of the cord between the levels of the eighth dorsal and the first lumbar nerves. Paralysis of lower intercostal muscles or of abdominal muscles may possibly occur, in addition to paralysis of the lower extremities. 'Girdle sensation' may be felt at different levels (the umbilicus corresponding with the tenth dorsal nerve, and the 'ensiform area' with the sixth and seventh dorsal nerves). There

may be prominence of certain of the lower dorsal spines, with possible tenderness.

(d) **Lumbar Region of the Cord.**—*This corresponds externally with the space between the lower border of the tenth dorsal spine (just below the twelfth dorsal nerve) and the upper border of the second lumbar vertebra.*

Here the symptoms are: Paralysis, not implicating the abdominal muscles, but limited to more or less of those of the lower extremities. No 'girdle sensations' around the trunk. Three superficial reflexes may be abolished, namely, the 'cremasteric,' which depends upon the integrity of the cord in the upper lumbar region; the 'gluteal' and the 'plantar,' both of which seem to be dependent upon the integrity of the lower part of the lumbar region of the cord. A deep reflex may also be abolished, namely, the so-called 'knee-jerk,' which is dependent upon the upper lumbar region of the cord. 'Ankle-clonus' may be met with when disease affects the upper or mid-lumbar regions of the cord, but not where the lower lumbar region is implicated. Loss of sensibility about the perineum and anus (if not due to disease of nerve-trunks) is indicative of disease of the posterior columns in the lower lumbar region. Absolute paralysis of the bladder and rectum may be present, with tendency to inflammation and ulceration of the former organ. (With lesions higher up in the cord there may also be, according to their extent, some of the alterations in regard to the action of the bladder and rectum which have been set forth in a table on p. 1528.)

Although it is true that the groups of symptoms presented in different diseases of the spinal cord, considered individually and collectively, afford the materials upon which a regional diagnosis must be founded, it is no less true that a part of the symptomatology (namely, that comprised in the mode of origin and the mode of establishment of the disease, together with what may be gathered from the patient's state generally, from his family history, and from his personal history) constitutes the basis upon which a pathological diagnosis has to be arrived at. Again, although the arrival at a regional diagnosis is often spoken of, and may seem to be a process altogether distinct from that involved in the arrival at a pathological diagnosis, yet, as a matter of fact, in the investigation of many individual cases of spinal disease, it will be found that the one problem is not settled first, and the other afterwards, but that both are tentatively considered more or less simultaneously. Thus, certain empirically known pathological conditions may afford at once a ready explanation of a given group or sequence of symptoms, as in 'infantile paralysis,' in 'locomotor ataxy,' or, in a more general sense, in angular curvature of the spine. Here, therefore, the pathological diagnosis goes hand in hand with the regional diagnosis, and in working them out each gathers additional confirmation from the establishment of the other. Sometimes, however, as in the case of traumatic injuries (including stabs, and fractures with dislocations of vertebrae), the pathological diagnosis is at once obvious, and the regional diagnosis alone requires to be settled in detail.

For the above reasons, it has been necessary to tabulate in this article certain pathological data concerning the spinal cord, though it would not be found specially advantageous were we to follow out

this part of the subject further, and attempt here to set down the more general *clinical data and deductions of pathological import*, necessary to be borne in mind for the arrival at a pathological diagnosis, in order to form a series of facts and deductions comparable with those already given in elucidation of the problems of regional diagnosis. These other problems will be dealt with, as far as possible, in the descriptions of the several diseases of the spinal cord.

H. CHARLTON BASTIAN.

SPINAL CORD, Special Diseases of.—These will be described under the following headings.

I. Diseases of the Spinal Cord dependent upon known organic changes:—

- (1) Spinal Cord, Concussion of, p. 1531.
- (2) Spinal Cord, Punctured or Gunshot Wounds of, p. 1532.
- (3) Spinal Cord, Sudden Crushing Lesions of, p. 1534.
- (4) Spinal Cord, Slow Compression of, p. 1535.
- (5) Spinal Cord, Anæmia of, p. 1538.

I. Spinal Cord, Concussion of.—SYNON.: *Commotio Medullæ Spinalis*; Fr. *Commotion de la Moelle Epinière*; Ger. *Erschütterung des Rückenmarks*.

ÆTIOLOGY.—This condition is met with principally in persons who have fallen from a height, or in those who have been present in a railway collision. In these cases the brain is apt to suffer as well as the spinal cord, and it is not always easy to unravel the respective symptoms due to shock of this or that great segment of the cerebro-spinal system.

ANATOMICAL CHARACTERS.—In many of these cases there are, in all probability, no morbid changes that would be discoverable. In others, however, minute extravasations of blood, or actual ruptures of the nerve-tissue, may occur. Sometimes, as in a case seen by the writer, even notable lesions are produced. An example of the slighter lesions is recorded by Gull, in which small extravasations of blood were found in the anterior and posterior cornua, as well as in the posterior columns of the cord. In neither of these cases was there any external or visible injury; but in each paraplegia was produced immediately after the fall that determined the lesions in the cord. In addition to hæmorrhages into the substance of the spinal cord itself, there is in these cases the possibility of the occurrence of meningeal hæmorrhages, pressing upon the cord or its nerve-roots; and within a day or two after the occurrence of the concussion itself, there is the possibility of some local and subacute inflammation being set up in the membranes of the cord.

SYMPTOMS.—In the great majority of these cases no complete paralysis is induced, even at first. There may at most be paresis of one or more limbs, general prostration, nausea with occasional vomiting, a rapid and possibly irregular or intermittent pulse (especially after the least exertion), with occasional startings and twitchings of the limbs, the sensibility of which may be diminished, exalted, or unaffected. The temperature will probably be at first depressed, as a result of shock, though subsequently a slight febrile elevation may continue for some days. The tongue may be furred, the appetite bad, the bowels constipated; while in regard to micturition there may be either some delay and difficulty, or, on the contrary, an irritability of the bladder, with difficulty in retaining its contents after the desire to micturate is once felt. With this there is often general restlessness, nervousness, and insomnia.

In more severe cases of concussion, even where there is no complication resulting from appreciable lesions, the shock to the system (*see SHOCK*) may be more profound, and there may be paralysis of limbs, lasting perhaps for some days, and then rather suddenly disappearing.

DIAGNOSIS.—The questions to be determined are, whether, looking to the symptoms presented by the patient, there is likely to be any organic lesion or change in the spinal cord or its membranes; or whether we have to do with mere functional perturbations induced by the shock or blow to which the patient has been subjected. In the absence of definite paralysis, or even with its presence for the first few days, the answer to this preliminary question will often be shrouded in doubt. To come to a definite opinion as to the precise nature of the change which a spinal cord, deemed to be damaged in some way after a concussion, has undergone, lapse of time and several examinations of the patient are often required.

In many cases in which compensation for an injury is claimed, a further complication appears. Here it is that the difficulty arises as to how much the symptoms experienced, or said to be experienced, may be due to an excited imagination, and how much to causes independent of the imagination, whether voluntarily or involuntarily aroused. It must be conceded that symptoms of injury are undoubtedly feigned by unscrupulous persons; and it seems also equally clear that, even unknown to

the patient, the excitement consequent upon the accident, the details heard concerning the injuries of others, combined with the inquiries of doctors and of sympathising friends, tend to keep up and to exaggerate symptoms in many nervous patients, over and above those which may have resulted from the shock. Such patients also may make a more speedy recovery subsequent to trial and compensation than they had been making before the trial, and yet they *may* not have been in any sense impostors. It is true that such persons, however, do not recover quite so quickly as those others who for their own unscrupulous ends have been previously exciting their imaginations in a voluntary manner. *See RAILWAY INJURIES.*

PROGNOSIS.—In only the severest cases of concussion or shock is there actual danger to life (*see SHOCK*). Where, however, great prostration is induced, and especially in those who may previously have been suffering from heart-affections, or from a very excitable nervous system, life may be speedily brought to a close; or at most such patients may not survive a severe concussion more than a day or two.

Severe concussions of the cord may also form the starting-points of many and varied deviations from health, which may not begin to show themselves for weeks, or perhaps even months, after the initial shock. Among such sequelæ, which have come under the writer's notice, may be mentioned the following: Loss of flesh with general failure of nutrition, epileptiform fits, progressive muscular atrophy, lateral sclerosis of the spinal cord, a slowly increasing paraplegia (of uncertain pathological basis), and caries of vertebræ followed by angular curvature and paraplegia.

In other and slighter cases, time and rest, with suitable medical treatment, may be expected to lead to perfect recovery, sometimes speedily, but sometimes only after protracted periods of impaired health.

TREATMENT.—In the first instance, symptoms of shock have to be combated by the employment of warmth and stimulants. In subsequent stages, rest in the recumbent position must be enjoined for a time. It is of the first importance to make sure that the patient does take complete rest, and is kept free from excitement during the first few days after any concussion-accident, and that he gets sound sleep at night, under the influence of bromide of potassium, or of this together with chloral hydrate. If the condition of restlessness, with disturbed sleep, can be checked, then a mitigation of other symptoms may be expected to follow. The application of ice to the spinal column may at times be desirable; or pain must be relieved by the subcutaneous injection of small doses of morphia. Later on, tonics, with a simple nutritious diet and plenty of fresh air, together with rest, will be needed for the complete restoration of the patient.

H. CHARLTON BASTIAN.

2. Spinal Cord, Punctured or Gunshot Wounds of.—**SYNON.**: Acute Traumatic Lesions of the Spinal Cord; *Fr. Plaies et Contusions de la Moelle Epinière*; *Ger. Rückenmarkszerreissungen.*

ÆTIOLOGY AND ANATOMICAL CHARACTERS.—Punctured or gunshot wounds of the spinal cord are commonly made with knife, dagger, sword, or bullet.

In each set of cases, the wound in the spinal

cord will be associated with perforation or rupture of some of the membranes, and also with hemorrhage, either between them or into the substance of the cord. The arches of the vertebrae or their articular processes and some of the ligaments connecting them may be more or less damaged, and a wound commonly exists through the contiguous skin and muscles. In the cord itself, there may be either a clean-cut wound through certain of its columns and parts, or a broader crushing lesion. In each case more or less blood may be effused upon and below the cut surfaces of the cord. At later stages, there may be signs of inflammation of the membranes, as well as of local inflammatory softening of the substance of the cord.

SYMPTOMS.—The signs and symptoms consequent upon wounds of this kind are subject to endless variations, in accordance with the different regions of the cord involved, the actual extent of the wound in its substance, and the possible presence of varying amounts of effused blood. These wounds often involve only a portion of the transverse area of the cord. It is indeed in this class of cases more especially that *hemiplegia spinalis* and *hemiparaplegia* are met with. Thus, where a unilateral lesion exists in the mid or upper cervical region, both arm and leg are paralysed, so that the state known as *hemiplegia spinalis* is produced; but where it occurs in the dorsal region, the one leg only is paralysed, and we have what is known as *hemiparaplegia*.

Since the experiments made many years ago by Brown-Séquard on the result of hemisection of the cord in certain animals, it has been commonly supposed that the essential peculiarity in the latter cases is that on the side of lesion there is complete motor paralysis in the limbs or limb below; while on the opposite side, the limbs or limb, and the trunk up to the middle line, are more or less completely anæsthetic—sensitiveness to impressions of touch, pain, temperature, and tickling being alike abolished. The subsequent researches of Mott are opposed to this view in regard to sensory troubles. He maintains that they exist on the same side as the lesion and as the motor paralysis, and, in confirmation, says that where the hemisection is accurately made, no ascending secondary degenerations are seen on the opposite side of the spinal cord.

Other minor peculiarities that have been described are these: On the side of *motor paralysis*, there is also vaso-motor paralysis, which carries with it, as consequences, (a) an elevation of temperature (from $1\frac{1}{2}^{\circ}$ to 2° F.), and (b) a hyperæsthesia for all modes of sensibility (owing in part to hyperæmia in the limb and cord). Surrounding the body, at the level of the upper margin of anæsthesia on the side of sensory defect, there is usually a narrow girdle of hyperæsthesia; while below this level, on the side of the lesion, there is a half-band of hemianæsthesia—whose depth varies with the longitudinal extent of the lesion. The complete zone of hyperæsthesia has been thought to be due to hyperæmia of nerve-roots, and of the grey matter of the cord immediately above the lesion; while the half-zone of anæsthesia is supposed to be dependent upon destruction of the nerve-roots, and of the spinal cord for a certain extent at the seat of lesion.

If bed-sores occur, they are met with on the side of paralysis; while in one or two cases signs of a

joint-affection (in the knee principally) have also occurred on the side of sensory and motor paralysis. There seems no reason for expecting any special muscular atrophy or diminution of faradic irritability on the side of paralysis, except in parts of those muscles whose nerve-supply comes from the portion of the anterior cornua actually destroyed by the lesion. In many cases, especially at first, there is paralysis of the bladder and of the rectum, or there may be incontinence of urine. Later on, these troubles tend to diminish. The superficial and deep reflexes are generally found to be exaggerated on the side of lesion.

In gunshot wounds, whether occasioned by pistol or rifle, splinters of bone may be depressed at times, so as to compress and irritate the cord, and thus the symptoms may be made to approximate more closely to wounds of the next category.

After a few days the symptoms may be complicated by those of spinal meningitis, or extended by the spread of an inflammatory softening of the cord above and below the seat of lesion.

DIAGNOSIS.—The primary cause of the patient's condition is generally only too obvious. It may be clear that we have to do either with a punctured or with a gunshot wound in some region of the spine; but subsequently many, and often very difficult, questions require to be solved. It is of first importance to learn whether the cord itself is really damaged, or whether the symptoms are in the main caused by epi-dural or subarachnoid hemorrhages (see MENINGES, SPINAL, Hemorrhage into). In the former case there will be evidence of complete or partial interruption of conduction in the cord, to or from all parts below the seat of lesion, and not of a mere local implication of nerve-roots. If it seem probable that the cord itself is injured, we have to determine whether it is completely cut across, or only partially damaged—and if the latter, to what extent. These questions must be decided in the main by reference to the signs given on pp. 1526 to 1531.

Should the case be seen for the first time several days after the injury, an exact diagnosis as to the amount of damage to the cord itself is often greatly obscured by the existence then of certain secondary pathological conditions—more especially localised inflammation of the meninges, or secondary inflammatory softening, extending perhaps above or below, or in both directions, from the original wound. A process of softening may also extend transversely through the whole substance of the cord, even where only a unilateral lesion had previously existed.

PROGNOSIS.—This, as a rule, is bad in all cases of traumatic injury of the spinal cord; and the gravity of the case is usually the greater the higher the wound happens to be situated in the cervical region. Wounds of the dorsal or lumbar region of the cord are rather less serious, so far as life is concerned.

The degree of recovery from paralysis of limbs will greatly depend upon the nature and extent of the wound. A clean-cut wound may be filled up by the growth of a kind of cicatricial tissue; but, so far as our knowledge goes at present, it must be said that there is no definite evidence that the nerve-substance of the cord can be reproduced in man. It is remarkable that this should be so, seeing that the power of repair in cut or damaged peripheral nerves has been so clearly established.

TREATMENT.—Absolute rest, with cold applications, and possibly local blood-letting, will be needed in the first instance.

Subsequently, when immediate danger from shock and from the spreading of local inflammation has passed away, the patient must be treated upon the general principles applicable to all cases of paraplegia—which principles will be found set forth in 9. SPINAL CORD, Softening of.

H. CHARLTON BASTIAN.

3. Spinal Cord, Sudden Crushing Lesions of.—Fr. *Compressions Brusques de la Moelle Épinrière*; Ger. *Rückenmarksquetschungen*.

ÆTIOLOGY AND ANATOMICAL CHARACTERS.—

The above form a class of wounds sufficiently distinct to need separate treatment. This kind of damage to the cord may be produced by the sudden giving way of a carious vertebra in any part of the spinal column; more rarely by a heavy blow on the back, which does not fracture the spine; or, in a modified form, by the bursting into the spinal canal of an aortic aneurysm, after its erosion through the vertebrae. But in the majority of cases such wounds of the spinal cord are the results of forms of external violence which cause fracture and dislocation of vertebrae, in some portion of the spinal column between the upper cervical and the upper lumbar region. When this occurs, displacement of vertebrae, even to a slight extent, especially in the dorsal region, in which the spinal canal is narrowest, is sufficient to produce severe pressure upon, or crushing of, the spinal cord. The membranes may not be torn across, and the actual dislocation may at times be only momentary, but the substance of the cord itself may be greatly compressed or reduced to a blood-stained semi-fluid mass of pulp. After some hours there are obvious signs of a commencing inflammatory reaction in the membranes; and above and below the seat of lesion similar changes are apt to be set up in the spinal cord itself, which may go on to the production of a variable amount of inflammatory softening. The patient may die, however, before any of these latter changes have been established.

SYMPTOMS.—These vary much, according to the region of the cord involved. Still, in spite of differences thus dependent upon the seat of injury, there is a certain general similarity in the symptoms produced by all crushing lesions of the spinal cord. They are usually of this nature: There may be more or less marked evidence of shock; complete paralysis, both motor and sensory, of parts below the seat of lesion; in addition to severe pains in the back, girdle-pains surrounding the body at the upper limit of sensory and motor paralysis; increased heat or possibly undue coldness of the body throughout the paralysed parts; complete paralysis of bladder with retention of urine, gradually giving place to incontinence; paralysis of intestine, extremely obstinate at first, but subsequently complicated with involuntary evacuations after the administration of purgatives; and extinction of all reflex actions at first.

In the course of two or three days, if the patient should survive, other general symptoms become well marked, owing to the establishment of a local meningitis, together with some amount of traumatic myelitis. Among these we have general fever, with an increase of the 'girdle sensation,' and of pains in the limbs; twitchings in the limbs or in parti-

cular muscles; and also a general increase in reflex actions, where the crush has been only partial, though where the whole thickness of the cord has been destroyed the deep and most of the superficial reflexes in the paralysed parts continue to be abolished.

The above-mentioned complicating pathological processes may gradually subside, but there will still be danger to life from the supervention of severe cystitis or of extensive bed-sores, together with one or other of the various sequelae to which such conditions are apt to give rise.

The additional symptoms and variations met with, according as the crushing lesion occurs in different regions of the cord, are as follows. They increase in number the higher the lesion occurs in the spinal cord. See SPINAL CORD, Diseases of: § 8.

When it is situated in the *lumbar swelling* we have, in addition to the limitation of the paralysis to the lower extremities, and a more or less complete extinction of related reflex actions, the appearance of rapid atrophy in some of the paralysed muscles, together with the manifestation of the electrical reaction of degeneration. The bladder and rectum are apt to be completely paralysed.

With the lesion in some part of the *dorsal region* we have sensory and motor paralysis of the trunk up to a certain level, with an absence of the rapid atrophy and before-mentioned electrical reaction in the muscles of the lower extremities, though some atrophy and the presence of this reaction may occur in some of the trunk-muscles innervated from the damaged region of the cord. In addition (and notably where the lesion is in higher parts of the dorsal region) there may be some weakness of voice, some interference with the movements of respiration (especially with those of expiration), as well as marked and continuous priapism. The superficial and deep reflexes may be depressed or exalted, according to the complete or partial nature of the damage at the seat of lesion.

With the lesion in the *lower cervical region* the upper extremities are partly paralysed, both as regards sensation and motion; the movements of respiration are much more gravely interfered with (expiration especially), while inspiration is of a purely abdominal type; the voice is notably weak and feeble. Continued erection of the penis is more frequently met with; and in some cases a remarkable hyperpyrexia supervenes, in which the temperature before death may rise to 108°–110° F. Should death not occur in this way, it is very apt to supervene in the course of a few days, by gradual failure of respiration, which grows worse than it was in the early days of the affection, owing to the secondary myelitis which becomes established implicating the cord and nerve-roots at a level higher than the original wound. The pulse is often much interfered with, but variously: it may be less frequent or much more frequent than natural; it may be small, irregular, and frequent; or full, regular, and infrequent in its beats. There may also be signs of paralysis of the vaso-motor nerves supplying the neck and head, perhaps to a more marked extent on one side than on the other.

Where the lesion occurs in the *upper cervical region* of the cord, complete paralysis of the trunk and of all four extremities may be recognised, if death does not occur too suddenly to allow even this to be observed. The sudden death, so apt to

occur in these cases, is due to shock, and to the fact that the diaphragm may be paralysed as well as the other respiratory muscles. Where the lesion does not involve the whole of the roots of the phrenic nerve, and where the shock has not been too abrupt and violent, life (with extremely difficult respiration and almost complete loss of voice) may be prolonged for a few hours.

DIAGNOSIS.—If the existence of fracture and dislocation of vertebræ can be substantiated, the probabilities are always in favour of the presence of a crushing lesion in the spinal cord. Otherwise, after a very severe fall or blow upon the back, doubts may be at first entertained as to whether we have to do with the effects of concussion alone, or with this *plus* some amount of crushing of the cord or of hæmorrhage upon or beneath its membranes. The subsequent course of the symptoms may, however, in a day or two, enable us to resolve these doubts.

PROGNOSIS.—The prognosis in lesions of this kind, as already indicated, is much graver than in the case of mere punctured wounds of the cord—these being oftener slight and partial in their transverse extent. Death may occur immediately, or at any time during the first week—in the main from failure of respiration and of the heart's action. It is only in exceptional cases, and where the lesion is in the dorsal or lumbar region, that life is prolonged for several weeks or months. Such lesions are probably too severe to admit of anything like thorough repair. Paralysis, therefore, of a more or less complete kind, is lasting, and the prognosis will always be distinctly bad wherever the superficial and deep reflexes remain absent after the symptoms of shock have subsided (see SPINAL CORD, Diseases of: p. 1520). But even where life is prolonged for six to twelve months or more, it is, as a rule, ultimately lost, owing to the establishment of sloughing bed-sores and ulcerative cystitis, followed perhaps by septicæmia, extensive meningitis, or other complications.

TREATMENT.—In many of these cases treatment is useless and death inevitable. In those which are of a less urgent nature, the possibility of bringing about some relief by trepanning, with the view of elevating any depressed fragments of the vertebral arches, need not be lost sight of; and, as Bowly has pointed out, this should be borne in mind especially in those cases in which the reflexes in the paralysed parts are not abolished. Except, indeed, for the fact that parts surrounding the cord are damaged, so that rest in one position is often indicated, the treatment of these cases after the first urgent symptoms have abated does not differ from that which is appropriate in other well-marked cases of paraplegia, where there is a tendency to the formation of sloughing bed-sores, and to the establishment of cystitis (see 9. Spinal Cord, Softening of).

H. CHARLTON BASTIAN.

4. **Spinal Cord, Slow Compression of.**—**SYNON.**: Chronic Traumatic Lesion of the Spinal Cord; Fr. *Compression Lente de la Moëlle Epinière*; (in part) *Paraplégie Douleureuse des cancéreux*; Ger. *Langsame Compression des Rückenmarks*.

ÆTIOLOGY AND ANATOMICAL CHARACTERS.—The most frequent causes of the set of symptoms grouped under this head are to be found in diseases

of the vertebræ, and especially simple inflammatory or tubercular caries of the bodies of the vertebræ, leading to *angular curvature*, or 'Pott's disease.' Still, other kinds of disease of the vertebræ may also be productive of slow compression of the spinal cord, and of that form of localised softening of the organ which is so commonly met with in this class of cases, the so-called 'compression-mylitis.' Among these may be mentioned *cancer* of the vertebræ, either primary or secondary; also *exostoses* projecting into the spinal canal, or more irregular thickening of the bones in this situation. In cases of vertebral caries, in addition to the not infrequent presence and pressure of abscesses, a tough, yellow, scrofulous growth often infiltrates the posterior vertebral ligament, and thence spreads to the dura mater, here producing thickening and irregular fungosities which may press injuriously upon the spinal cord—more especially upon its antero-lateral columns. In these cases, though no tubercular disease is found within the dura mater, the spinal cord, as a result of degenerative changes, may, in the worst cases, be distinctly softened opposite, and perhaps for a very short distance above and below, the site of compression. At first such softening is principally apparent in the columns above mentioned; but in cases of longer duration it may involve nearly the whole thickness of the cord, and be followed by the usual ascending and descending 'secondary degenerations' (see p. 1523). The softened matter itself is generally reduced to an almost bloodless fluid or semi-fluid pulp, either of a whitish or dull yellowish-white colour, and there is generally no undue vascularity of the immediately adjacent portions in the cord.

In certain cases of very slowly induced compression no such softening of the cord is produced; there is rather a gradual atrophy or disappearance of the nerve-substance as the pressure increases, together with a sclerosis of what remains. This may occur, for instance, where the cord is pressed upon by some exostosis, or by irregular growth and thickening of the inner surface of the spinal canal, such as occurs occasionally in one or other of the cervical vertebræ.

It has long been known that no constant relation exists between the amount of angular curvature and of paralysis in different cases of vertebral caries. Paralysis may be absent where curvature is most marked. On the other hand, with no curvature and with only a slightly marked projection of one or two vertebral spines, paralysis may yet exist to a well-marked degree. This is due to the fact, that in such cases the cord is only very rarely compressed by the bones, while it is frequently more or less pressed upon by abscesses or by the yellowish growths which protrude from the inflamed or carious vertebræ, or which produce thickening and infiltration of the dura mater at the seat of disease; and changes of this sort may be well marked even where angular curvature is scarcely appreciable.

Again, where angular curvature is present, the posterior surface of the bodies of the vertebræ, corresponding with the angle, is often bent, rough, and eroded, and the cord over it is apt to become softened, though there may be no compressing growths or thickenings of the membranes.

Thus it happens that the paralysis in these cases may be variously produced. And seeing that it is often due to pressure by inflammatory products

rather than to pressure or irritation from the diseased bones themselves, we may the better understand the fact that occasionally a great improvement may set in and become established in regard to the paralysis, although the angular curvature of the spine remains as obvious as it ever has been.

In addition to slow compression of the cord resulting from diseases of the bones or the spine, a somewhat similar condition may be induced by the various kinds of tumours of the meninges, or by hydatid growths implicating these parts (*see* p. 1558). Confined within the narrow limits of the spinal canal, such tumours, even though of small size, may soon come to exercise a very injurious amount of pressure upon the spinal cord.

SYMPTOMS, COURSE, AND TERMINATIONS.—We shall point out some of the distinguishing characteristics of the paralysis which is often associated with vertebral caries, and afterwards refer to the peculiarities met with where meningeal tumours exist.

In *vertebral caries* with commencing pressure upon the spinal cord, the symptoms will be different, according to the part of the column implicated. The affection is frequently ushered in by an abiding pain in the spine and parts adjacent, often supposed to be 'rheumatic' in nature. Such pains commonly disappear when the patient is in the recumbent position, except during the acts of sneezing or coughing. They are commonly induced by particular kinds of movements, which are more or less difficult on this account. There is also some weakness in the lower part of the body and in the lower extremities. The mere 'weakness' may continue for weeks or even months before there is anything like actual paralysis; though at last this may show itself somewhat abruptly. The patient now becomes unable to stand, though still able to move the legs slightly while lying in bed. At this stage sensation is little, if at all, interfered with; but there may already be some increase in the readiness with which the knee-jerk manifests itself, and ankle-clonus may also be easily attainable. Next there may be startings of the limbs, and commencing rigidity of the muscles when passive movements are attempted; followed after a time by a more marked rigidity, which, when present in the calf-muscles, will often prevent the manifestation of ankle-clonus and of the knee-jerk. Later, if pressure increases either upon the spinal cord or upon its posterior nerve-roots, sensibility in its various modes becomes implicated. At this period the exaltation of the reflexes often diminishes. For a time the degree of impairment of sensibility and the freedom with which the knee-jerk and ankle-clonus may be obtained fluctuate. Meanwhile, painful spasmodic contractions of the legs (with flexion of hip- and knee-joints) becomes habitual, persisting through day and night with only rare intermissions.

Although there is some general wasting of the muscles, together with a flabby condition when they are relaxed, they still react almost normally to the faradic current. The skin is often dry and scurfy. The temperature of the limbs is generally slightly lower than normal.

At the first onset there may be for a few days a difficulty in voiding the urine, but this power soon returns, and it often continues long after the limbs have become powerless. The bowels are perhaps somewhat constipated, but there is no incontinence of *fæces*, unless diarrhoea supervenes from any

cause, or unless the reflex activity of the bowel is greatly exalted under the influence of aperient medicines.

The above condition of things may last long without much variation. But after a time there will be a gradual mitigation of the symptoms, or the reverse. In the latter case loss of voluntary control over the bladder and rectum appears; and (especially when the sensibility of the body and limbs becomes impaired) the tendency to the formation of sloughs and gangrenous bed-sores becomes increased. With these conditions other complications, such as cystitis, blood-poisoning, &c., may appear and greatly aggravate the condition of the patient, helping to bring about a more speedy termination.

In the case of *tumours arising from the meninges*, the onset of the affection may also be very gradual at first, though, perhaps, rather suddenly intensified at last. Here, however, the pressure very often comes upon the cord from behind, or it may at the same time implicate one or both lateral regions of the cord. At first, therefore, we commonly get variously impaired sensibility and neuralgic pains, or pains mixed with startings and cramp-like contractions in certain muscles, occurring in those particular regions of the body or limbs which are in relation with the nerve-roots slightly pressed upon and irritated by the new-growth. Great differences exist in different cases in regard to the degree and persistence of the initial pains. Subsequently these nerves and the cord itself may become more severely pressed upon, and then loss of sensibility over the field of distribution of the nerve-roots is met with, together with loss or impairment of sensibility in all or some parts of the body the nerve-supply of which is from the cord below the compressed region. With this a minor amount of motor paralysis also occurs, which, however, subsequently becomes more marked, and ultimately complete. When this takes place we have all the signs and symptoms met with in a case of total transverse softening of the spinal cord at the level implicated (*see* 9. SPINAL CORD, Softening of). This change is, in fact, commonly established by the persistence and increase of pressure due to the new-growth.

These are the broad outlines of the symptoms met with in such cases, which, of course, are subject to innumerable variations in individual cases, in accordance with differences in the region of the cord affected, together with the rate of growth, mode of incidence of pressure, and size of the tumour.

In *cancer of the vertebrae*, also, we have much the same grouping of symptoms; the preliminary pains being here especially severe.

DIAGNOSIS.—In the paralysis associated with *vertebral caries* the diagnosis depends upon the recognition of this causal condition, which, in the early stages, is often a matter of some difficulty. Much will depend upon the existence of pain in particular regions of the spine, or radiating therefrom; of pain which is relieved by the recumbent position, and greatly aggravated by coughing, sneezing, or stooping movements of different kinds, or from jarring of the spine by making sudden pressure upon the patient's shoulders. And yet in the absence of signs of caries, or of a tubercular habit of body or history, or of an exciting cause for caries, in cases where there may be little or no prominence of vertebral spines, and even no pain from firm pressure or the application of a hot sponge, we may be helped in our diagnosis of the existence

of caries by the distinctive characters of the paralysis itself, namely, its implication of motility principally, the exaggeration of the tendon-reflexes, the more or less marked rigidity of the legs, and the continuance of control over the bladder and rectum.

In cases of this type, or where there is only a slight prominence of two to four vertebral spines, it may be difficult, however, to establish a diagnosis between caries and *cancer* of the bodies of the vertebræ. It is true that a rounded prominence of several vertebral spines is met with in cancer more frequently than the angular projection commonly associated with caries; yet this single character will not always aid us: we must look also to the presence or absence of severe pains, to the clinical grouping of symptoms generally, and to the history of the patient, bearing in mind that it may be met with as a sequel of cancer of the breast.

The diagnosis of the other causes of slow compression of the cord to which reference has been made (exostoses or meningeal tumours) is usually a matter of extreme difficulty. We must be guided by probabilities based upon other associated states or conditions that may be recognisable in our patient, and also by the mode of onset of the affection.

PROGNOSIS.—We can only speak in general terms concerning the prognosis of the rather miscellaneous conditions which form the subject of this article. Cancer of the vertebræ or of the dura mater, compressing the cord, is the most serious of them all. The progress of such cases is usually both rapid and very painful, so that the end comes inevitably before many months have elapsed.

In vertebral caries associated with compression of the cord, the prognosis is extremely uncertain, especially where the disease occurs in the cervical region. It is also generally more grave where the pressure upon the cord is due to an abscess rather than to mere thickening of the dura mater. Under suitable treatment many of these cases practically recover more or less fully; in others complete transverse softening of the cord is produced. In the former class of cases the process of caries is arrested, the spoiled vertebræ are strengthened and bridged over by growth of new bony tissue (though, of course, the angular curvature of the spine remains), while recovery from the paralysis may be more or less complete. This latter kind of recovery takes place occasionally even after paralysis, with almost persistent contractions of the lower extremities, has existed for from twelve to eighteen months or even longer.

In cases of exostosis, hydatids, or meningeal tumours compressing the spinal cord, the prognosis will depend upon the part of the cord involved, upon the rate of increase of the symptoms of compression, and upon the extent to which a secondary myelitis or softening is established. The disease in these cases, in spite of stationary periods, or even those of slight improvement, is more or less continuously progressive, though it may last for many months, or, occasionally, even for a year or two. Some of the complications or accidents incident to the paralytic condition ultimately bring the patient's life to a close.

TREATMENT.—Rest in the recumbent or in the prone position is, of course, absolutely essential in cases of vertebral caries or of cancer of the vertebræ. In vertebral caries the mere rest in bed must often be supplemented by extension of the spine—that is by

fixation above, together with weights attached to the feet. In other cases of vertebral caries, a poroplastic or plaster jacket may be needed, in order more effectually to secure absolute immobility of the affected portion of the spinal column. This, however, would have to be reserved for the more chronic cases or stages—for those in which active local treatment was no longer considered to be necessary or desirable, though a prolonged rest in bed may still be needed. Under such conditions the application of the jacket is a means of obtaining more complete rest for the damaged spine. Some surgeons, however, prefer to have recourse to the method of 'elastic extension' above referred to for procuring this fixation of the spinal column.

In cases of paraplegia associated with vertebral caries, the patient's general health requires the utmost attention during the period in which we are endeavouring to check the disease by the influence of rest. Good nutritious food and cod-liver oil will be required, combined with steel wine or the syrup of phosphate of iron. In some cases 10- to 20-grain doses of iodide of potassium (together with iodide of iron or small doses of perchloride of mercury) seem to do good. Where the patient suffers much from painful contractions of the legs (which may greatly disturb sleep), these may be very distinctly lessened by suspending weights to the feet (each being from two to four lbs.) from leather anklets, by a cord which passes over a pulley. Such weights may be used for weeks or months together, where necessary.

In regard to local measures, counter-irritation of some kind is generally had recourse to, either in the form of flying blisters near to and on each side of the portion of the spinal column which is affected, or else by the renewed application of moxas or the actual cautery to these regions. The latter more severe measures are still recommended by some authorities, though the experience of others is against their employment, as being of little or no use, and therefore adding needlessly to the sufferings of the patient. The writer is inclined to think that all the good which moxas or the actual cautery are intended to bring about may generally be as effectually achieved by the application of the strong iodine-solution of the pharmacopœia over the affected region of the spine about every fourth day.

There can be no doubt that treatment of this kind is often successful, though frequently only after prolonged periods. The question, therefore, naturally presents itself, whether shortening the duration of the illness, and in some cases the saving of life, may not be brought about by an early resort to surgical operation, with a view to opening any abscess that may exist and, by laminectomy, diminishing pressure upon the spinal cord. If some signs of recovery do not commence in three or four months—and especially if there are marked sensory defects, showing that the cord is severely pressed upon—it will probably be advisable to have resort to operation. Each case, however, will require anxious consideration in regard to this point.

Again, it must be borne in mind that some cases of compression of the spinal cord by meningeal growths may also be greatly relieved for a time, or even cured, by operative measures.

In the case where a hydatid tumour presses upon the spinal cord, and is also situated in part outside the vertebral spines, tapping might bring much relief. In the majority of the other conditions

comprised within the limits of this article, little can be done to cure the state of things which is the cause of the spinal disease, so that it would only remain for us to treat the paraplegia and its attendant conditions upon the general principles applicable to them. These are fully considered under 9. SPINAL CORD, Softening of. H. CHARLTON BASTIAN.

5. **Spinal Cord, Anæmia of.**—Anæmia is not to be considered as the basis of any ordinary or common disease of the cord: in other words, there is no definite group of symptoms the existence of which is likely to be recognised more than once in a lifetime in any actual patient, which would justify the diagnosis 'anæmia of the cord.'

First, the writer would repudiate the notion that *anæmia* or *chlorosis*, as a mere blood-disease, is capable of producing, on the side of the spinal cord, any set of symptoms which can be marked off from those characterising the condition as a whole. In these diseases the functions of all the organs are impaired by reason of the impoverishment of the blood. The brain and spinal cord, on account of the delicacy of their functions, will, of course, suffer to a notable degree; and when general debility is extreme, a paresis of the lower extremities may be notable beyond that of other parts of the body, because the legs in standing or in walking have to support so great a weight. Where anything more than such paresis exists—that is, where there is actual paraplegia, such symptoms are not to be explained by a mere anæmia of the cord. Other causes are to be looked for. Jaccoud's whole group of *paraplégies dyscrasiques* will probably disappear before a more thorough knowledge of the actual mode of causation of these and many other obscure forms of paraplegia. We now know that in association with some cases of pernicious anæmia there is most marked degeneration of the lateral and posterior columns of the cord of comparatively rapid onset. See COMBINED DEGENERATION OF THE SPINAL CORD.

Secondly, *embolism* and *thrombosis* of spinal arteries will produce temporarily, and in quite limited regions of the cord, a condition of anæmia. Such local anæmia would probably soon be rectified by the establishment of a collateral circulation; and in the event of this not taking place, local 'softening' of the organ would ensue. A paralysis owning such an origin would not, therefore, be spoken of as resulting from 'anæmia of the cord.'

Thirdly, *pressure* upon parts of the cord will occasion anæmia and ultimately softening, but the symptoms in a case of this sort will depend mainly upon the pressure itself interfering with the functions of the nerve-tissue thus affected.

Beyond the conditions above referred to, there is the possibility that definite groups of paralytic symptoms may be occasioned by anæmia induced by mere functional *spasm of the arteries* in certain regions of the cord—spasm, that is, which persists day after day. This has been supposed by Brown-Séquard to be the condition existing in the cases of so-called 'reflex paraplegia' (see No. 28), and also in some forms of functional paralysis of spinal type (see No. 30). If such a condition of persisting arterial spasm be possible, and an actual cause of paralytic symptoms, we may well ask whether it too ought not after a time to lead to actual softening, or at least to some degree of degenerative

change in the spinal cord. It seems possible, however, that where the amount of blood sent to a part of the cord is but small, the degradation of function may be more marked than the degradation of structure.

There will still remain a very few exceptional cases, in which a condition of real anæmia of the spinal cord is brought about in man, just as it has been brought about in some of the lower animals whose abdominal aorta has been tied or compressed. When the blood-supply is thus suddenly cut off from the lumbar region of the cord in animals, their hinder limbs become paralysed almost immediately, and continue paralysed as long as the blood-supply of the cord happens to be arrested. But if, after a mere brief interval, the blood is again allowed to take its natural course, the temporary paralysis disappears completely in a very short time. A condition of this kind seems to have occurred in a patient formerly under the care of Gull, who suddenly became paraplegic, apparently owing to an abrupt arrest of the blood-current through the abdominal aorta, as was indicated by the cessation of the femoral and other pulses in the lower extremities. The man continued paraplegic for months, and only recovered when the collateral circulation became, after a time, pretty fully established. In a very few other cases referred to by Erb, in which paraplegic symptoms were associated with an obstruction of some kind in the abdominal aorta, he thinks that these symptoms, supervening as they did rather less suddenly, may have been in great part due to the deficient blood-supply to the muscles and nerves of the lower extremities, rather than to anæmia of the cord—to a peripheral, that is, rather than to a centric anæmia.

H. CHARLTON BASTIAN.

6. **Spinal Cord, Hyperæmia of.**—This condition again is more frequently talked of than it deserves—looking to the small amount of positive knowledge we possess upon the subject.

Hyperæmia of the cord must be either passive or active, that is, it must be a result of *mechanical congestion* or of *arterial determination*.

Mechanical congestion.—In obstructive heart-disease extreme congestion of the spinal cord may exist for months without producing any distinct symptoms of disease of the spinal cord. A constantly congested spinal cord would doubtless perform its functions in a less vigorous manner than natural, but such effects would be slowly evolved and comparatively obscure. After a long time the effects might become more marked, owing to the overgrowth of connective tissue within the organ. We may indeed have the starting-point of a general sclerosis of the spinal cord under such conditions; but this secondary change, when only slightly marked, may, even in the spinal cord, produce no very definite symptoms.

General mechanical congestion of the cord is probably more frequent and more easily brought about than a congestion involving parts of the organ. Still from various causes there may be undue pressure upon certain veins, which directly or indirectly convey blood away from special regions of the cord and its membranes. Such an event cannot, however, be regarded as a likely cause of a congestion productive of morbid spinal symptoms, if we consider the absence of distinct symptoms resulting from extreme general congestion of the cord; and

also the fact of the very free anastomosis of all the spinal veins.

Active hyperæmia may in its origin be of two kinds—'reflex' or 'inflammatory.'

'Reflex' hyperæmia of the cord and its membranes is possibly a phenomenon of great frequency, manifesting itself locally in certain regions—the seat of the process varying according to the conditions under which it arises. It might be immediately caused by vaso-motor paralysis, implicating certain vessels of the cord and their branches; and would thus involve an increased afflux of blood to the tissues contained in the corresponding vascular territories. We know that such an increased afflux of blood may exist in other tissues for some time without inducing tissue-changes of an appreciable kind (Brown-Séquard). It is fair to suppose, moreover, that any symptoms induced by such increased afflux of blood to certain regions of the cord would be indicative of exalted rather than of depressed function; for example, hyperæsthesia, actual pain and spasms, or increased reflex excitability, rather than their opposites.

In weak and irritable states of the nervous system it is quite possible (though nothing more definite can be said) that such vaso-motor paralysis, and also vaso-motor spasms inducing localised anemias, may manifest themselves in spinal vessels as they do in cutaneous vessels, by familiar flushes or pallors. If occurring in the spinal cord, however, these would mostly be temporary phenomena, and not capable of producing the symptoms of an abiding disease. How frequent such reflex local hyperæmias (whether brief or prolonged) may be in the spinal cord, and in what precise manner they are excited, we do not know. Suppression of the menses or of hæmorrhoidal fluxes, the presence of worms in the intestine, the prolonged incidence of cold and wet, or severe concussions of the spine, any or all may operate in this particular manner—but for proof that, as matter of fact, they do, we may look for evidence in vain.

The subject of 'inflammatory hyperæmia' will be briefly considered under the next heading. In this case, in addition to changes in the vascular system, the effects of the inflammatory process as a whole have to be taken into account. Even in the first stage of inflammation something prior to and beyond the mere 'active' congestion has to be thought of.

From what is said above, it may be seen how shadowy is our present knowledge concerning the existence of any definite sets of symptoms which can be ascribed to non-inflammatory hyperæmia of the cord, either general or local.

H. CHARLTON BASTIAN.

7. Spinal Cord, Inflammation of.—SYNON.: *Myelitis*; *Myelitis Acuta*; Softening of the Spinal Cord (in part); Fr. *Myélite*; *Myélite aiguë*; *Inflammation de la Moelle Epinière*; *Ramollissement de la Moelle Epinière* (in part); Ger. *Myelitis*; *Rückenmarksentzündung*; *Erweichung des Rückenmarks* (in part).

NATURE, ÆTIOLOGY, AND PATHOLOGY.—To speak definitely on this subject, in the present state of knowledge, is extremely difficult. This is due to several causes. In the first place, it is owing to the fact that so much uncertainty exists in the minds of many eminent pathologists and physicians as to what ought rightfully to be included under this

term; and, secondly, because by a very large number of writers the term is understood and used in the vaguest manner, but with a manifest tendency to comprise under it the largest possible number of affections of the spinal cord. Critical discrimination seems to have been, and still to be, in abeyance with many who describe or report cases of disease of the spinal cord. They set down as instances of 'myelitis' not only all cases in which the substance of the spinal cord is softened, but still more all those in which it is indurated—and, no less impartially, those in which it is merely degenerated.

(1) The notion that common 'softenings' of the spinal cord are of inflammatory origin has persisted with little alteration, although for nearly thirty years pathologists have been interpreting altogether differently the mode of production of apparently similar 'softenings' of the cerebrum and cerebellum. Can it be that 'softening' as it occurs in the majority of cases in these latter organs is of non-inflammatory origin; while in the majority of apparently similar cases occurring in the spinal cord, the process is really inflammatory in its nature? It is true that in association with the majority of cases of primary softening in the brain thrombosis or embolism of its arteries may be detected, and that, owing to the peculiarities of its vascular supply, no such occlusions of vessels can often be detected in association with softening of the spinal cord. See p. 1522.

(2) Then, again, perhaps it may be said that without adequate cause the very localised changes occurring in and around the great ganglion-cells of the anterior cornua, in 'acute' and 'chronic spinal paralysis,' have been set down as inflammatory in their nature, and new names have been given to these affections, tending to ratify this view as to their origin. Thus they are spoken of by some as cases of *anterior polio-myelitis*, or more briefly, and, so far, better, as cases of *cornual myelitis*. But localisation of an inflammatory process to great ganglion-cells and their immediate surroundings at present constitutes a rather unintelligible process to many pathologists. And mysterious as these particular changes are, from the point of view of their ætiology, on any hypothesis that has yet been started, it would perhaps be simpler, and more harmonious with the nature of the observed conditions themselves, to regard them as of a degenerative type. If the slower and more isolated changes characteristic of 'progressive muscular atrophy' are to be placed in this category (and in regard to them there is absolutely no evidence either clinical or pathological that can be adduced in favour of an inflammatory origin), then also it becomes easy to believe that, under some at present imperfectly defined toxic conditions, a change of the same kind may set in more rapidly in these, the most specialised of all the anatomical elements met with in the spinal cord, so as to produce the more acute affections above referred to. The slight secondary overgrowth of neuroglia commonly occurring around the degenerated ganglion-cells does not in the least militate against this view as to the pathology of the process; a similar secondary change occurs also in the process next to be referred to, and will be found to be easily explicable without the necessity of having recourse to the ever-ready and fashionable hypothesis of inflammation.

(3) 'Secondary degenerations' of the spinal cord

have indeed, in spite of their name, and of what is known as to their origin, been erroneously regarded by some writers as inflammatory changes. When nerve-fibres are cut across, those portions which are severed from their connection with certain ganglion-cells are no longer able to preserve their nutritive integrity. Simultaneously throughout their whole length fatty degeneration affects their white substance. Myelin breaks up, and becomes disintegrated as it does in non-inflammatory softenings in the brain; and very speedily granulation-corpuscles begin to form abundantly throughout the changing area. But though fatty degeneration thus occurs simultaneously in all the cut fibres of the band, the vascular supply of this tract of tissue has not been altered. Since the blood in the diseased area is not utilised by the nerve-tissues proper, except to a very small extent, a large excess of nutriment is placed at the disposal of the neuroglia, and this undergoes a well-marked hyperplasia. Thus a band of tissue-change is produced in which some of the characteristics of softening are blended with those pertaining to a patch of sclerosis. In brief, we have effects resulting from a primary fatty degeneration of the nerve-fibres, and a secondary hyperplasia of the neuroglia; and from first to last there is not the least reason for believing in the existence of an inflammatory process.

(4) If we turn now to 'sclerosis' of the cord of primary origin, we again meet with processes which are commonly regarded and described as forms of '*chronic myelitis*.' This kind of nomenclature is objectionable as applied to the processes in the spinal cord, just as it is in its application to like processes occurring in other organs, as the liver, the lungs, or the kidneys. Fibroid overgrowth, which forms the basis of so many examples of 'cirrhosis' or 'sclerosis' in different organs and tissues of the body, is a process pathologically intermediate between inflammation on the one hand and degeneration on the other. What were formerly named 'interstitial inflammations' are now the 'non-inflammatory hyperplasias' of some pathologists, and the 'fibroid degenerations' of others. It would seem that the view as to the inflammatory nature of such processes is erroneous, if we look either to what is known concerning their modes of initiation, or to the actual nature of the changes themselves (which agree in many particulars with those of infiltrating new-growths); it would seem, moreover, not less erroneous if we look to the clinical history of the affections themselves in which these sclerosis occur. It conveys, therefore, an altogether erroneous implication to speak of such mere fibroid overgrowths as so many instances of 'chronic myelitis.'

Thus, it will be seen that the writer attributes to inflammation a far more restricted rôle in the production of morbid conditions of the spinal cord than is customary. The various forms of so-called 'chronic myelitis' he would exclude from that category. He would do the same for the set of changes known as 'secondary degenerations'; and also for those which are characterised by more or less acute degenerative processes implicating the great ganglion-cells of the anterior cornua.

Of the processes above referred to in order, there remains, therefore, only the class of 'softenings' of the spinal cord. That many of these are of a simply degenerative type (due to vascular occlusions and disturbances of blood-supply), and that, in the

great majority of cases, these are the instances in which 'softening' appears to occur as a *primary* process, is the view which seems to the writer most in accordance with existing knowledge. On the other hand, it seems clear that in many cases changes, truly inflammatory in their origin and progress, may terminate in the production of states of 'softening' of the cord, which are indistinguishable by the naked eye from the softenings of degenerative type, and which, except in their early stages, can as yet also be very imperfectly discriminated by the microscope.

These latter true *inflammatory softenings* very rarely occur as primary pathological states, and then principally as sequelæ of one or other of the acute infective diseases; they are met with far more commonly as *secondary* changes.

Thus we may get inflammatory softenings (a) spreading around and from wounds or other traumatic lesions of the spinal cord; or (b) starting from some blood-clot or tumour situated in or pressing upon the substance of the cord. It is not by any means clear, however, that all the forms of softening which arise in the latter manner should be regarded as of an inflammatory nature; and much room for doubt also exists as to the real pathogenesis of many cases of so-called 'compression-myelitis.' Again, inflammatory softenings, going on even to suppuration, may be set up in the spinal cord (c) by embolism or thrombosis of septic origin. Still another cause of true inflammatory changes in the spinal cord (*myelitis peripherica*) is to be found (d) in spinal leptomeningitis. See MENINGES, SPINAL, Diseases of: Leptomeningitis.

Suppuration is clearly a process of inflammatory origin, and might therefore be expected to occur occasionally in the midst of 'softenings' which result from inflammation. In the light of what has been said above, the following statement by Erb is of considerable interest. 'Actual suppuration occurs very rarely,' he says, 'in acute myelitis. When abscess of the cord does form, it is generally secondary to a severe traumatic lesion or to suppurative meningitis. In spontaneous myelitis, on the other hand, suppuration is exceedingly rare, and has only been observed in a very few cases.' Thus suppuration is met with just in those forms of softening which are undoubtedly of inflammatory origin; and, on the other hand, it is not met with in the ordinary cases of primary or spontaneous softening, here assumed to be of non-inflammatory nature.

One other condition requires to be referred to here, and that is the so-called *acute central myelitis*. These are cases in which apparently spontaneous 'softening' is met with, implicating in the main the central grey matter, and that often through a considerable extent of the cord. At times, however, the softening extends beyond the grey matter, so as to involve more or less of the surrounding white substance, when it has been termed *myelitis diffusa*. Considerable obscurity still prevails in regard to the ætiology of these affections. In some cases, such a change has been met with as part of an infective process, in which minute vessels in the grey matter of the cord have been found obstructed with micrococci. Occasionally, moreover, in certain at present imperfectly known conditions, minute thromboses may, as Hamilton has shown, occur throughout the spinal cord, and

more especially in its grey matter, and thus lead on to the production of a central softening. In this latter case, the patient was suffering from pyelitis, and it is supposed that there may have been some blood-poisoning. Still it was not ascertained that the multitudes of minute thrombi were either associated with or caused by micrococci in the vessels. It appears probable, however, that if from any cause minute widespread obstructions of small vessels occur in the spinal cord, softening would take place principally in the grey matter, owing to its greater vascularity. We should thus get that particular distribution of this change which is met with principally in cases of so-called 'acute central' or 'diffuse myelitis.'

A careful study of the two cases of this disease recorded by Hayem has by no means sufficed to convince the writer that they ought to be regarded as having had an inflammatory origin. Neither the mode of onset nor the symptoms of the disease lend any distinct support to this view; nor do the results of the elaborate examination, to which the spinal cords were submitted by this accomplished observer, at all satisfy the writer that the pathological conditions met with were inflammatory either at their commencement or in their subsequent progress. See 9. SPINAL CORD, Softening of.

SYMPTOMS, COURSE, AND TERMINATIONS.—From what has been said, it will be seen that true inflammatory conditions of the cord are only rarely of *primary* origin, and that they occur, for the most part, as *secondary* complications in association (a) with wounds or injuries of the cord; (b) with foreign bodies in its substance; (c) with pyæmic processes; or (d) with spinal leptomeningitis, either simple or tubercular.

The supervention of a real myelitis in the course of either of these diseases of the spinal cord would perhaps be associated with an exaggeration of the already existing febrile condition; with an increase in the amount of paralysis, and in the degree of interference with sensibility; possibly also with more pain, restlessness, and spasms.

Myelitis may become associated with more or less of distinct suppuration, and almost certainly goes on to the formation of well-marked foci of softening. These may remain limited in site, but occasionally they have a distinct tendency to spread above and below the original seat of injury or disease. Such deposits would probably undergo subsequent changes, very similar in kind to those which occur in foci of non-inflammatory softening.

DIAGNOSIS.—All that can be said under this head has been referred to above in connection with the symptoms characterising the supervention of myelitis.

PROGNOSIS.—The gravity of any wound or lesion of the spinal cord, or attaching to the presence therein of blood-clot or tumour, is, of course, greatly increased by the supervention of inflammatory changes about their immediate confines. Again, the fact that an inflammation of the spinal meninges is complicated with similar changes in the substance of the spinal cord itself, cannot fail greatly to aggravate a case of simple spinal leptomeningitis. For, even should recovery from the acute affection take place, the actual degree of abiding paralysis, ataxy, or impairment of sensibility would much depend upon the degree in which the substance of the spinal cord had been itself implicated.

TREATMENT.—The amount of power that we possess in controlling an inflammatory condition of the spinal cord is probably not great. Little, if anything, is at present to be done with mere drugs. The patient should, if possible, lie in the prone position, or, failing this, on his side, with absolute rest. The advisability of abstracting blood locally by cupping or leeches should be entertained, and must depend upon the amount of local pain or tenderness. In some cases it seems to be of service. Or we may trust rather to the application of cold externally, in the form of ice-bags, along the spine. At the same time the patient should be kept upon spoon-diet, with a sparing amount of stimulants; and the bowels should be relieved by the aid of copious warm enemata, which may also act usefully as derivatives. The limitations circumscribing our efforts at direct therapeutics must be compensated as far as possible by attention to the state of the general health, and by the most careful and assiduous nursing, in the hope that the morbid process may after a time abate, and that, in the absence of collateral complications, the patient may make at least a partial recovery.

H. CHARLTON BASTIAN.

8. Spinal Cord, Hæmorrhage into. —
SYNON.: *Hæmatomyelia*; *Hæmorrhagia Medullæ Spinalis*; Spinal Apoplexy; Fr. *Hématomyélie*; *Apoplexie de la Moelle Epinière*; *Des hémorrhagies intrarachidiennes*; Ger. *Rückenmarksapoplexie*; *Spinalapoplexie*.

ETIOLOGY AND ANATOMICAL CHARACTERS.—Hæmorrhage into the spinal cord is a comparatively rare event. It occurs under three different conditions, namely: (1) as a result of concussion or violence; (2) as a secondary event, consequent upon some definite pre-existing morbid condition; and (3) as a primary event, or local pathological accident.

We are here specially concerned with hæmorrhages into the spinal cord belonging to the third of these categories, and may in a few words dismiss the other two.

(1) Traumatic hæmorrhage, small in extent, may, as already stated, occur in almost any region or part of the cord as a result of some severe concussion (see 1. SPINAL CORD, Concussion of). Again, it may occur in the grey matter, and even in the white substance to a smaller extent, close to and as an appanage of wounds of the cord. In each of these cases symptoms due to the hæmorrhage itself would probably be obscured by the general set of symptoms resulting from the concussion or injury.

(2) Secondary hæmorrhages are, however, more closely connected, from the point of view of symptomatology, with those forming the special subject of this article. During the growth of certain soft tumours in the cord, a rupture of some of their vessels may take place, so as to cause hæmorrhage either into the growth itself, or else into contiguous regions of the cord. Such an event would be signalled clinically by the sudden exacerbation of the symptoms previously existing. But a combination of greater importance, though one of considerable obscurity, consists in the co-existence of a 'central myelitis' of the grey matter of the cord through more or less of its length, with a central hæmorrhage of nearly similar extent. The existence of any such 'central myelitis' as an independent disease of the cord seems to the writer very doubtful.

It is at least equally probable that the hæmorrhage has been primary, and that the 'myelitis' is of secondary origin around the blood-clot. It need not be denied, of course, that in other cases hæmorrhage does occur occasionally into the midst of a focus of softened tissue in the spinal cord, just as it occurs occasionally under similar conditions in the midst of softened brain-tissue. Again, hæmorrhage may take place into or on the confines of a soft sarcoma or glioma in the substance of the spinal cord.

(3) Primary hæmorrhages differ as regards the amount, the site, and the distribution of the blood effused in different cases. In connection with scorbutic states, and also independently of these, small hæmorrhages may occasionally occur in the substance of the cord, without producing any very distinct symptoms. But, at other times, a comparatively large quantity of blood may be effused into the cord, and then it occurs almost invariably into the central regions of the grey matter, through which it may extend for a variable distance, upwards or downwards, or both. When the quantity is smaller, the blood may be effused into the grey matter of one side only.

Though this kind of hæmorrhage is, in contradistinction to the others, spoken of as primary, yet it is almost invariably preceded by some pathological changes in the vessels of the cord. These constitute the predisposing conditions, and the actual rupture takes place, rarely, when the person is at rest, but more frequently under the influence of some distinct exciting cause—such as muscular exertion of one kind or another.

Primary hæmorrhage, though rare, is most prone to occur in persons between the ages of twenty and forty, and not with increasing frequency as age advances. This constitutes a further notable difference between hæmorrhages of the spinal cord and those into the brain.

SYMPTOMS.—These are necessarily subject to great variations, according to the amount of blood effused, and as the hæmorrhage takes place into the cervical, the dorsal, or the lumbar region respectively. The kind of variation thus induced may be gathered by reference to the article, *SPINAL CORD, Diseases of*, pp. 1526 to 1531.

Here it is of importance to set forth the peculiarities (both as regards mode of onset and nature of the symptoms) which belong to hæmorrhage as compared with other pathological conditions of the cord. First, its tendency is to take place suddenly and without warning; and, secondly, for the blood to be effused into the grey matter for some distance, thus giving rise to a characteristic grouping of symptoms. There may, therefore, be a sudden onset of pain in the back (possibly severe), followed almost immediately by complete motor and sensory paralysis of the legs and trunk up to a certain level, together with complete paralysis of the bladder and rectum. At first there may be an abolition of all reflexes, and possibly a lowering of temperature in the legs; though after a day or two—should the injury be in the dorsal or lower cervical region of the cord—there may for a time be increased heat of legs, owing to vaso-motor paralysis, and a return, with some exaggeration, of various reflexes. Rapid atrophy, with the appearance of the electrical 'reaction of degeneration,' occurs in all muscles that are in immediate functional relations with the portions of the anterior cornua of the cord that may be damaged. Cystitis, together with sloughing bed-

sores and all their consequences, tends to occur early, and that often in spite of all precautions that may be taken.

Where the hæmorrhage invades pretty fully, but is limited to, the grey matter of one-half of the cord, we may have groups of symptoms that take the form of *hemiplegia spinalis* or *hemiparaplegia*. See 2. Punctured or Gunshot Wounds.

DIAGNOSIS.—The absolutely sudden onset of the paralysis, which may be complete in the lower extremities in the course of a few minutes (especially when associated with a sudden painful sensation in the back, or one which radiates into the limbs), as well as the almost complete and sudden loss of sensibility in the paralysed parts, form a group of symptoms which are typically distinctive of hæmorrhage into the grey matter of the cord.

The condition most likely to be confounded with it is a large hæmorrhage outside the *dura mater*, causing compression of the cord. Here the onset would also be sudden, but almost invariably associated with some mechanical injury or shock. The paralysis of motion, too, would generally be much more marked than the interference with sensibility. The subsequent progress of such a case would further tend to separate it from a case of intramedullary hæmorrhage, since (even with a severe meningeal hæmorrhage in the cervical region), if the patient should survive the first effects of the lesion, the symptoms might be expected soon to grow less and less urgent, and recovery may be more or less complete. No such amelioration is, however, to be expected in the case of a well-marked hæmorrhage into the grey matter of the cord, in the cervical region or elsewhere.

On the other side of the brain *embolism* is capable of initiating paralytic symptoms with as much suddenness as a hæmorrhage, but in the spinal cord, for reasons previously stated, this does not occur. See *SPINAL CORD, Diseases of*, p. 1522.

It does, however, happen occasionally that a process of softening—probably caused by *thrombosis*—has its occasioning conditions initiated suddenly. When this occurs, paraplegia sets in almost as abruptly as if it were produced by hæmorrhage; but then it is usually an incomplete paraplegia, and, for a time at least, unaccompanied by loss of sensibility. In the course of a few days, in such a case, sensory paralysis may supervene, and the motor paralysis may become more complete. In the exceptional cases of paraplegia of sudden onset due to this cause, there is generally no initial pain in the back, though there may be pains and burning sensations in the limbs.

PROGNOSIS.—Where the hæmorrhage is at all large, so as to extend through the grey matter for the distance of an inch or more, the prognosis is always grave. Very few of such cases recover. They are, in fact, liable to be aggravated by the establishment of a secondary process of softening in the grey matter, which may slowly extend both above and below the blood-clot as well as around it. Should this softening reach far into the cervical region, or should the hæmorrhage itself implicate this part of the cord, the patient may not survive more than a few days. But if the primary and secondary pathological changes are limited to the lumbar or to the dorsal region of the spinal cord, the fatal event is usually brought about more slowly, after an interval of weeks or perhaps even of months—and then commonly from the occurrence

of sloughing bed-sores, together with cystitis and other frequent accompaniments of a severe paraplegia.

In the case of small hæmorrhages limited to some fractional part of the transverse area of the cord, and of slight longitudinal extent, the prognosis is, of course, much more favourable, and there is no reason why partial recovery, at least, may not occur.

TREATMENT.—In the treatment of a case of spinal hæmorrhage, should the patient be seen immediately after its occurrence, absolute quietude, with rest in the recumbent or prone posture, should be ensured.

Bleeding, either local or general, is useless. Purgatives also are contra-indicated.

Should the pulse be full, and the heart's action excited, decided benefit may be derived from 10-minim doses of tincture of digitalis, in combination with 15 or 20 grains of bromide of potassium, given for the first three doses at intervals of three or four hours, and subsequently every six or eight hours, for two or three days. These drugs will also favour sleep, and exercise a general calmativè influence.

Position and rest are perhaps the means to be principally relied upon to prevent a recurrence or continuance of the hæmorrhage: such measures may be supplemented by warm applications to the feet and calves of the legs; though the patient should in other respects be kept perfectly cool. Ice to the spine may be applied, but is of doubtful utility. Spoon-diet should be strictly enjoined for a few days at least.

The patient's urine will require to be drawn off by catheter; and extreme care ought to be taken to ensure the antiseptic cleanliness of the instrument. After a day or two, if the bowels have not been moved, a laxative or an enema should be administered, since, as in many other forms of paraplegia, there may, at first, be obstinate constipation rather than incontinence of fæces.

Subsequently, the case requires to be treated in all respects like any other very bad case of paraplegia—extra precautions being observed throughout, in order, as far as possible, to guard against the onset of bed-sores and cystitis. Fuller details concerning such treatment will be found under 9. SPINAL CORD, Softening of, since this is by far the most common cause of paraplegia.

H. CHARLTON BASTIAN.

9. Spinal Cord, Softening of.—**SYNON.:** Non-inflammatory, White, or Simple Softening; *Myelomalacia*; *Mollities Medullæ Spinalis*; Acute Myelitis (in part); Compression-Myelitis (in part); *Fr. Ramollissement de la Moelle Epinière*; *Ger. Erweichung des Rückenmarks*.

NATURE OF CHANGE.—The writer has already intimated his opinion that far too large a share is assigned to inflammation in the pathogenesis of diseases of the spinal cord. This mistake is particularly obvious in regard to acute inflammations. It has long been the fashion to speak of almost every focus of 'softening' that occurs in the spinal cord as being the result of an 'acute myelitis'; and we find even Erb putting forward, as characteristics of an inflammatory softening, peculiarities which certainly ought not to be regarded in such a light—and this although he seems otherwise strongly inclined to hold a similar opinion to that above expressed. While admitting that a

true myelitis is not distinguishable macroscopically, in the great majority of cases, from a simple or non-inflammatory softening, Erb adds a statement to the effect that the 'microscopical examination can alone furnish conclusive evidence.' In the opinion of the writer, however, such evidence as that which is cited by Erb is quite inconclusive.

It is evident, indeed, that we are still almost as destitute of microscopical as we are of macroscopical characters, of a trustworthy description, for enabling us to decide whether any given focus of softening has been of inflammatory or of simple non-inflammatory origin. In the early stages, or on the confines of a focus of inflammatory softening, we may expect to find a very distinct infiltration of the tissues with leucocytes, which would, of course, at once give a key to the true nature of the change in question. In the present state of knowledge, however, it would appear that the 'non-inflammatory softenings' of the cord are represented by the great majority of the primary and apparently idiopathic 'softenings' which frequently occur in this organ.

ÆTIOLOGY AND PATHOGENESIS.—Concerning the ætiology of non-inflammatory softening of the spinal cord, it is impossible to speak positively. The disease presents itself as a spontaneous or idiopathic affection, sometimes without apparent cause or definite antecedent conditions of any kind, but at others as a sequel of one or other of various known and common precursors of diseases of the spinal cord.

Thus in certain cases the symptoms set in more or less suddenly after some great bodily fatigue; in others after extreme sexual excesses; or they may occur during the period of convalescence from certain acute fevers, such as variola, typhus, and other exanthemata, or after rheumatic fever. During the first week or two after childbirth there is likewise a liability to such symptoms; and also in the later stages of syphilis. These different conditions may act very variously in contributing to bring about a focus of softening in the spinal cord, and nothing more than conjectures can be advanced in regard to its pathogenesis in the several cases. It may be recognised, however, that most of them tend to entail cardiac weakness, either alone or in association with blood-changes which may favour the occurrence of thrombosis.

Again, the symptoms indicative of a primary softening of the cord may set in after the action of other conditions, regarded by some as exciting rather than as predisposing causes. Of these the following may be enumerated: Prolonged exposure to cold and wet; sudden suppression of the menses or of other accustomed fluxes; violent emotional disturbances; or the existence of some inflammation in one or other of the pelvic organs, such as the uterus or the bladder and urethra (instances of the latter class being some of the cases formerly supposed to be of 'reflex' origin). In regard to these 'exciting causes,' all that is certainly known is, that softening of the cord seems to set in not infrequently in persons who have been subjected to one or other of them; but in what precise mode either of them is related to the subsequent softening, nothing very definite can be said. Something, nevertheless, may be advanced by way of suggestion, with the view more especially of giving direction to the investigations needful for clearing up this subject.

Spinal and cerebral softenings probably own a

similar mode of origin. Of the obstructions of vessels which so largely determine cerebral non-inflammatory softenings, it is those due to thrombosis, rather than to embolism, which intervene in the main for the production of corresponding conditions in the spinal cord. See SPINAL CORD, Diseases of, p. 1522, (8) and (9).

It is well known that the causes of thrombosis are principally three, and that in different cases, now one, now another of them may be most influential; while in other instances two or more of these causes may co-operate. These three causes are—(a) thickenings, irregularities, or degenerations of the inner coats of the vessels; (b) slowness of blood-current; (c) peculiarities in the chemical composition of the blood, rendering it more than usually prone to coagulate, or the occurrence of micro-organisms therein.

The thrombosis may take place in the arteries or in the veins, and the plexiform arrangement of the spinal vessels, together with the slowness of their blood-current, may favour the occurrence, as well as the spread of the process when it has once been initiated. Thus a process of coagulation, beginning, perhaps, in some very small vessel, may gradually extend so as to involve many other contiguous branches, and thereby gradually increase the area of the cord which is deprived of its proper blood-supply. The small size of the vessels, however, makes it extremely difficult to establish the fact of their occlusion, whereas in the large vessels at the base of the brain, thrombosis is easily enough detected. And it is especially worthy of note, in this connection, that the blood-supply of the lower end of the cord (where primary softenings are most common) is peculiar and easily interfered with. In short, the anatomical conditions existing in the cord, both on the arterial and on the venous side of its circulation, are probably of a kind distinctly to favour the occurrence of thrombosis.

ANATOMICAL CHARACTERS.—In regard to their distribution or extent in the cord many varieties of softening exist which have been commonly recognised, though they have been mostly described under corresponding designations as so many varieties of 'myelitis.' Thus, we may have a 'complete transverse softening,' involving the entire thickness of the cord for a variable longitudinal extent, either in the lumbar, the dorsal, or the cervical region. Or the softening may be more limited to certain subdivisions of the cord in one or other of these regions—and then constitute an 'incomplete transverse softening.' Thus it may, in one set of cases, principally affect the anterior columns and grey matter; in another set the posterior columns and more or less of the grey matter. Or the softening may be central, and almost confined to the grey matter through a considerable extent of the cord, as in 'diffuse central softening'; when this change involves the white columns as well as the grey matter for a considerable extent, we have what is called 'diffuse softening' of the cord. When a small focus of softening exists which only involves part of the transverse area of the cord, and that for a very limited extent, we have what is commonly spoken of as a 'circumscribed softening' of the cord; and when many of these small foci are scattered through different parts and regions of the organ, we have what is known as 'disseminated softening.'

An accidental damage during the opening of the

spinal canal must not be confounded with the results of pathological change. In a spinal cord bruised in the manner indicated the nerve-substance may be softened and diffident, and somewhat resemble a patch of real pathological softening. Examination with the microscope, however, would show, among the fragments of myelin from the broken nerve-tubules in the former case, an entire absence of the large granulation-corpuscles, which are, on the contrary, invariably present in a patch of real pathological softening. If there were, after such an examination, still room for doubt, this might be resolved by the fact that the softened nerve-matter in a patch of real softening of the cord has its specific gravity lower by 3-5 degrees than that of other healthy portions of the organ, while in the patch of merely bruised nerve-substance it would not be appreciably lower than normal. The normal specific gravity of the spinal cord varies commonly from 1033-1041 in different individuals—the higher figures being most frequently met with in elderly persons. The modes of estimating the specific gravity have been discussed by the writer in *Journ. of Ment. Science*, vol. xi. 1866.

Where the process of softening has gone on to its final stages—in a case, for instance, of 'complete transverse softening'—the whole substance of the cord in the affected site is reduced to a rather dirty-looking milky fluid, which, when the membranes are cut across, flows out so as to leave a complete gap in the cord-substance for an extent, it may be, of one to three inches. All intermediate stages may be found between such a condition and a slight degree of softening, in which the cord-substance is only a little more pulpy than natural.

SYMPTOMS, COURSE, AND TERMINATIONS.—The symptomatology of this disease presents an extremely wide range, in accordance with the varying extent and sites of the softening in the cord, as existing in different patients.

In 'circumscribed' and 'disseminated' softening, for instance, the symptomatology would be excessively variable in different patients; and, especially in the latter class of cases, it might be extremely difficult to arrive at a diagnosis. The symptoms could, in fact, only be interpreted by the light of the general principles applicable to the regional and pathological diagnosis.

Again, in cases of 'diffuse central softening' the symptoms—except for the fact that they set in gradually rather than abruptly—would bear a close resemblance to those of hæmorrhage into the spinal cord, where the blood is effused into the central grey matter for a certain extent (see 8. SPINAL CORD, Hæmorrhage into). There is some doubt, indeed, whether these latter cases may not occur principally as epiphenomena sequential to a primary central softening.

The symptomatology of 'incomplete transverse softenings' of the cord is for the most part exemplified by the second stages of various forms of so-called 'compression-myelitis'—cases, that is, in which the anterior regions of the cord more especially are, in one set of cases, principally pressed upon either by tumour, or by the inflammatory products associated with vertebral caries ('Pott's disease'); while in another set the posterior columns and posterior grey matter may undergo a similar softening, under the influence of the pressure of a new-growth impinging upon the cord from behind. Cases of this type, however, may easily and do often

merge into 'complete transverse softening' (commonly known as 'complete transverse myelitis'). Both complete and incomplete forms also often occur in the cord quite independently of pressure.

Of these states it will be well, for the sake of brevity, to confine our attention principally to '*complete transverse softening*.'

In a case of *complete transverse softening* involving the mid-dorsal region, the temperature in the axilla usually varies between 98° and 100° F., though with an extension of the pathological process, or towards the close of the disease, it may rise to 101°, 102°, or even higher. Meanwhile the lower extremities themselves are often distinctly cold to the hand—the temperature being in some cases more or less subnormal. It is important to note this, because it might have been supposed that hyperæmia and a slightly elevated temperature would exist, owing to the vaso-motor nerves of the limbs being paralysed.

The motor paralysis of the lower extremities is absolute, and the abdominal muscles are also powerless. The feet, as the patient lies in bed, are extended and often inverted, so that the great toes cross one another. The skin after a time tends to become dry and scurfy. The muscles feel flabby to the hand, but they waste only to a slight extent, and continue week after week to show only a small amount, if any, of diminution in the degree of their irritability to faradic and to galvanic currents.

The sensibility of the limbs is completely abolished both for tactile and painful impressions, as well as for differences of temperature and for tickling. A like abolition of sensibility exists over the trunk up to the level of the 'ensiform area,' while above this level the sensibility is found to be quite natural. Though the upper limit of anaesthesia may be quite sharply defined, yet in these cases of complete transverse softening there is often no distinct 'girdle-sensation.'

The muscles of the lower extremities may show some slight irritability when they are forcibly tapped, and when the soles of the feet are strongly tickled there may be very slight movements of the toes; but beyond this there is often an entire absence of all reflex movements—there is no ankle-clonus, no knee-reflex, and a similar absence of the cremasteric and abdominal reflexes.¹ In the initial stages of the affection, however, and especially when the softening is not completely transverse, all these reflexes may be extremely well-marked for a time, though they tend gradually to diminish.

For the first ten days or a fortnight there is often complete retention of urine, but after this time, when the lumbar region of the cord again becomes capable of manifesting to some extent its centric functions, the initial retention gives place to incontinence of urine. This fluid may be discharged at intervals of two to three hours in small quantities, owing to the

occurrence of reflex contractions of the bladder whenever the organ attains a certain degree of fullness. The passage of a catheter, however, in these cases will often show that the bladder is never completely emptied—two to four ounces remaining after the reflex contractions. Unless special precautions are taken, the urine, in such patients, speedily becomes ammoniacal, and more or less loaded with mucus.

The bowels are usually constipated, and relieved only after the administration of aperients or enemata. At these times there is generally incontinence of feces—the patient having no power of controlling the reflex actions concerned in defecation when they have once been strongly excited. The actual passage of the motion is, moreover, unfelt.

Under the irritative influences emanating from the seat of softening during the period of its establishment, a small bed-sore may begin to form, often amenable to treatment. Later on, sloughs are prone to appear upon the heels, over the malleoli, and in other situations habitually exposed to continuous pressure. But the most frequent site for intractable sloughing bed-sores is over the sacrum. Inflammation of the mucous membrane of the bladder is at last set up; and the inflammation may extend up one or both ureters, so as to implicate the pelvis of the kidney, when minute abscesses may also form in the kidney itself.

Under the influence of these various conditions the patient's appetite and strength gradually fail; emaciation proceeds; and death after a time may come from sheer exhaustion, aided, perhaps, by some intercurrent inflammatory affection of the lungs. Such complications may, however, be occasionally warded off for eighteen months or more. Other modes of death are pointed out in the section on Prognosis.

DIAGNOSIS.—The recognition of this disease at the bedside often presents considerable difficulties. We must be guided partly (*a*) by the patient's history and state; partly (*b*) by the mode of onset of the disease; and partly (*c*) by the symptoms of the fully established affection.

(*a*) The points in regard to previous history which are of principal significance are referred to under the head of *Ætiology*. In regard to (*b*), the mode of onset, this is usually not abrupt and sudden; there is rather a slow increase of paralysis during a week, ten days, or a fortnight. Still, it is a fact that softening of the cord (apparently due to thrombosis) does occasionally cause a sudden incomplete paralysis, though such paralysis increases subsequently in the manner above stated. Such a case must not therefore be confounded with hemorrhage into the cord, merely by reason of its absolutely abrupt onset.

The extent to which the diagnosis turns upon (*c*), the nature of the symptoms of the fully established affection, cannot be very strictly defined except in some cases. When the softening is slight and partial, it gives rise to no distinctive symptoms; but where there are clinical signs of the existence of a complete transverse lesion, the chances are that the lesion itself is, if not a primary, at all events a secondary softening.

In regard to the *regional diagnosis* of softening of the spinal cord, the following points require to be borne in mind:—

The indications as to the transverse area involved, and as to the upper limits of the change in the spinal cord, are wholly derivable from the presence or absence of the various signs and symptoms

¹ In one case in which paraplegia had existed for over three months, in consequence of a complete transverse softening in the upper dorsal region (with the above-mentioned clinical signs), the writer was much struck with the extremely pallid appearance of the grey matter through the whole length of the cord below the seat of softening. The absence of the reflexes may be in part due to such condition of the grey matter, and this itself may be caused by a spasm of its vessels in some way induced by the lesion above. Some amount of spasm may also exist in the vessels of the limbs, whose temperature is often rather sub-normal. See a paper by the writer on 'The Symptomatology of Total Transverse Softening of the Spinal Cord,' in *Med.-Chir. Trans.* vol. lxxiii. 1890.

which have been set forth in the article, SPINAL CORD, Diseases of, pp. 1526 and 1530.

The attempt to ascertain the lower level of the lesion, and consequently its longitudinal extent in the cord, is always difficult, and often cannot be achieved with any success. The indications are all obscure, uncertain, and apt to fail. This is especially the case if we attempt to base an opinion on the fact of the existence or absence of superficial reflexes (*see* § 4, (a)). Thus, complete transverse softening may exist in the upper dorsal region, and extensive secondary degenerations may have been produced, yet for week after week there may be a complete absence of all the reflexes, superficial and deep, dependent upon the cord below the upper dorsal region. This the writer has ascertained by repeated clinical examinations of cases whose nature has been subsequently verified *post mortem*.

PROGNOSIS.—The prognosis in a case of paraplegia must always involve a twofold problem: (1) as to the duration of paralysis, or the probability of recovery; (2) as to the danger to life.

(1) The chance of ultimate recovery from paralysis would vary inversely with the size or extent of the lesion existing after the first ten days or a fortnight—that is, by the time softening has been unmistakably established, and when the chance of such an event being warded off by the establishment of a collateral circulation no longer exists. But where a pretty complete reinstatement of blood-supply does take place, all symptoms of paralysis may gradually disappear in the course of some weeks, or, it may be, months.

(2) Danger to life is brought about in many ways, and a fatal result may be entailed (a) by a gradual extension upwards of the process of softening (especially where it exists in the lower cervical or upper dorsal region), so as to involve paralysis of the diaphragm, or an extreme interference with the heart's action. (b) Inflammation of the bladder, followed by implication of other portions of the urinary tract, may lead on to death after the paralysis has lasted for some months, or perhaps for a year or two. (c) About the same period (sometimes early and sometimes late) extensive bed-sores may form, and the patient may, after a time, die exhausted, or from blood-poisoning. (d) Again, the supervention of an intercurrent pneumonia may lead on to a fatal result; or (e) the end may come from the extension inwards of the process of sloughing, so as to lead to the establishment of a rapidly fatal spinal meningitis. Still in some cases, as above indicated, the patient may remain paralysed for even two years or more before a fatal termination is brought about.

TREATMENT.—Our power to deal with the softened condition itself of the spinal cord is extremely small, whether it may have been caused by thrombosis or by compression. During the early stages probably the less that is done in the way of active interference the better. The principal indications are that the patient should have absolute rest in bed, and for the first few days at least a rather sparing diet; spoon-diet being desirable where distinct elevation of temperature exists. The secretions should be regulated, and the urine, if necessary, drawn off by a thoroughly clean catheter smeared with carbolised oil, and kept in the intervals in a perchloride-of-mercury solution. Sedatives, such as bromide of potassium, either alone or in combination with chloral hydrate, may be needed

at night, for a time, so as to ensure an adequate amount of sleep.

Should the patient's general health be weak or deranged, as is so often the case, every effort must be made to improve it by means of an easily assimilable but generous diet, gradually increased, and by the exhibition of suitable tonics, with or without small doses of cod-liver oil. It is far better to trust to such general means than to the supposed influence of phosphorus, or any other drug. To expect any of them to have a direct influence in restoring softened nerve-tissue is vain; and any good that may be achieved by drugs alone is probably brought about either by their power of regulating some of the principal functions of the body, or by improving its nutritive processes generally.

Still scarcely any morbid condition exists in which more constant care and vigilance are needed than in the *paraplegic state*, in order to correct or ward off its numerous incidental troubles or complications.

One of the first points claiming attention in the early stages of a case of paraplegia is to take such measures as will stave off the occurrence of bed-sores as long as possible. These precautions are especially needful where the paraplegia is complete, and where loss of sensibility exists. The patient should at an early stage of the disease be placed upon a water-bed; and those forms are most suitable in which there is a canal through the centre for the passage downwards of the evacuations. The patient must be kept scrupulously clean and dry; and no folds of the bedclothes must be permitted to press against the skin. If possible, the patient should not be allowed to lie continually upon his back, but occasionally in a prone or lateral position. The skin over the sacrum especially must be carefully watched, and on the least sign of a patch of undue redness there, it should be rubbed once or twice a day with a mixture of equal parts of olive oil and spirits of wine. If it becomes actually abraded, it should be dressed with zinc ointment, smeared over a piece of soft lint.

For the first fortnight or more there may be complete retention of urine, which then requires to be drawn off night and morning by catheter. During this period the greatest care should be taken in regard to the cleanliness of the catheter employed. Carelessness in this respect will tend to bring on cystitis at an early date, with alkalinity of urine, and may thus quite prematurely aggravate the bladder-troubles. As soon as the bladder begins to empty itself again, in a reflex manner, at intervals throughout the day, the use of the catheter may be discontinued as long as the water which comes away continues to be clear and acid. During this period of incontinence it will be necessary to draw off the urine from time to time for the purposes of examination. As before stated, the bladder never completely empties itself. After this state of things has continued for some months, the urine is apt to become alkaline, ammoniacal, and more or less mixed with mucus. At this stage the bladder should again be emptied once or twice daily, and washed out each time with 6 to 8 oz. of quinine-solution (2 grains to the ounce, with enough of diluted sulphuric acid to dissolve it); or with a 2-per-cent. boric-acid solution. This will prove the best means of warding off or of mitigating inflammation of the bladder; and thus perhaps

of preventing its extension to the ureters and kidneys.

In regard to the bowels, purgatives will probably be required from the first, as without their use there will be no evacuation. Sometimes a simple enema will suffice. Scybala tend to accumulate in the large intestine, unless its contractility is aroused occasionally by a large injection, consisting of three pints of warm thin gruel, together with half an ounce of spirit of turpentine and an ounce of castor oil.

Where the disease has reached the chronic stage, and when death is not inevitable, the muscles should be faradised or galvanised three times a week, while massage may be employed on alternate days, with a view to maintaining their nutrition as far as possible.

When in the final stages of paraplegia large and sloughing bed-sores have formed, they will require the most constant care and attention. Poultices may be at first needed till the sloughs have separated, and afterwards the wounds must be variously dressed according to their condition. An ointment composed of ten grains of carbolic acid to one ounce of vaseline may be employed; or more stimulating applications may be needed. Sometimes iodoform or the iodide-of-starch paste forms a suitable dressing.

H. CHARLTON BASTIAN.

10. Infantile Paralysis.—See PARALYSIS, INFANTILE.

11. Acute Spinal Paralysis of Adults.—SYNON.: *Polio-myelitis Anterior Acuta*; Acute Inflammation of the Grey Anterior Horns; Acute Atrophic Spinal Paralysis; Fr. *Paralyse Spinale Atrophique Aiguë*; Ger. *Polio-myelitis Anterior Acuta*; *Acute Spinallähmung bei Erwachsenen*.

This is essentially the same disease as that known as infantile paralysis (see PARALYSIS, INFANTILE), though presenting certain differences from the fact of its occurring in adults. The disease is more difficult to recognise in adults, because in them other affections occur with which it is quite possible that it may be confounded.

ÆTIOLOGY.—The ætiology of this affection in adults is just as obscure as it is in children. Sometimes it manifests itself without any assignable cause; while at other times there is the possibility that exposure to wet and cold, some shock or blow, or some antecedent acute febrile illness may have had to do with its origin. The causative conditions are, in fact, in part similar to those of multiple neuritis (see NEURITIS, MULTIPLE), and the two affections in different proportions sometimes co-exist. There exists, perhaps, in some persons a special vulnerability or instability of the motor ganglion-cells of the grey matter of the spinal cord. To this view Bernheim inclines, in consequence of his having collected nineteen cases in which persons who have suffered from infantile paralysis have in adult age become affected either with acute, sub-acute, or chronic poliomyelitis—sometimes involving the same and sometimes different regions of the spinal cord.

SYMPTOMS.—It will principally be necessary in this case to point out the manner in which the group of signs and symptoms characteristic of the disease in infancy becomes modified when it occurs in the adult.

The first set of differences is due to the minor

irritability of the nervous system in the adult, as compared with that of the young child. The initial febrile symptoms may be so slight as to escape notice; convulsions have never been met with; and preliminary head-symptoms are generally absent or very slight. Still some headache, or mental dullness, may be present; and vomiting occurs not infrequently.

Paralysis then sets in speedily—it may be within a few hours—and is more or less widespread. The muscles are flaccid; reflex actions are abolished or greatly diminished. In the course of a few days, generally, improvement as regards motor power sets in, and very slowly progresses. It may go on continuously to complete recovery in the course of a few months; or, as often happens, such recovery is only partial. In the latter case certain muscles or groups of muscles remain paralysed, and in them a rapid atrophy occurs. When tested electrically, these muscles exhibit the 'reaction of degeneration.' The affected parts are cold, and sometimes more or less cyanotic. There is no impairment of sensibility; and no interference with the functions of the bladder or rectum.

All the characters mentioned in the last paragraph accord with those which present themselves in infantile paralysis, but later on differences again show themselves. One of the characteristic features in the child is arrest of growth in the parts affected, so that the limbs or parts of limbs paralysed remain more or less abortive. This, of course, cannot occur in the adult; and also, owing to the fact that the joints are stronger, the secondary deformities (often so serious in the child) are not met with to the same extent in adults.

DIAGNOSIS.—The mode of onset of the disease; the fact that the paralysis is purely motor, associated with no pain or tenderness, and accompanied by no interference with sensibility; the fact that after the first few days at least the functions of the bladder and rectum are not interfered with; and also that in later stages there is atrophy of muscles, and the existence of the electrical 'reaction of degeneration'—these constitute a group of conditions which, taken as a whole, is thoroughly distinctive.

The disease with which it is most liable to be confounded is that hereafter to be described (see 13. Spinal Paralysis, Chronic Atrophic). The points of distinction will, therefore, be given under it. 'Progressive muscular atrophy,' if we bear in mind its very chronic onset, is much less liable to be confounded with the present disease, as also if we recollect that in it atrophy makes its appearance before paralysis rather than after, and that the electrical reactions are, except in the later stages of the disease, notably different.

The fact of the absence of spasms, the diminution of reflexes, the non-interference with sensibility and with the sphincters, together with the abrupt origin of the disease, suffice to separate the acute spinal paralysis of adults from all other affections of the spinal cord, though not from all cases of multiple neuritis. As to this latter difficulty, the reader may refer to the section on Diagnosis in the article on NEURITIS, MULTIPLE.

PROGNOSIS.—This is not a disease dangerous to life. Complete recovery not infrequently takes place, and that too, as the writer has seen, where the paralysis may have been widespread, affecting all the limbs for a time, and leading to marked atrophy in the muscles of the lower extremities. In

other cases there is left in particular parts a chronic remainder of paralysis with atrophy, just as we find to be the case in children. In so far as any part of the patient's symptoms are due to some co-existing peripheral neuritis, we are generally entitled to make a more hopeful forecast.

TREATMENT.—This disease must be dealt with on precisely the same principles as those which are applicable to the corresponding affection in young children. Repetition is, therefore, here unnecessary. See PARALYSIS, INFANTILE.

H. CHARLTON BASTIAN.

12. Acute Ascending Paralysis.—SYNON. : *Paralysis Ascendens Acuta*; Landry's Paralysis; *Fr. Paralyse Ascendante Aiguë*; *Ger. Paralysis Ascendens Acuta*.

DEFINITION.—A mysterious affection of the spinal cord, first definitely described by Landry in 1859; characterised on its clinical side by the existence of a progressive paralysis, advancing rapidly from below upwards, so as finally to implicate parts dependent for their innervation upon the medulla oblongata; characterised also on its anatomical side by the absence of any appreciable pathological change.

On account of the latter peculiarity, the disease ought not to be described in the present place, but rather to constitute the first of Class II (see p. 1531). But this disease, together with 'acute spinal paralysis' and 'subacute spinal paralysis,' have such an amount of similarity from a clinical point of view, that it seems very desirable for their descriptions to follow one another, so that mutual alliances as well as differences may be the more distinctly appreciated.

ÆTIOLOGY AND PATHOLOGY.—The causes and pathogenesis of this affection are even more obscure than those of the disease last referred to. Exposure to cold, and emotional disturbances (with or without suppression of menstruation in the female), have been observed occasionally as precursors. Occasionally, too, this disease has supervened during convalescence from some previous acute febrile malady, such as small-pox or typhoid fever. Syphilis is thought by a few (but on no sufficient evidence) to have something to do with the pathogenesis of this affection.

Westphal, again, who pointed out that the spleen became enlarged in this affection, inclined to believe in the existence of some toxic influence—a view in support of which there is distinctly more in the way of evidence.

The disease seems principally to occur in persons between the ages of twenty and forty, and to be decidedly more frequent in males than in females. Although the brain and spinal cord of those who have died from this affection have now been frequently examined by skilled observers, the results have hitherto been almost entirely negative, so far as morbid anatomy is concerned. No definite changes have, moreover, been met with in the peripheral nerves with any constancy, though the predisposing influences and the symptoms are such as to have created a strong suspicion that the affection might be due to a multiple neuritis. Further evidence is, however, needed before definite conclusions can be arrived at as to the exact nature of this very puzzling malady.

SYMPTOMS, COURSE, AND TERMINATIONS.—About the prodromata there is nothing distinctive—

they may be absent. When present there may, for a few days, or even for a few weeks, be a slight febrile condition from time to time, with a sense of weariness, and more or less numbness in the limbs, especially in the tips of the fingers and in the feet.

The disease then more definitely declares itself, and follows a very variable course as regards rapidity of evolution; sometimes causing a generalised paralysis which may prove fatal on the second or third day, and at other times lasting as many weeks before death occurs or recovery sets in. The disease commences by a marked weakness of the lower extremities; soon to be followed by actual paralysis, which, as in the 'subacute and chronic spinal paralysis,' shows itself first in the distal portions of the limbs, and gradually approaches the trunk, so that in the course of two or three days, or even much less time, the paralysis of the lower extremities becomes complete.

The trunk-muscles are next, and soon, implicated in a similar manner. The patient can no longer sit up or turn in bed. Respiration becomes more and more affected, and defecation is interfered with, through weakening of the abdominal muscles.

Next, though sometimes after a distinct interval, the upper extremities become implicated; though here again the paralysis first involves the distal portions of the extremities, and thence gradually spreads (after a period in which mere paresis exists), till the whole limbs become completely powerless.

The paralysed limbs, both upper and lower, are lax, and show no trace of contraction. Though the muscles are flaccid, they do not undergo a marked amount of atrophy, as is the case in 'acute spinal paralysis.'

In accordance with this latter peculiarity, there is the further striking characteristic that the *electrical reactions of nerves and muscles continue perfectly normal*. This seems now to be a well-attested fact, and it has been verified by good observers even after complete paralysis (without atrophy) has existed, in the more chronic cases, for several weeks.

Sensibility is scarcely, if at all, affected; nor, as a rule, are pains complained of in the paralysed parts.

The reflexes, both superficial and deep, are generally abolished, though in the more chronic cases they may reappear after a time.

The nutrition of the skin is not impaired, so that there is no tendency to the formation of bed-sores. Coldness and cyanosis of the limbs do not seem to be characteristics of this affection.

The sphincters are usually not at all affected. Constipation is often marked, and defecation may be rendered difficult owing to paralysis of the abdominal muscles.

As a rule, there is no febrile elevation of temperature, though to a slight extent this has been present in some cases.

At the stage above indicated, in nearly one-third of the recorded cases, or it may be even before the arms have become much implicated, the disease becomes arrested, and after a brief interval recovery of power begins to manifest itself—usually in a reverse order, so that power is regained first over the arms, then over the trunk, and subsequently (and perhaps only in the course of several weeks) over the lower extremities.

But in the remaining two-thirds of the cases,

after the arms have become paralysed, the disease still progresses so as to affect the cervical muscles, the diaphragm, and finally the muscles innervated by the motor nerves of the medulla. Thus, in its later phases the disease is characterised by a greatly increasing difficulty in respiration; great weakness of voice; extreme rapidity of pulse; and possibly by inequality of the pupils. Finally, increasing paralysis of the muscles concerned with articulation and deglutition sets in; and, owing to the augmenting difficulties of respiration, death may arrive at any moment by asphyxia. This climax of the disease may be reached in the course even of three or four days; on the other hand, it may not be reached until as many weeks have elapsed. Whenever the disease has advanced so far as seriously to implicate the medulla, recoveries are comparatively rare.

In quite exceptional cases the disease may pursue a reverse order throughout; implicating the nerves of the medulla first, then those of the cervical region of the cord, and so on. The celebrated Cuvier is said to have died from the disease progressing in this very unusual manner.

DIAGNOSIS.—So far as the established disease is concerned, we have in this affection, in 'acute spinal paralysis of adults,' and in subacute forms of 'chronic spinal paralysis,' maladies that present certain well-marked points of similarity. In each we have to do, in typical cases, with simple motor paralysis, with no fever, no tenderness or pains in the spine, no pains in the limbs, or contractions, and with no incontinence of urine or feces, or tendency to the occurrence of bed-sores.

'Acute ascending paralysis' differs from both these affections, however, in the important fact that rapid atrophy does not set in in the paralysed muscles, and that the electrical reactions in no way differ from those met with in healthy nerves and muscles. In the very acute cases, of a few days' duration only, these distinctions would be worthless, as sufficient time would not have elapsed to make it possible to attach any value to such differential indications. In such rapid cases, therefore, the distinctly *progressive* character of the disease is that which will serve to distinguish it from the more severe cases of 'acute spinal paralysis,' in which the paralysis sets in simultaneously throughout the whole of the parts affected (the area of the paralysis subsequently tending to diminish), and often with a pretty distinct initial, though brief, febrile disturbance. Then, again, there is the fact (for consideration further on) that this latter disease has little or no tendency to involve the medulla, and is only very rarely fatal.

It is in the diagnosis of the more slowly evolved forms of 'acute ascending paralysis,' from the similarly progressive cases of 'chronic spinal paralysis,' that the development of rapid atrophy of the muscles, together with the 'reaction of degeneration,' comes to be distinctive of the latter affection. Again, in 'acute ascending paralysis' there is a longer persistence of reflex actions; and a far greater tendency to the manifestation of symptoms showing that the medulla oblongata is involved.

PROGNOSIS.—Nothing can be added concerning prognosis beyond what has been above indicated in speaking of the course and terminations of the disease. It seems the rule that, the more rapid the progress of the disease, and the earlier the medulla is affected, the more is a fatal termination to be

feared. Still, even in the most acute cases, improvement *may* take place.

TREATMENT.—The absence of any known pathological substratum for this disease makes it extremely difficult to lay down any directions for treatment. It would appear that we have to do with a simple alteration of the molecular condition of some parts of the spinal motor nerve-centres, unaccompanied by any known inflammation or irregularity of vascular supply.

Under these circumstances, the patient should be put upon a nutritious but easily assimilable diet, with a fair amount of stimulants; and, further, we may endeavour to induce a change in the nutritive and functional activity of the spinal cord, by having recourse to frictions of the skin or gentle shampooing of the limbs, together with brief daily applications of weak faradic currents to many of the affected muscles.

From drugs, perhaps the best chance of beneficial results may be looked for from combinations of iron and arsenic, or from the cautious use of small doses of strychnine. Iodide of potassium would probably be useless.

H. CHARLTON BASTIAN.

13. Spinal Paralysis, Chronic Atrophic.
SYNON.: Subacute and Chronic Inflammation of the Grey Anterior Horns; *Poliomyelitis Anterior Subacuta et Chronica*; Fr. *Paralysie Générale Spinale Antérieure Subaiguë*; Ger. *Subacute Spinal-lähmung Erwachsener*; *Subacute Spinal-paralyse*.

NATURE, ÆTIOLOGY, AND PATHOLOGY.—This disease was described by Duchenne in 1853, and then again more completely in 1872, as a more or less rapidly advancing motor paralysis, associated with atrophy of the muscles affected, and loss of their faradic excitability.

He believed the disease to be dependent upon a chronic degeneration occurring in the grey anterior horns, and this view is supported by the examinations which have as yet been made of persons who have been the subjects of this affection. The pathological changes in the anterior horns have been associated with atrophy of the anterior nerve-roots.

The causes of the malady are at present almost wholly unknown; but it occurs principally in individuals between the ages of thirty and fifty years. As with other chronic spinal affections, so here, there has often been one or other of the following events occurring some little time before the onset of the disease: Exposure to cold and damp, some shock or concussion, venereal excesses, or great fatigue induced by other causes. But what share the pre-existence of one or other of these conditions may have had in initiating the disease cannot at present be defined.

SYMPTOMS.—In the subacute cases, paralysis may become developed (usually in the lower extremities first) in the course of a few days or weeks; at the same time there may be some very slight initial febrile disturbance, and possibly some shooting pains in the back and limbs.

In the more chronic cases, the latter symptoms may be absent, and the onset of paralysis is very much slower. There may be at first mere paresis, felt most in the ankles and knees; but gradually (often after many months) this deepens into distinct paralysis of certain groups of muscles, or of the entire limbs. The muscles are flabby and progressively waste; at the same time they cease to respond well or even at all to the faradic current, and

become more sensitive to the voltaic. There may also be notable fibrillar twitchings in the muscles undergoing this atrophic process.

Sensibility is unaffected. Skin- and tendon-reflexes are abolished. The temperature of the affected limbs is lowered; and the feet especially are apt to be more or less cold and cyanotic.

Soon the arms become affected in a similar manner, and here the paralysis may first affect either the extensors or the flexors. It may remain more or less limited to certain groups of muscles, or may gradually extend so as to implicate the whole limb. The distal parts are usually, however, more completely involved than the proximal. In the arms the same kind of phenomena occur as in the lower extremities, and there is a similar absence of rigidities or contractures.

There is no tendency to the formation of bed-sores, and the nutrition of the skin seems to be unimpaired.

The rectum, the bladder, and the sexual organs are usually quite unaffected.

After a time, the excessive reaction of the wasted muscles to the galvanic current decidedly diminishes; though in the earlier stages of this affection the electrical 'reaction of degeneration' often exists with all its characteristic details.

DIAGNOSIS.—This malady bears a closer resemblance to the 'acute spinal paralysis' of adults than to any other affection. The two diseases are naturally distinct in their modes of initiation, but as established diseases (that is, in their later phases) they would be very difficult to discriminate from one another in the absence of definite information as to modes of onset—and such information, of a reliable kind, is often not to be obtained. It is the abrupt commencement of the paralysis over a wide area of the body that is met with in, and which is so distinctive of, 'acute spinal paralysis'; while in the subacute forms, and more especially in 'chronic atrophic spinal paralysis,' we have to do with a distinctly progressive spread of the disease from part to part.

In regard to the discrimination of the subacute and chronic forms of spinal paralysis from some other varieties of spinal-cord disease, the reader may refer to what has been said concerning the grounds on which the diagnosis of 'acute spinal paralysis' is to be made. See *Acute Spinal Paralysis of Adults* (p. 1547).

In 'amyotrophic lateral sclerosis' the upper extremities may be paralysed, wasted, and flaccid, as they are in 'chronic spinal paralysis'; but then in the former disease there may be the different combination of paralysis without much wasting, but with more or less rigidity, in the lower extremities.

For the distinguishing characters of 'acute ascending paralysis,' see the account of that affection, in the preceding article (p. 1548).

PROGNOSIS, COURSE, AND TERMINATIONS.—In the subacute cases, after a month or two, improvement may gradually begin to manifest itself; and in exceptional instances this may go on slowly, but steadily, to complete recovery. In other of these cases, however, certain muscles or groups of muscles do not undergo the same improvement as the others; they may continue paralysed, and become more and more atrophied.

In the more chronic cases, recovery is scarcely to be looked for; though, after the symptoms have

developed to a certain extent, it occasionally happens that no further advance is made.* Such patients may remain in much the same condition for years.

In another class of cases the malady proves more continuously progressive, so that, after implicating the upper and lower extremities severely, the morbid process may extend to the upper cervical region of the cord, so as greatly to interfere with respiration; or it may even extend to the medulla, so as to involve the tongue and pharyngeal muscles, and more or less interfere with the functions of articulation and deglutition. In such cases death is liable to occur through asphyxia or slowly progressing exhaustion.

In the majority of cases of this disease, more or less complete recovery occurs, though it may be only after two to four years.

TREATMENT.—Possibly counter-irritation to the spine in the early stages by means of the strong solution of iodine, painted over patches every four or five days, may do good, and should certainly be tried, where the patient comes under treatment at this period. A nutritious and easily digestible diet, tonics (such as a combination of iron, strychnine, and small doses of arsenic), and rest are essential in the early stages, together with a thorough supervision of the general health. Later on, massage and electrical treatment by the voltaic current must be had recourse to, and must be perseveringly continued for long periods, until the muscles again begin to respond to the faradic current. The electrical treatment with massage is what is principally to be relied upon; and except in the subacute cases it may be commenced almost from the first, should the patient happen to come under observation during the early stage of the malady. Sulphur- or brine-baths, two or three times a week, seem also at times to do much good.

H. CHARLTON BASTIAN.

14. Progressive Muscular Atrophy.—See *PROGRESSIVE MUSCULAR ATROPHY*.

15. Locomotor Ataxy.—See *TABES DORSALIS*.

16. Spinal Paralysis, Spastic.—**SYNON.** : *Paralysis Spinalis Spastica*; Primary Sclerosis of the Lateral Columns; Idiopathic or Primary Lateral Sclerosis; Primary Spastic Paraplegia; *Fr. Tabes Dorsal Spasmodique* (Charcot); *Ger. Spastische Spinalparalyse; Primäre Sklerose der Seitenstränge des Rückenmarks; Primäre Lateralsklerose des Rückenmarks.*

ÆTIOLOGY.—This disease is distinctly more common in males than in females. It occurs in the majority of cases in adults from twenty to fifty years of age. Erb and others have also described spasmodic forms of paralysis occurring in children, as a result of double cerebral disease, which have several clinical features in common with this affection ('Little's disease,' see p. 269). The writer met with the ordinary form of the affection once in a child of about ten years of age, but then the lateral sclerosis seemed only to form a prominent part of what was really a 'multiple sclerosis' of cerebro-spinal type.

In some cases the disease appears independently of any appreciable predisposing or exciting causes; but, in other instances, falls or other traumatic influences, or great fatigue after some very prolonged walk, seem to be connected with its origin. On rare occasions exposure to wet and cold has ap-

peared to have had some influence over the genesis of this, as well as over that of so many other forms of spinal disease.

ANATOMICAL CHARACTERS.—In the first undoubted case which was investigated *post mortem*, the following pathological conditions were observed: 'The cord, when examined in the fresh state, showed to the naked eye no abnormality, except softening in the lowest dorsal region. After hardening in bichromate of ammonium, sections of the cord showed already to the naked eye one light-coloured patch in each lateral column'—and this throughout the cervical, the dorsal, and the lumbar regions of the cord. This band of morbid tissue, presenting all the typical characters of a sclerosis, occupied the greater portion of the lateral columns, but without implicating the grey matter or extending quite to the surface of the cord. The anterior and the posterior columns were perfectly healthy. The microscopical characters of primary sclerosis in the spinal cord are briefly described in the article on 'multiple sclerosis.' See Multiple Sclerosis, p. 1553.

The occurrence of the slight softening in this case was an accidental complication, otherwise the lesions actually found agreed very perfectly with Charcot's scientific predictions as to the probable pathological changes peculiar to this affection of the spinal cord. Similar changes have subsequently been encountered in other cases.

SYMPTOMS.—This disease often sets in almost imperceptibly, and the symptoms continue to develop in a very slow and gradual manner.

Patients begin to complain first of mere weakness of the lower extremities, and this continues to increase till a well-marked condition of paresis exists. There is great difficulty in getting upstairs, and the feet begin to drag even when the patient walks on level ground. This paresis may soon be associated with more or less of muscular twitchings, often more marked in the morning, but sometimes more especially at night, and of a painful character. Later, an actual stiffness of the muscles of the legs begins to manifest itself, which becomes apparent principally when passive movements are attempted, or even when the patient seeks himself to move the limbs. At last some amount of rigidity of muscles may be more or less continuously present, so as greatly to interfere with locomotion, or in some cases even to prevent it altogether.

In the early stages of the disease, ankle-clonus can be elicited with the greatest ease, and the knee-jerk is found to be distinctly exaggerated on both sides. When one of these patients is in the sitting posture, commencing pressure on the toes of one foot, as in the act of rising, will often at once initiate the characteristic tremors of ankle-clonus. All such signs, however, will probably diminish as the rigidity becomes more marked. The plantar reflex is of the extensor type.

While the patient is able to walk he often exhibits a typical 'spastic gait.' The legs are generally kept close together, owing to a spasmodic contraction of the abductors of the thighs; the toes are dragged along the ground; and then, when the heel is beginning to be brought down, in some rare cases a spasmodic contraction of the calf-muscles may take place, tending to raise the patient upon his toes and almost throw him forward. In this way a mixed and very irregular kind of walking is necessitated, partly to be accounted for by mere powerlessness, and partly by

the occurrence of strong muscular spasms. In some instances, either owing to variations in the amount of the spasms, or, it may be, to the great weight of the patient, this spastic walk is not well-marked. In all cases, however, it is quite different from the ataxic gait; and when standing with feet close together, no increase of unsteadiness or feeling of vertigo is occasioned on the patient closing his eyes.

Sensibility is little, if at all, affected; still, in some instances, it is apt to be slightly impaired. In one case, not long since under the writer's care, ability to recognise differences of temperature was for a time greatly lessened; and although tactile sensibility was scarcely at all interfered with, the patient had frequently complained of a diminished power of appreciating the exact positions of his legs. Skin-reflexes, other than the plantar, are often normal, but occasionally they may be slightly increased.

The muscles do not very appreciably atrophy, and their electrical reactions continue to be almost normal; while, according to Erb, that of the nerves is slightly but distinctly lowered to both currents. Sexual desires are not affected, but sexual disability may be occasioned to a variable extent—partly owing to weakness or actual paralysis, and partly to mere spasms of muscles. Micturition is often scarcely at all interfered with; there is nothing like incontinence of urine or of feces, though there may be an obstinate amount of constipation.

No vaso-motor or trophic disturbances in the limbs are usually present.

As the disease progresses (it may be very slowly, and in the course of years) the muscles of the trunk become affected, so that weakness and spasms, often of a very painful character, occur in the abdominal and dorsal muscles. After a time the arms also may become implicated, and in the same fashion as the legs, excepting that when permanent contractions of the muscles come on, they mostly fix the arm to the side, while the forearm is pronated and half-flexed, and the fingers and wrist are strongly flexed.

In rare cases the disease is limited to one side of the body, beginning, for instance, first in one leg, and then extending to the arm on the same side, so as to present a kind of hemiplegic distribution. Just as rarely, too, the disease may first affect the two upper extremities, and then extend down the trunk so as ultimately to involve the lower extremities.

During the development of the disease, shivering-fits, affecting the muscles of the jaws as well as almost all the muscles of the body, may occur from time to time, lasting for half an hour or more; and though quite unaccompanied by any changes of temperature, they may, nevertheless, be provoked by cold. Sometimes, however, such attacks occur spontaneously; or they may spread from some accidentally initiated ankle-clonus, or other well-marked spasm.

Persons suffering from this malady often remain in an almost stationary condition for a series of years, at any particular stage of the disease that may happen to have been attained. Ultimately, however, there is a tendency to complete paralysis of the parts affected, with permanent contractions—the legs at this stage being often immovably fixed in a condition of rigid extension, though they are sometimes flexed at hips and

knees. As a rule, pains are not complained of at any stage of the disease, though some patients suffer much from painful cramp-like contractions, occurring either in the lower extremities, or else in some of the abdominal muscles.

COMPLICATIONS.—So long as the morbid process remains limited to the lateral columns, no other symptoms present themselves. Should it, however, invade the grey matter in particular regions of the cord, then characteristic complications are apt to arise, and it may also be said that the gravity of the disease becomes very distinctly increased. The way for a fatal termination may then be paved through the gradual increase, for instance, of bladder-troubles; or through the occurrence of severe bed-sores, and collateral events to which they may give rise.

Another possible extension of the sclerosis is to the posterior columns, so that we may get a variable mixture of the symptoms pertaining to 'spasmodic spinal paralysis,' and to 'locomotor ataxy.' It should be borne in mind, however, that such a complicated clinical grouping sometimes develops in the reverse order.

Usually in patients suffering from this disease, there is no association with cerebral symptoms, nor is there any tendency to the springing up of cerebral complications. Still, in one case under the writer's care a subacute maniacal condition became developed; while in another case diabetes mellitus to a slight but tractable extent has manifested itself. In both instances, however, there happens to have been a marked hereditary predisposition to the occurrence of insanity and of diabetes mellitus respectively.

DIAGNOSIS.—The grouping of symptoms met with in this disease is so characteristic, that there ought in most cases to be no difficulty in recognising it. In no other organic affection of the spinal cord have we the combination of a gradually progressive paralysis beginning in the lower extremities, associated with muscular twitches and rigidities; greatly exalted tendon-reflexes; plantar reflexes of extensor type; no impairment of sensibility and no pains; no wasting of muscles or other trophic changes; and no interference with the functions of the bladder and rectum.

It happens, however, that certain functional diseases of the spinal cord, occurring principally in young women, may present nearly all these characters, and may for a time be excessively difficult of diagnosis from early stages of lateral sclerosis. In other of these functional cases there is an altogether unusual amount of sensory impairment of one or other kind occurring as additional symptoms, and in these the diagnosis is more easy. *See* Functional Paralysis of Spinal Type, p. 1562.

Another difficulty arises in the recognition of the complex forms of the disease, or of combinations of this disease with others, then coming under observation for the first time. This, for instance, is the case where we have to do with a combination of posterior and lateral sclerosis, in which, in order to arrive at a diagnosis of the existing condition, the observer must be able to recognise the respective effects or modifications that may result from the combination of the two diseases. A further difficulty of the same kind arises when the symptoms of the disease are complicated by extension of the sclerosis to the grey anterior horns. Symptoms will then present themselves more or less resembling

those which are described below under the head of Sclerosis, Amyotrophic Lateral.

Again, when 'multiple sclerosis' affects in the main the lateral columns, the real diagnosis can only be arrived at by the recognition of symptoms which could not be produced by a mere affection of the lateral columns. Thus the writer has recently had under his care a little girl, ten years of age, first brought to him on account of head-symptoms, which suggested the possibility of intracranial tumour, but in whom, after a few months, signs of lateral sclerosis have become developed in a very typical manner. She presented the most characteristic spastic gait, being frequently raised quite upon the points of her toes as she walked. There was also great exaggeration of the tendon-reflexes, and no impairment of sensibility. The case seemed clearly one of 'multiple' or 'cerebro-spinal sclerosis.'

PROGNOSIS.—So long as the disease-process remains limited to the lateral columns, as it does in the great majority of cases, 'spasmodic spinal paralysis' carries with it no danger to life. Such patients may, with careful nursing, survive for an indefinite time, even though for years after permanent contractions have become established they may have been absolutely confined to bed.

TREATMENT.—In the treatment of 'spasmodic spinal paralysis,' as in that of locomotor ataxy, we must use such means as are most likely to be of avail in checking the process of sclerosis in the columns of the cord which is the cause of the symptoms. The general health of the patient, and the regulation of his mode of life, must receive our most careful attention. Sound sleep must also be ensured, as far as possible.

Nitrate of silver has been praised by some; but the writer believes that, on the whole, more good is to be obtained from iodide of potassium in eight- or ten-grain doses, either with or without liquor arsenicalis, given for a time at intervals. Small doses of cod-liver oil, either alone or in combination with maltine, also seem to do good. There is no particular indication for electrical treatment in this disease; but stimulation of the skin and subjacent parts, by frictions and massage, may be of service in the early stages, and so also may hot brine- or sulphur-baths. There are mostly no pains to be allayed; but occasionally painful cramp-like contractions of the muscles cause much distress to patients suffering from this disease. These pains are difficult to relieve, though good may be done, in some cases, by the extract of Calabar bean in increasing doses. For the rest, any accidental accompaniments of the malady must be treated upon the general principles applicable to the management of other spinal affections. H. CHARLTON BASTIAN.

17. Sclerosis, Amyotrophic Lateral. — SYNON.: Fr. *Sclérose Latérale Amyotrophique*.

This is a combination of symptoms first described by Charcot as a separate disease. Clinically, there is an admixture of the signs of progressive muscular atrophy with those of lateral sclerosis, while towards the close there is often the addition of a glosso-laryngeal paralysis. The affection is undoubtedly a rare one, and doubt has been felt by some as to how far this combination of symptoms is entitled to an independent place in our nosology.

PATHOLOGY AND ANATOMICAL CHARACTERS.
The peculiarity of this form of lateral sclerosis is

said to lie principally in the fact that it commences in the cervical region, and soon spreads to the contiguous anterior horns of grey matter; thence, after more or less of an interval, it extends in two directions: (a) downwards, so as to involve the dorsal and lumbar lateral columns, and also the contiguous anterior cornua of grey matter; and (b) upwards, so as to implicate the upper cervical region of the cord and the medulla oblongata in a similar fashion.

Thus it will be seen that three peculiarities are asserted concerning this form of lateral sclerosis: (1) that it begins in the cervical region of the cord, and subsequently affects the dorsal and lumbar portions; (2) that it does not remain limited to the lateral columns, but soon spreads to the contiguous anterior cornua, where it leads to destruction of the great motor ganglion-cells; and (3) that it almost invariably extends upwards also, so as to involve the medulla oblongata, and thus gradually brings about the death of the patient.

SYMPTOMS, COURSE, AND TERMINATIONS.—Being marked by the anatomical characters above described, it will be easily understood that patients suffering from this disease present an admixture of such signs and symptoms as may be met with separately in 'lateral sclerosis,' in 'progressive muscular atrophy,' and in 'bulbar paralysis.' We are said to have, in fact, the following grouping and sequence of symptoms:—

(1) Paresis, gradually increasing to actual paralysis of the upper extremities, and soon associated with distinct muscular atrophy and fibrillary twitchings. Any movements that can be executed are weak, and associated with tremors. More or less marked rigidity of muscles, and finally actual contractures occur, in which the arms are fixed close to the sides of the body; the forearms are semi-flexed and pronated, while the hands and fingers are strongly flexed.

(2) After an interval of some months, a similar group of symptoms becomes developed in the lower extremities. Again, we have paresis gradually increasing, with muscular twitchings, exaggerated tendon-reflexes, and an increasing amount of rigidity of the lower limbs, which are usually fixed in the extended position. At a later period in the lower extremities, as compared with the arms, a process of muscular atrophy sets in, with development of the 'reaction of degeneration,' and fibrillary twitchings in the affected muscles.

During the whole of this time, there is little or no interference with sensibility. There is usually no implication of the sphincters, and no tendency to the formation of bed-sores.

(3) In the last stage of the disease, there is evidence of extension of the morbid process upwards to the upper cervical region and the medulla. Signs of bulbar paralysis present themselves in the usual way, by paralysis with atrophy of the tongue and lips, and by progressive weakening of the muscles of the palate, pharynx, and larynx. The phrenic nerve has also generally become involved, and when weakness of the diaphragm is added to weakness or actual paralysis of the other muscles of respiration, this all-important function becomes more and more impaired, and thus a fatal termination may at any time be easily brought about. Increasing difficulty of articulation and deglutition may have existed for some months before death.

In the writer's experience this order of development is by no means always met with. Several

cases have of late been seen in which the initial changes have been most marked in the lower extremities.

Many neurologists are now of opinion that no independent disease such as Charcot has described under this name of 'amyotrophic lateral sclerosis' exists. It is recognised by many to be only a variety of progressive muscular atrophy, and this view is most in accordance with the writer's own experience. It must be admitted, in fact, that more or less of lateral sclerosis almost invariably co-exists in progressive muscular atrophy together with the more distinctive degenerative changes in the ganglion-cells of the anterior cornua; and in some cases it happens that the clinical signs of the former change are obvious, rather than much dwarfed or non-existent as they are in the large proportion of cases of progressive muscular atrophy. The writer is thoroughly in accord with Gowers when he says: 'It is probable that the pyramidal tracts are degenerated, if not constantly, at any rate in such a very large proportion of the cases of progressive muscular atrophy, that Charcot's distinction is in effect giving a new name to an old disease. Whether there are [clinical] indications of lateral sclerosis or not depends on the circumstance whether the degeneration of the pyramidal fibres is or is not more extensive than the complete degeneration of the nerve-cells that cause atonic atrophy. If the latter is universal, the pyramidal tracts may be totally degenerated, and yet there may be none of the characteristic indications of such degeneration. On the other hand, both arms and legs may be the seat of the spastic paralysis that indicates pyramidal degeneration, and atonic atrophy may be limited to a few muscles of the hands.'

The writer in his practice has often found the atrophy of muscles either preceding or occurring simultaneously with the signs of spastic paralysis, and no regular division into stages such as has been described by Charcot. That bulbar symptoms occur in association with the other signs of progressive muscular atrophy is of course well known; and though their development may be often a late event, it is by no means always so.

The disease being, then, only a variety of progressive muscular atrophy in association with bulbar symptoms, nothing separate need be detailed concerning its **DIAGNOSIS, PROGNOSIS, and TREATMENT**, apart from what has been said concerning this latter disease. See **PROGRESSIVE MUSCULAR ATROPHY**. H. CHARLTON BASTIAN.

18. Multiple Sclerosis of the Spinal Cord.

SYNON.: Disseminated Sclerosis; Insular Sclerosis; Multilocal Sclerosis; Fr. *Sclérose en Plaques Disséminées*; Ger. *Multiple Sklerose des Rückenmarks*.

NATURE and ETIOLOGY.—This is a disease produced by the development of patches of sclerosis of varying size and shape throughout the spinal cord, and most frequently also in different parts of the brain. Clinically the disease is met with under the most diverse forms, according to the different sites and sizes of the patches of sclerosis occurring in different cases. These different forms of the disease are divisible into three partially distinct types, according as the morbid changes and symptoms occur in and are referable to: (1) the spinal cord alone (*spinal type*); (2) the cerebrum alone (*cerebral type*); or (3) the brain and spinal cord

(*cerebro-spinal type*). As the dominant symptoms of the disease are often those of the spinal type, even where there is also an extension of the morbid process to the cerebrum, it will be most convenient to speak here in the main of the 'cerebro-spinal' type. It is, moreover, both more frequent and a more characteristic malady than either of the simpler forms.

In regard to the aetiology of the disease little can be said. It may occur with or without the predisposing influence of a neurotic tendency. It is at least as common in females as it is in males; and though rarely occurring in children under ten years of age, it is perhaps most common between the ages of ten and thirty years. Beyond the age of forty it again becomes very rare.

Among the exciting causes, exposure to wet and cold would seem to take the first rank. After this come traumatic influences of various kinds, mental shocks or troubles, great fatigues from mental or bodily labour, and finally the state of convalescence from several acute diseases, such as typhus, cholera, variola, or other specific fevers. The disease has been said to occur sometimes as a sequel to severe and long-continued hysteria; but in some of such cases at least it would seem to be far more probable that the early and obscure symptoms connected with this affection were those which were regarded as hysterical. 'Hysteria' may be produced or simulated in many ways, but as itself a producer of organic changes its rôle is assuredly open to grave doubts.

ANATOMICAL CHARACTERS.—The patches of sclerosis which constitute the anatomical basis of this disease differ somewhat in their appearance (macroscopic and microscopic) and probably in their nature from the similar overgrowths of the neuroglia that occur in primary lateral sclerosis.

On the cut surface of the spinal cord, medulla, or other portion of brain, the foci of sclerosis mostly reveal themselves as greyish, greyish-red, or semi-gelatinous yellowish patches, differing principally, by reason of slight contrasts in colour, from the dead white of the more healthy columns of the cord, and from the natural appearance of the grey matter. The tissue of the patches may either be level with, project slightly above, or sink slightly beneath, the general cut surface of the cord. The same differences also exist in regard to those patches which involve the external surface of the cord—they may at times, when the new tissue is excessive, rise slightly above the surface; while later on, when shrinking has occurred in the cirrhotic patch, some amount of superficial depression may be met with.

The patches vary much in size; in the spinal cord they range from that of a mere pin's head to that of a large pea, or of a bean; while in the cerebrum or in the cerebellum they may attain still larger dimensions. In the spinal cord the patches occur in all parts of its longitudinal extent, and they may occupy very variable portions of the transverse area of the cord. Some involve principally the lateral, others the anterior or the posterior columns of the cord; or portions of the grey matter, either alone or in conjunction with one or more of these columns, may be implicated for a variable extent, transversely and longitudinally. Patches of different sizes, and varying in their transverse extent, occupy different levels of the cord, and may thus occur in an irregular series throughout the organ.

These spinal foci of sclerosis, again, may be associated with patches of the same kind distributed through the medulla, pons, and cerebral peduncles, in part superficially and in part within their substance. Similar patches may be found in variable number, and quite irregularly distributed, through other parts of the cerebrum, as well as through the cerebellum.

In regard to the *microscopical characters* of these foci of sclerosis, certain differences are met with in different cases, principally dependent upon the age, or stage of formation, of the patches. Without going into minute details, it may be said that there is in all cases a hyperplastic overgrowth of the neuroglia which naturally exists around and between the nerve-elements. The nature of this change becomes quite distinct when properly prepared sections of the cord have been stained with logwood or other dyes. The new tissue takes the staining fluid freely, and when the circumference of a patch (especially some small one) is examined, it becomes obvious that numerous thickened processes of neuroglia connect it with the healthy tissue around. It is by the hypertrophy and gradual fusion of these circumferential prolongations that the morbid growth progressively encroaches upon the previously healthy portions of the cord. As this more intermediate tissue grows, it presses upon and constricts the nerve-fibres and nerve-cells, so as to cause atrophy of the latter and a partial atrophy of the former. For there is reason to believe that the nerve-fibres do not wholly disappear; in these patches of primary sclerosis (as in the case of 'secondary degeneration') it is the white substance of Schwann which disappears, while the axicylinders, or a considerable number of them, persist. In the new tissue itself we find the usual granular or very finely fibrillary matrix, containing minute spherical or ovoidal plastides, also branched cells, and occasionally a few granulation-corpuscles. The latter are met with especially during the earlier stages of a patch of sclerosis; just as corpora amylacea or colloid bodies may be found in older patches. The walls of the capillaries as well as of arteries and veins are generally greatly thickened, and the vessels in a patch of this kind may be both numerous and large; in other cases, however, the number of vessels existing in the patch is by no means so conspicuous. It is well known that the adventitia or outer coat of the vessels in these patches is specially apt to become thickened, and that this sort of overgrowth may extend inwards, so as to cause fibroid degeneration of the middle coat, and even of the intima. It is probable that proliferation also takes place from the inner surface of the intima (an endarteritis), and that occasionally, owing to this cause, a thrombosis may be brought about. Certain it is that the writer has on several occasions found the larger vessels of a patch of spinal sclerosis blocked by an old and firm thrombus.

PATHOGENESIS.—With reference to the starting-point of a patch of sclerosis nothing definite can be said. Not infrequently disseminated sclerosis may be met with in the absence of any cachexia, syphilitic or other; and, moreover, patches of sclerosis may occur in the nervous system only, or to no notable extent in other organs of the body. This, therefore, would indicate the existence of some process of an abnormal kind taking place in the spinal cord or brain, and again not uniformly through them, but in foci situated here and there.

It is no explanation, as some seem content to suppose, merely to say that the abnormal processes are 'chronic inflammations'; since, whether it is or is not advisable to speak of the changes by this name, we should still have to ask what is the cause of such local departures from healthy nutrition. Does the process begin in the connective-tissue elements themselves? or is there some primary change in the small vessels (possibly of the nature of endarteritis) leading to obstructions and a sequential overgrowth of the neuroglia? It would seem pretty certain, at all events, that the change in the nerve-elements proper follows the overgrowth of the neuroglia—as certain, indeed, as that throughout a band of 'secondary degeneration' the order of these changes is exactly reversed. (There fatty degeneration and atrophy of the nerve-fibres are the first events, and these are followed by hyperplasia of the neuroglia.) See SPINAL CORD, Diseases of, p. 1523.

One of the most interesting facts in connection with these patches of primary sclerosis is to be found in the circumstance that they themselves rarely lead to bands of descending 'secondary degeneration' in the anterior or lateral columns, or of ascending degeneration in the posterior or lateral columns. The fact itself has been long observed, and always regarded as rather surprising. The writer believes it to be explicable by the fact previously mentioned, that the bulk of the axis-fibres remain, so that the nerve-fibres below the seat of lesion (or above in the case of the posterior and parts of the lateral columns) are not absolutely cut off from the nerve-cells which exercise a 'trophic' influence over them. Some nerve-tremors may still pass along the damaged fibres in the sclerotic patch,¹ and thus the nerves in the parts beyond do not degenerate, as they would do if the fibres had been absolutely cut across. Some fibres may be completely strangled and then absorbed, and in such a case the continuations of these nerve-fibres would degenerate. In the final stages of a sclerotic patch this kind of sequence is apt to occur; so that towards the end there may be the tendency to the occurrence of some amount of secondary degeneration, even though the degenerated fibres may not constitute a very compact band.

SYMPTOMS.—It can easily be understood, from what has already been said, how much the symptomatology of this disease is liable to vary in different cases, according to the varying situation, extent, and order of evolution of the morbid patches. That it is possible to assign anything like a definite symptomatology for this affection, is due to the fact that there are certain seats of election in which the patches of sclerosis are specially apt to occur. The sites affected with special frequency are the lateral columns of the cord, the medulla, and the pons; and it is with the occurrence of patches of sclerosis in these situations that we have the following set of correlated symptoms pertaining to the 'cerebro-spinal' type of the disease.

A slowly ensuing paresis of the lower extremities begins first in one limb, and then after a time involves the other. During this time the paresis develops into a more and more marked paralysis, though the sensibility of the limbs remains almost

completely unaffected—nothing more than a temporary numbness being complained of in the majority of cases, while 'lightning-pains' and girdle-sensations are altogether absent. After an interval, first one and then another upper extremity may become weak and subsequently more or less paralysed. During these early stages of the disease more or less distinct remissions of symptoms may occur from time to time.

Meanwhile a most typical sign soon shows itself in the paretic or semi-paralysed limbs in the form of a marked trembling or shaking of those muscles or parts of a limb which are called into voluntary action with any intensity (the so-called 'intentional tremor'), although these phenomena immediately subside when the voluntary exertion ceases. The involuntary movements consist either of extremely well-marked tremors, like those met with in some cases of paralysis agitans, or else of movements of greater range, more resembling those of chorea.

Later some paresis and tremors of the trunk-muscles may occur, as well as of those of the neck; and this may be followed by a similar affection of the tongue, lips, and facial muscles—possibly, also, of those of the palate, pharynx, and larynx. When a patient affected in this manner, who has been previously lying perfectly still in bed, is told to endeavour to sit up, shakings and tremors begin in almost all parts of the body, and the scene is strangely changed until all voluntary efforts cease, and the recumbent position is again assumed. The same kind of thing is seen when movements of particular parts of the body are attempted: thus when, in the sitting posture, the patient attempts to hold up one leg, tremors of it immediately begin; ask him to take hold of something or to squeeze a dynamometer, and the upper extremity called into action at once begins to shake; request him to put out his tongue, and immediately irregular protrusions of the organ occur, associated with twitches about the angles of the mouth and even in other parts of the body. The act of walking may cause, in more or less advanced cases, tremors of the legs, arms, trunk, head, and neck—all at the same time.

Movements of slight intensity occasion either no shakings or merely tremors of a very fine kind. The latter are seen in the early stages of the disease when writing is attempted. Almost every letter registers a number of fine tremors, mixed here and there with greater irregularities. In more advanced cases, however, the movements are so disorderly that writing becomes either impossible or wholly illegible.

Just as there is for some time only slight or patchy loss of ordinary sensibility, so we find that patients often remain fully conscious as to the positions and movements of their limbs, and that closure of the eyes causes no increased uncertainty of their movements unless the posterior columns be distinctly affected; and, except under these latter conditions, when in the standing position, they are not rendered more giddy or more unsteady by closure of the eyes. Later on this sign is very commonly met with, just as there is also an impairment of muscular sense in the upper extremities, so that the patient cannot, with eyes closed, readily touch the tip of his nose with either fore-finger. The co-existence of intentional tremor would, of course, exaggerate this disability.

Up to this stage there may be no distinct interference with the functions of the bladder or the

¹ In support of this, there is the fact mentioned by Charcot, that an optic nerve which was affected through its whole thickness by sclerosis was yet capable of performing its functions.

rectum. The tendon-reflexes are, however, generally distinctly exaggerated: ankle-clonus may be obtained with readiness, and the knee-jerk is often more pronounced than usual. The plantar reflex is of extensor type. There is no tendency to the formation of bed-sores (unless sensibility is gravely impaired); no wasting of muscles; nor is any alteration in their electrical excitability met with.

After variable and often long periods, the affected lower extremities, which have become more and more paralysed, may in some cases show signs of commencing bar-like rigidity. The limbs, as the patient lies in bed, are closely drawn together, and in a condition of rigid extension, which is generally increased when any attempts to move them are made. At first this condition of the limbs ensues from time to time, in the form of paroxysms lasting for an hour or two. But, later, the attacks become both more frequent and longer, so that ultimately the condition of rigidity becomes permanent. Contractions of the arms are less common, and when they occur they become fixed at times in a different position from that met with in simple lateral sclerosis (*see* 16. Spastic Spinal Paralysis); that is, like the lower extremities, in a condition of extension, and closely drawn to the sides of the body. At this period ankle-clonus can often be elicited with the greatest ease, and the movements set up in the one leg may extend to the opposite lower extremity, and may indeed lead to more or less of general tremor throughout the body. Exposure to cold, or irritation of the skin in various ways, will also often suffice to initiate this general tremor, which, as Brown-Séquard showed, may commonly be caused to cease instantly by a forcible flexion of one of the great toes. With the cessation of the tremors consequent upon this manœuvre, the limbs may also be left for a time in a supple and flaccid condition.

The manifestation of tremors of the tongue, lips, and face, together with the existence of a distinct jaw-jerk, is of course a sign that the bulb is affected; and when this occurs, simultaneously or very soon after, other evidences of implication of the bulb and of contiguous portions of the cerebrum may be met with. Articulation may become more or less affected, the speech being rendered slow, hesitating, and measured, syllable by syllable; or it may be jerky in character—becoming especially thick and blurred in the later stages of the disease. The power of swallowing is less frequently impaired, but in advanced stages it is apt to be affected.

Nystagmus is almost invariably met with. Diplopia, or actual paralysis of the ocular muscles, is rare. Amblyopia not infrequently exists, perhaps in one eye only, associated with a variable amount of atrophy of the optic discs. Actual blindness is very rare.

Vertigo, sometimes to a marked extent, is no uncommon symptom; and as the cerebrum becomes more and more affected, a condition of well-marked hebétude, or actual dementia, gradually becomes pronounced. This betrays itself externally by a blank, expressionless aspect of the face; the patient becomes childish in manner, his memory fails, and he takes interest only in trifles; he may also laugh constantly without adequate cause, or, on the other hand, is very easily moved to tears.

During this condition of things a subacute maniacal condition may supervene; or the patient may develop 'delusions of grandeur' precisely

similar to those met with in general paralysis of the insane—examples of which the writer has recently seen in two of his own patients. In other cases persons suffering from this disease may lapse into a profoundly melancholic condition. *See* p. 769.

At this stage, too, apoplectiform or epileptiform attacks are particularly apt to occur from time to time. After such attacks, of whichever kind, the limbs on one side of the body and the face are left more or less paralysed; and where the attack has been epileptiform in character, the convulsive twitchings are often limited to this one side of the body. As Charcot has pointed out, these attacks are precisely similar to those which occur in general paralytics, or in cases of old hemiplegia with descending sclerosis. They answer to the so-called 'congestive attacks,' but they do not seem to be associated with any new appreciable lesions of a 'gross' order. Such epileptiform attacks may be brief, or they may last for hours; or, off and on, even for days. In all of them the temperature begins to rise almost at once—without any initial period of depression—and may even reach 104° in a few hours, or in a day or two. The temperature then begins to fall again; or, should it continue to rise to a still higher point, the attack is very apt to terminate fatally.

Every attack of this kind leaves the patient in a manifestly worse condition, both bodily and mentally; and perhaps in one of them at least death may occur.

VARIETIES. — The symptomatology of this disease is likely to be considerably modified in different cases, but principally in two directions, productive of complications of the same kind as those which are also apt to occur in 'spasmodic spinal paralysis.' In each disease there may in some cases be a special affection of the posterior columns, in one or other region of the cord, bringing with it more interference with sensibility, and an admixture of other symptoms pertaining to locomotor ataxy. These are some of the cases which have been described under the separate name of 'ataxic paraplegia' (*see* PARAPLEGIA, ATAXIC). It is, perhaps, principally in these cases that the '*crises gastriques*' (pains, vomiting, and occasionally diarrhoea) are also met with. In other instances there may be an extension of the sclerosis to the grey matter of the anterior cornua in one or other region (as well as to other parts of the grey matter), leading, among other phenomena, to muscular atrophy in related regions of the body. In either of these ways the symptoms of the original disease may be complicated, and, to a certain extent, obscured.

Many other differences also present themselves in special cases, owing to the varying situations in which the morbid patches make their first appearance. In a distinct minority of the cases the disease seems to reveal itself first in the brain rather than in the spinal cord.

TERMINATIONS. — After this disease has pursued a very slow course for years (often five to ten), the miserable sufferers from it may at last be carried off in various ways. Death may take place in one of the apoplectiform or epileptiform attacks, occurring either in patients who are merely slightly demented, or in those who are otherwise actually insane; or, at last, in cases in which there is great interference not only with articulation but also with deglutition, the functions of the heart or of

respiration may also become affected, and this disturbance may lead on to a fatal termination.

In other cases, after the disease has lasted for years, and when the grey matter of the cord has become seriously involved, accidents may supervene similar to those which occur in the final stages of many cases of paraplegia. The bladder may become paralysed, and after a time inflammation and ulceration may be set up, followed by secondary inflammation of the ureters or kidneys. Or bed-sores may form, sloughing may go on extensively, and the patient may at last die exhausted, or from the supravention of blood-poisoning. At other times the patient is cut off by some acute inflammatory disease.

DIAGNOSIS.—In its early stages the diagnosis of this disease may present very considerable difficulties. This is especially the case when the morbid process begins in the cerebrum. Here for a time there may be nothing distinctive, and we have to wait for the further development of the disease before anything like a positive diagnosis is possible. Similarly, where the disease begins only with spinal symptoms, it is often extremely difficult to diagnose it with certainty in its very early stages. The important characters in the more typical forms of the disease are the comparative youthfulness of the patient, the paresis gradually increasing, first in one and then in the other lower extremity, with little or no alteration in sensibility or in the electrical irritability of the nerves or muscles, but with ankle-clonus and exaggerated knee-jerks. Still it must be borne in mind that all these signs may be met with in the spastic forms of Functional Paralysis of Spinal Type (p. 1562); and, especially when they occur in young women, the diagnosis is often beset with the greatest difficulties. Even the most experienced observer may remain for a time in doubt as to whether he has to do with the beginnings of organic disease, or with mere functional derangements of the spinal cord. But when the peculiar tremors and disordered movements on voluntary excitation of the muscles are met with, together with the absence of any such tremors in the condition of rest, and some amount of paresis or of similar symptoms in one or both upper extremities, the diagnosis of the 'spinal' type of this disease can be no longer difficult or doubtful.

By far the most typical cases, however, are those of the 'cerebro-spinal' type, in which, with such symptoms as are above indicated, there are also some others due to disease of the medulla, pons, or adjacent parts, such as tremors about the lips and tongue, altered speech, and nystagmus. In these cases the disease is really quite distinctive; so that the malady ought to be readily recognised when the patient is seen at this stage for the first time. Chorea is the affection with which such a stage of the disease is most apt to be confounded; but the absolute cessation of all tremors and disordered movements in multiple sclerosis when the patient is at rest, and their immediate re-initiation (mainly in the parts moved, but also generally to a less extent in others) on the occurrence of voluntary efforts, is a thoroughly distinctive characteristic.

Paralysis agitans ought to be distinguished from disseminated sclerosis with even more ease. It is scarcely ever met with in persons under the age of thirty-five, while multiple sclerosis does not very often begin in persons beyond such an age. Again, the stooping gait of paralysis agitans is very dis-

tinctive, and the slow movements of patients suffering from this disease are only to a slight extent exaggerated by voluntary exertion of the parts, while sometimes they are actually lessened thereby; and such movements, in the form of fine tremors, do not cease to anything like the same extent under conditions of rest. There is also no shaking of the head and neck in paralysis agitans.

Mercurial poisoning with tremors can be easily distinguished, on inquiry into the history of the patient, and the mode of onset of the disease.

In those more irregular cases of multiple sclerosis, in which there is either an unusual amount of implication of the posterior columns of the cord, or of the grey matter in some region or regions, the diagnosis of the complex nature of the affection must be based upon the general principles applicable to the regional diagnosis of spinal-cord disease.

PROGNOSIS.—Absolute cure of this disease is scarcely to be hoped for. The most that has been done, hitherto, as a result of treatment, has been to help to bring about more or less distinct remissions, and also to delay the progress of the disease. Death often occurs in from five to ten years, in one or other of the modes already indicated, though at times there may be long periods of quiescence, and the duration of life may be much more protracted.

TREATMENT.—Many drugs have been tried, but hitherto with little or no positive result, in the treatment of this affection. Nitrate of silver has seemed to do good in some cases, especially in the early stages. But the writer is much more disposed to trust to iodide of potassium in eight- or ten-grain doses three times a day, with or without moderate doses of liquor arsenicalis, or of perchloride of mercury; combining the use of those drugs with cod-liver oil, alone or with maltine, and a good nourishing diet. From time to time, however, the above medicines should be omitted, and simple tonics taken in their place. In the early stages of the disease, hot brine- or sulphur-baths and massage of the limbs may be of service; and in all cases it is of great importance to see that the patient obtains sound sleep, since in this, as in all other chronic spinal diseases, the patient's downward course is likely to be hastened where an adequate amount of sleep is not obtained.

No distinct indications exist for the treatment of this affection by electricity, and no advantages have as yet been recorded from its use. The complications of the disease, which may occur in its later phases, must be treated in accordance with the general principles applicable to this as well as to other spinal affections. Every effort must be made to preserve the general health of the patient, as this will probably be found to be the surest means of holding in check the progress of the disease.

H. CHARLTON BASTIAN.

19. Friedreich's Ataxy.—See FRIEDREICH'S ATAXY.

20. Combined Degeneration of the Spinal Cord.—See COMBINED DEGENERATION OF THE SPINAL CORD, p. 325.

21. Spinal Cord and Membranes, Tumours of.—SYNON.: Fr. *Tumeurs de la Moelle*; *Tumeurs Rachidiennes*; Ger. *Krankhaften Geschwülste des Rückenmarks*.

ÆTIOLOGY AND ANATOMICAL CHARACTERS.—Tumours originating in the substance of the spinal cord may be regarded as belonging to two classes,

according as they represent (a) mere local accidents in the form of perverted tissue-changes; or (b) such local accidents developing under the influence of a distinct *general state*, such as syphilis or tuberculosis.

(a) Of the purely local overgrowths, the most typical, and perhaps also the most frequently occurring, are *gliomata*. The consideration of these growths comes in natural sequence to that of *sclerosis* affecting different regions of the cord. In such a tumour we have an exuberant overgrowth, as Virchow and other pathologists suppose, starting from the neuroglia of a certain portion of the cord. At first the growth infiltrates and substitutes itself in the place of a certain amount of nerve-tissue; but it soon grows excessive in quantity (spreading in area perhaps at the same time), and thus comes to exercise a more and more marked compression upon the remaining tracts of nerve-tissue composing the cord at the same level, within the narrow and unyielding boundaries of the spinal canal. In extreme cases a spinal cord may, as the writer has seen, become so infiltrated with new-growth throughout the greater part of the cervical and dorsal regions, that it attains almost twice its natural bulk. These gliomata are oftentimes extremely vascular. They are liable to undergo a certain amount of central softening; and into their substance, especially in the softened foci, hæmorrhages are very apt to occur. Softening of nerve-tissue may also, at a certain stage, take place around a circumscribed growth, and thence may extend for a variable distance above and below.

Other tumours of an allied nature, such as *sarcomata* and *myxomata*, also at times develop, either in their pure types or with blended characters, within the spinal cord. They present few intrinsic peculiarities in their manner of affecting the cord. They rarely attain any large size; indeed the limitations of the spinal canal only permit of much increase in one direction. Thus elongated growths are occasionally met with. To a considerable extent, such tumours have an infiltrating mode of growth, though their boundaries are apt to be rather more defined than are those of gliomata.

In regard to the causes of these tumours, almost nothing more definite can be said than that they seem, at times, to find occasion and conditions suitable for their initiation after some blow upon the spine or concussion of the spinal cord.

(b) Of the growths which tend to occur in the spinal cord (as occasionally in other parts of the body) under the influence of some *general disease* or diathetic condition, two are especially to be named. These are *tubercular growths* and *syphilitic gummata*. The former are generally small, varying in size from a mustard-seed to a pea, and only very rarely attaining the dimensions of a hazel-nut. Next to gliomata, they are the new-growths most frequently met with in the substance of the spinal cord. When small, they may occur in association with a cerebro-spinal tubercular meningitis; but at other times they are found, and especially the larger growths, existing independently of any acute inflammation of the meninges. In this latter case, the tumours may be combined with a certain amount of adjacent and secondary softening of the substance of the cord.

Syphilitic gummata, originating in the cord itself, occur only with the greatest rarity. They are more frequently found starting from the meninges, and

then they may press upon or actually grow into the nerve-substance.

Cancer is believed not to occur primarily in the substance of the spinal cord, though it may grow into its substance, or seriously press upon it, when originating either in the meninges or in the vertebræ.

Growths from the spinal meninges, or adventitious products within the spinal canal pressing upon the cord may most advantageously be referred to here. The *new-growths* that occur are similar to those met with in the cord itself, with the addition of others, and more especially *sarcomata* and *myxomata*. The principal adventitious products are such parasites as *cysticerci* and *hydatids*. The former are very rare and comparatively unimportant. Hydatids, however, are of much more importance. They may be found within the dura mater, but they have been met with much more frequently outside this membrane, often forming large tumours contiguous to and encroaching upon the spinal canal.

SYMPTOMS, COURSE, AND TERMINATIONS.—The difficulties of diagnosis are almost always very great in the case of tumours of the spinal cord, because in their early stages, and occasionally for prolonged periods, they are associated with slight and somewhat vague symptoms.

Independently of the variations in different cases, consequent upon the longitudinal situation or level of the tumour in the spinal cord, the symptoms to which they give rise in various parts of the body may be more or less vague anomalies of sensibility in different regions, associated with a certain degree of weakness, often not amounting to actual paralysis.

Growths from the meninges, or from the vertebræ, pressing upon the spinal cord, are not quite so apt to run a latent course for any length of time, since they are rather more prone to involve the anterior or the posterior roots on one or on both sides—at first irritating them, and subsequently causing paralysis from pressure. Thus localised numbness, pains, or anæsthesia, either alone or associated with twitching, cramps, or paralysis, confined to certain parts of the body, are rather more common incidents during the growth of extra- than of intra-medullary tumours. Still the diagnosis between these two classes of tumours may be impossible.

Sclerosis, in its 'insular' form, especially when the patches are few or close together, may also present symptoms almost inseparable from the first stage of some intra-medullary tumour. The important fact is, however, that sclerosis in the cord tends to become more and more generalised, and thus gives rise to a proportionately widening range of symptoms; or else it limits itself to special columns, and thus becomes associated with more special sets of symptoms.

With any of these tumours of the spinal cord, the symptoms are, after a time, liable to undergo a sudden and grave increase, owing to the occurrence of a hæmorrhage into its substance and perhaps into adjacent regions of the spinal cord, or else owing to the commencement of a process of secondary transverse softening. Beyond these possibilities of sudden grave augmentation of symptoms, the course of intra-medullary tumours is also apt to be marked by peculiar exacerbations and remissions from time to time, in association with periods of altered growth or vascularity of the tumour itself.

DIAGNOSIS.—The very gradual onset of the symptoms in cases of tumour of the spinal cord or of its

meninges is a point of great importance in the diagnosis of these conditions. Thus, for instance, we eliminate arachnoid or intra-medullary hæmorrhages, and also the numerous class of cases of softening of the spinal cord, with other affections having a more or less abrupt origin. The diagnosis of tumour of the cord as distinct from its compression by disease of vertebræ (where there is also generally a slow evolution of paralytic symptoms) must be based in part upon the absence of distinct pains and of any evidence of vertebral disease. The diagnosis from meningeal tumours has already been referred to under the head of Symptoms; and so also has the diagnosis from mere sclerosis of the spinal cord, in which the connective-tissue overgrowth is not sufficiently bulky to amount to an actual tumour.

If the arrival at a diagnosis as to the existence of a tumour of the spinal cord is a process beset with difficulties, these by no means cease when, passing from the primary, we have to approach the secondary question as to the *nature* of the growth presumed to exist. But little is possible in this direction. It is true that, with a history of pre-existing syphilis, even without the evidence of other simultaneous manifestations, we should be warranted in assuming it to be even more than possible that an existing growth was syphilitic in nature, and in treating the patient accordingly; and that all the more because this is about the only kind of new-growth as to which we have distinct evidence of its amenability to the influence of remedies. The presumptions in favour of the tubercular nature of a supposed new-growth in the spinal cord would rarely carry with them more than a moderate amount of cogency. Still, occasionally the general habit of the patient, together with the fact of the existence of scrofulous enlargement of glands, or of some forms of phthisis, might give more or less probability to such a conclusion. Beyond this, not much can be done in the way of diagnosing special kinds of tumours. We might be guided in our opinion as to the possible existence of a sarcoma by the presence of one or more of such growths in other parts of the body; or, failing this, we may recollect that primary cancer affecting the spinal cord is almost unknown, and that gliomatous tumours are, next to the tubercular, those which are most frequently met with in the cord itself. The diagnosis of hydatids may be impossible, as the writer has seen in a recent obscure case in which there was no evidence of hydatids elsewhere, and no local swelling in the tissues outside the spinal canal. Operation, on the assumption that the paraplegic condition might be due to Pott's disease, revealed the true nature of the case, and terminated in recovery.

PROGNOSIS.—The prognosis in all the cases of intra-medullary growth is bad. Life, it is true, may last for months or even years, but the tendency is for the primary affection to set up other secondary accidents, in the form either of hæmorrhage or of softening. Thus, paralysis is rendered more complete, and the way is paved for an ultimate fatal termination, through the intervention of cystitis and renal mischief; by way of bed-sores with exhaustion and blood-poisoning; or by extension of softening upwards to the cervical region, and the supervention of respiratory paralysis.

In the cases of extra-medullary growths the prognosis is not so grave. Syphilitic growths from, or

thickenings of, the spinal meninges may yield to treatment; while other forms of meningeal growth or adventitious products may be capable of diagnosis and of relief by operation.

TREATMENT.—In the case of the existence of a syphilitic tumour in the spinal cord or in its meninges, we may attempt (and with some expectation of success) to treat the causal morbid condition with large doses of iodide of potassium (gr. xv–xxx) in combination with perchloride of mercury. But in almost all other cases of intra-medullary growth little can be done in this direction, and we are reduced to the necessity of dealing with the paraplegic state and its attendant conditions as best we can, and also of attending to the general health, with the view of arresting the progress of the disease and keeping its possible complications in check.

See 9. SPINAL CORD, Softening of.

For tumours of the spinal meninges or hydatids within the spinal canal, we must call in the aid of the surgeon.

H. CHARLTON BASTIAN.

22. Syringomyelia.—**SYNON.**: Syringomyelitis; Hydromyelia; *Hydorrhachis Interna*; Central Gliomatosis; Fr. *Myélite Périépendymaire*; Ger. *Syringomyelie*.

This condition has been long known on its pathological side, but it has been only of late years connected with anything like a definite symptomatology. Formerly, therefore, the disease was never diagnosed during life; the morbid condition was only recognised after death as the cause of previously obscure and little-understood symptoms. During recent years, however, it has been otherwise—many diagnoses have been made during life and subsequently verified.

ÆTIOLOGY AND PATHOLOGY.—There are two principal conditions in which cavities are found in the spinal cord; and though in their typical forms they may be quite distinct from one another, in many other cases they exist in combination and are not separable conditions. The simple condition is known as *hydromyelus* or *hydromyelia*—a state in which there is a dilatation of the central canal of the cord, and in which this canal is distended with fluid; this being either a congenital condition, or perhaps a result later in life of the pressure of a tumour on a portion of the central canal, which obliterates it at the seat of pressure, and leads to the dilatation above. The more complex condition is what is known as *syringomyelia*, in which, though there is dilatation of the canal of the cord as before, there is also a gliomatous overgrowth or new-formation around this dilated canal, which extends more or less into different parts of the posterior half of the cord.

It is commonly supposed that there is some congenital defect in the structure of the cord in these latter cases, so that the central canal remains large, and has around it a variable amount of the unaltered embryonic tissue of the organ, closely allied in structure to the neuroglia, some amount of which always exists at the surface of the cord as well as around its central canal. At some variable period in the life of the individual (but mostly between puberty and the twentieth year) growth seems to take place to a more or less marked degree in this embryonic tissue, resulting in the production of a gliomatous new-formation, which infiltrates to a variable extent the grey matter, and also the posterior and postero-lateral columns. The symptoms

of the disease are thus gradually produced by the increase and invasion of the new growth, and they will naturally vary in their rapidity of evolution with the rapidity or otherwise of increase in the new tissue itself. Cavities other than the enlarged central canal are frequently found co-existing in this gliomatous new-formation, which have probably been formed therein by degenerative changes.

The dilatation of the central canal sometimes exists throughout the entire length of the cord, and there may likewise be a dilatation of the *iter* between the third and fourth ventricles of the brain. In other cases—and this is the most frequent condition—the cavity only involves the cervical and the upper dorsal region of the cord, or perhaps a still more limited longitudinal area. The transverse section of the cavity may be oval or circular, while in other cases there are narrow chink-like extensions into one or both posterior cornua. Other independent more or less chink-like cavities are also frequently found, which, as before indicated, are supposed to have resulted from degenerative processes or from hæmorrhages occurring in the new gliomatous tissue.

In brief, the condition seems to be due in the first place to a congenital arrest of development, supplemented most frequently somewhere between the fifteenth and the thirtieth year, without assignable cause, by an overgrowth of gliomatous tissue of varying extent and rapidity around the dilated central canal and into contiguous regions of the cord; the symptoms being due in the main to this latter process, to pressure occasioned by the fluid or by the new tissue itself, as well as to the subsequent changes taking place in the infiltrated regions of the cord.

SYMPTOMS.—The symptoms of the disease often begin between the fifteenth and the twentieth years (rarely later than the thirtieth), and they may continue for ten to twenty years before a fatal termination occurs.

Patients complain of variable pains in the cervico-scapular region, and some amount of muscular atrophy soon shows itself about the arms or shoulders. Occasionally there may be atrophy also of some of the muscles of the leg.

The arms, or arms and legs, also become more or less weak; the deep reflexes are exaggerated; and some amount of rigidity may likewise show itself in the lower extremities.

With these symptoms there are very characteristic modifications of sensibility. Tactile sensibility and the muscular sense may be little if at all impaired, but painful and thermic impressions (which are conducted to the brain through the central regions of the cord) are lost in one or both arms and in contiguous parts of the trunk. The distribution of the areas affected by this loss of sensibility varies much in different cases; sometimes they are unilateral and sometimes bilateral. In one case under the writer's care the whole of the trunk and the two upper extremities were involved, except for a broad band about six inches wide which encircled the body just above the level of the umbilicus. Less frequently, and mostly in the later stages of the disease, there may be complete anæsthesia of the skin and mucous membranes over the whole or part of one side of the body. The special senses are generally unaffected, and power over the sphincters is also unimpaired. Some of the ocular muscles may be weakened or paralysed where the dilatation of the central canal

extends upwards so as to affect the *iter*, and is so great as to lead to pressure upon some of the contiguous nuclei for the ocular nerves. Under similar conditions nystagmus may also not infrequently be present.

Trophic troubles, other than the muscular atrophy, are not at all uncommon in the course of this disease. In the first place it may be said that such patients frequently burn themselves about the upper extremities, owing to the loss of painful and thermic sensibility. Other changes, however, occur spontaneously, such as alterations in the joints of the tabetic type, or ulcerations of the skin. In these cases it may be suspected that affections of the peripheral nerves are associated with the changes in the spinal cord—a combination which has been proved to exist in a remarkable variety of syringomyelia first recognised in Brittany, and known as 'Morvan's disease,' which is characterised by neuralgic pains, cutaneous anæsthesia, and painless but destructive whitlows. See p. 1028.

DIAGNOSIS.—The diagnosis of syringomyelia is now fairly easy in the majority of cases. It is the combination of loss of painful and thermic sensibility, without loss of tactile sensibility, in association with muscular atrophy in the upper extremities more especially, which is characteristic of the disease.

Formerly this affection was sometimes confounded with anomalous cases of disseminated sclerosis, though such a mistake is much less likely to occur now. It bears most resemblance to certain cases of 'hypertrophic cervical pachymeningitis' (see MENINGES, SPINAL, Inflammation of, p. 977), though these latter cases may usually be distinguished by the greater amount of pain in the nape of the neck and in the upper extremities, together with a certain amount of spasm, and the loss of tactile as well as other modes of sensibility, instead of the dissociated anæsthesia so characteristic of syringomyelia.

PROGNOSIS.—The prognosis is hopeless as regards cure or control of the disease, but the affection is a very chronic one, and therefore not specially dangerous to life till a rather long series of years has elapsed.

TREATMENT.—Treatment can only be directed to the maintenance of the general health, and to the alleviation of pains where they are distressing by means of acetanilide or of morphine. Massage and electrical treatment may also be of some use during the early stages of the disease.

H. CHARLTON BASTIAN.

23. Spinal Cord, Malformations of.—Various conditions are comprised under this head which are of little or no interest to the practitioner. The spinal cord may be absent, imperfectly developed, or double. Again, cases occur in which the spinal cord is either unduly long or unduly short, or in which it may present some trifling lack of symmetry. One of the most interesting of these latter conditions is due to the fact discovered by Flechsig of the possible non-uniform distribution of the pyramidal tracts upon the two sides of the cord, so that the amount of decussation of the motor fibres, not only in different individuals, but also in the two halves of the same cord, may be quite unequal. In the latter case a slight asymmetrical development of the antero-lateral columns on the two sides would be met with.

Congenital Dilatation of the central canal of the Spinal Cord (*Hydrorrhachis interna*, or *Hydromyelus*) has already been referred to as constituting one side of the disease described as 'Syringomyelia'; in which, however, other cavities are frequently found resulting from the breaking-down of the gliomatous new-growth.

Congenital dilatation of the central canal in its most developed form is apt to be met with also in some cases of *spina bifida*; while in others the canal in the lumbar region is open posteriorly, and the halves of the posterior columns are more or less widely separated; there is, in fact, a congenital arrest of development in the spinal cord very similar to that which exists in the spinal canal. See SPINA BIFIDA.

28. Reflex Paraplegia.—SYNON.: Urinary Paraplegia (in part); Fr. *Paraplégie Reflexe*; Ger. *Reflexlahmung*.

GENERAL REMARKS.—Some practitioners believe that paralyzes of various kinds are brought about purely by reflex influences. They would include under this category some of the cases of paralyzes of separate muscles, such as the ocular; some cases of paralysis of one or both arms; or some of the cases of paralysis of one or both lower extremities. It is the last class of cases with which we are now specially concerned, though most of what is to be said in the present article may, *mutatis mutandis*, be considered applicable to the whole class of so-called 'reflex paralyzes.'

Those who believe in the frequent existence of this form of paralysis are considerably less numerous than they were about forty years ago, when the notion of its frequency and importance was warmly espoused by Brown-Séquard, at a time when the morbid anatomy of the spinal cord was very imperfectly known. The number of competent observers was then smaller, and the difficulty in detecting morbid changes in this organ was also much greater than it is at the present time, when we are accustomed to employ more elaborate methods for its preservation and for its examination. Yet one of the strongest of the arguments brought forward in favour of the existence of 'reflex paraplegia' was the absence of discovered lesions in the spinal cord in a class of cases reported upon by Stanley, in which paraplegia was associated with various morbid conditions of the urinary organs—cases, in fact, of the so-called 'urinary paraplegia.' And one of the main supports for the opinion of those who still believe in the existence of a class of reflex paraplegias would even now lie in the absence, in certain cases of paraplegia terminating fatally, of any actually discovered lesion.

ÆTIOLOGY AND PATHOGENESIS.—The interpretation of the paralyzes of this class put forward by Brown-Séquard was as follows: That an irritation, operating upon certain sensory nerves, produced impressions which, after impinging upon the pro-

perly related grey matter in the spinal cord, are thence in part reflected along vaso-motor nerves regulating the calibre of certain blood-vessels which supply either (a) the portion of the spinal cord in relation with the paralysed parts, or else (b) the great nerves or the muscles themselves of the paralysed parts. In either case this reflection of impressions resulting from irritation of sensory nerves, upon such special groups of vaso-motor nerves, is supposed to lead to a persistent spasm of the vessels which they innervate, so as to cause a continuous anæmic condition, either of certain vascular territories in the spinal cord itself, or else of the related nerve-trunks and muscles. In either case, too, the nutrition of the parts involved in this anæmia is supposed to suffer—so that their functions can no longer be carried on, or only in a very imperfect manner—and thus a more or less complete paralysis results, which is capable, however, of being mitigated from time to time, of actually intermitting, or indeed of being abruptly cured, according as temporary diminutions or a complete disappearance of the original exciting cause may lead to a diminution or to an actual cessation of the supposed profound anæmia produced by the postulated spasms of vessels. These are the theories upon which the doctrines of 'reflex paraplegia' are based.

Among the sources from which the initial irritation is supposed to proceed, almost all parts of the body, internal as well as external, are included. Thus irritative impressions, it is thought, may emanate from almost any part of the urinary tract—from the urethra to the kidney; in other cases similar impressions may emanate from some portion of the female genital organs; in others from the intestinal canal, owing to the presence of worms or some such persistent causes of irritation; in others from some portion of the thoracic organs; or, as it seems to be held, from irritated sensory nerves in almost any part of the body, whether situated near the surface or deep among the tissues.

The assemblage of symptoms supposed to characterise these forms of reflex paralysis presents nothing like a distinctive mode of grouping. And of the several components of the group put forward by Brown-Séquard, as pertaining to one of the most typical varieties, namely, 'urinary paraplegia,' none can now have any pretensions to be regarded as distinctive, excepting the alleged tendency of the paralysis to vary in degree with variations in the malady on which it is supposed to depend, together with its tendency to spontaneous or easy cure coincidentally with or soon after the cessation of the urinary troubles, whatever they may have been. In harmony with this latter character also are the alleged facts that speedy cures have been brought about of cases of paraplegia, especially in children, after the expulsion from the alimentary canal of tapeworms or round-worms; or of cures of the same disease in adult females after the cessation of some uterine inflammation; or of cures of a paralysis of ocular muscles after the removal of some carious tooth which had previously been exercising an irritative influence upon branches of the dental nerve.

It would be useless to attempt to deny the existence of such cases; they are theoretically possible. On the other hand, the writer is compelled to believe, after a very extensive experience, that, if they exist, they can only occur as extremely rare events.

Although it is theoretically possible that an irritation of a sensory nerve may be reflected on to vaso-motor nerves, so as to lead to arterial spasms in certain territories of the spinal cord, or in certain groups of muscles, it is difficult here, as it is when postulated in explanation of other functional diseases of the spinal cord, to imagine that such a condition of spasm could be maintained for weeks or even months. Nor, if it could occur for these prolonged periods, and to such an extent as to annul some of the most important functions of the spinal cord during this time, is it at all clear that the nutrition of the cord in the affected regions would not be seriously interfered with by such prolonged anæmia; and, if so, the assumed speedy resumption of healthy functions *pari passu* with the diminution or disappearance of the vascular spasms would constitute another difficulty, since such speedy recovery would be scarcely compatible with the theory upon which the explanation of the disease is based.

Again, it is almost certain that many of the cases formerly supposed to belong to this category of 'reflex paralysis' had no right to figure therein. Cases of diphtheritic paralysis have been proved to belong to a different category; and there is good reason to believe that in other instances the morbid conditions really existing as causes of the paralysis have simply been overlooked, either because the appreciable changes were only slightly advanced at the time of the patient's death (owing to the brief duration of the illness); or because of the want of a thorough examination of the cord, conducted with all needful aids, care, and expenditure of time; or, finally, because the disease may have been in the peripheral nerves rather than in the spinal cord itself.

It seems clear, therefore, that the opinions of those who believe in the existence of 'reflex paralysis,' and of 'reflex paraplegia' in particular, stand much in need of further support and definition. Well-observed and well-recorded instances of the disease are urgently wanted, if 'reflex paraplegia' is to retain its claim to a place in our nosology.

H. CHARLTON BASTIAN.

29. Intermittent Paraplegia.—SYNON.: Intermittent Spinal Paralysis; Fr. *Paralysie Spinale Intermittente*; Ger. *Intermittirende Paralysis Spinalis*.—Very few cases of paraplegia of this type have been recorded, and it must also be a condition of extreme rarity.

The earliest recorded example was made known by Romberg, and as this, both in its nature and its course, seems to have been a typical instance, it may be cited here. 'A woman, sixty-four years of age, after being quite well the day before, was suddenly attacked with paralysis of the lower extremities and of the sphincters. Sensibility was unchanged, consciousness clear, the temperature cool, pulse 80, small and empty, no pain in the spinal cord. The next day there was an astonishing change in the condition. The patient could walk again and void urine voluntarily, and only complained of weakness in the legs. The following morning there was paraplegia again, which had set in at the same hour as it had done two days before. A third paroxysm was awaited, which also set in at the appointed time, although without paralysis of the sphincters. Quinine effected a rapid cure.'

Additional cases have since been recorded by Erb, Hartwig, and other observers; and the view now

entertained concerning them is that they are due to multiple neuritis or to a multiple peripheral neuritis, rather than to any disease of the spinal cord itself. See NEURITIS, MULTIPLE.

Any future cases should be observed and recorded with the greatest care. Meanwhile it must be remembered that those already observed seem to have proved extremely amenable to the influences of quinine and of arsenic.

H. CHARLTON BASTIAN.

30. Functional Paralysis of Spinal Type. SYNON.: Hysterical Paraplegia.

It is generally admitted that paralysees of the 'hysterical' type more frequently belong to the paraplegic than to the hemiplegic variety. Even good observers, however, are rather too prone to look upon the terms 'functional' and 'hysterical' as interchangeable. This is apt to create confusion. Surely there may be functional paralysees which have no right, merely as such, to the appellation 'hysterical.' Certain it is that in a considerable proportion of cases, which we seem justified in regarding as functional, there may be, apart from the paralysis, no symptoms or mental peculiarities which could be described as 'hysterical.'

This whole subject bristles with difficulties, for, as the writer has endeavoured to point out, the different forms of functional paralysis must be dependent upon faulty nutrition and faulty functioning (apart from gross organic disease) of this or that territory of the brain, and probably also of this or that region of the spinal cord. This being so, functional paralysees should closely accord in their characters with the forms of paralysis caused by actual gross lesions in different regions of the brain and spinal cord; though the two classes may differ in severity and in curability—one or both.

'Some appear to think (or their language seems to imply) that all cases of paralysis not due to a structural cause must be of a hysterical order; and, as they believe hysteria to be due to a perverted activity of the brain, it perhaps never occurs to them to consider whether some of the cases of functional paralysis coming before them may not have their origin in a depressed or perverted activity in some portion of the spinal cord. For one or other of these reasons, it happens that up to the present time almost nothing has been said upon this subject; so that no rules of any kind are laid down in our text-books to help us in distinguishing spinal from cerebral cases of functional paralysis.'

SYMPTOMS.—It seems clear, however, that if there are in reality cases of functional paralysis of *spinal type*, they at least could have no sort of right to be spoken of as 'hysterical,' seeing that hysteria is now generally admitted to be a functional disease of the brain. The writer believes that such cases are to be met with not infrequently, and for the present he is disposed to range them tentatively in two classes, viz.:—

A. *Cases of the Spastic Type, due to functional perversion or defect in some part of the pyramidal system of fibres in the spinal cord.*

B. *Cases of the Flaccid Type, due to functional defect in the anterior cornua in certain segments of the spinal cord.*

In both sets of cases there is mostly a complete absence of ordinary hysterical symptoms. Instances of Class A approximate somewhat in their symptoms to those of 'spastic spinal paralysis'; that is,

there is paresis or actual paralysis, with more or less of rigidity and exaggerated reflexes in the lower extremities. Defects of sensibility may or may not be present in the paralysed parts and over the trunk to a certain level, though the distribution of anæsthesia is often unequal on the two sides of the body.

In Class B we have to do with cases of paralysis of flaccid type unassociated, it may be, with any diminution of muscular sense. But in other of these cases, where the functional defect is more diffused over the grey matter rather than limited to the anterior cornual regions, there may be a more or less marked impairment of common modes of sensibility, and possibly also some amount of diminution of muscular sense owing to interference with its afferent channels. It may, perhaps, be assumed that the functional defect in the anterior cornua of the cord is adequate to bring about a more or less definite paralysis, even though the defect may not be sufficiently severe to entail any special muscular atrophy.

DIAGNOSIS.—The characteristics of hysteria and of hysterical paralysis have been set forth elsewhere (see HYSTERIA); it must suffice, therefore, to say here that true hysterical paralysis (while it may be hemiplegic or paraplegic) is very frequently associated with a hemianæsthesia of cerebral type (in which the special senses are more or less involved), while there may be the association of hysterical convulsions, and more or less special mental peculiarities. In the cases of functional paralysis of spinal type, however, with which we are now concerned, there is an absence of these associated symptoms; anæsthesia is not always present, and when it is it does not affect the head and face, with the special senses. Future investigation will probably lead to the recognition of other more definite differences between these two classes of functional paralysis.

In the diagnosis of these cases, reliance is always to be placed principally upon the absence of distinct evidence of organic disease such as would be furnished by muscular atrophy together with the electrical reaction of degeneration, by incontinence of urine or of feces, and by the occurrence of bed-sores. The diagnosis has, in fact, to be made by way of exclusion; we must be satisfied that the symptoms in the case before us are not explicable by supposing the existence of any known organic disease of the spinal cord.

It may be said, moreover, that the cases of organic disease which are most likely to be confounded with functional paralyses, whether of cerebral or of spinal type, are spastic spinal paralysis, disseminated sclerosis, subacute or chronic spinal paralysis, Friedreich's disease, or the paralysis associated with Pott's disease. In many cases, however, such mistakes are made as much from the want of a sufficiently thorough examination of the patient, as from defective knowledge of the respective characteristics of the organic diseases just named.

PROGNOSIS.—The prognosis is of course always very much more hopeful in functional cases than it would be in anything like corresponding cases due to organic disease. The ultimate establishment of a cure may be considered the rule in cases of functional paralysis, of this as well as of other types, provided the cases come under systematic and efficient treatment; though the duration of the

disease must be considered to be altogether uncertain. Sudden cures are not to be expected in this class of cases as frequently as they are in the functional paralyses of cerebral type. For the most part they will require many weeks or months of continuous treatment before the patient slowly recovers.

TREATMENT.—This must be conducted upon very much the same principles that are applicable to the treatment of functional paralysis of cerebral type, so that details need not be here recapitulated. See HYSTERIA.

H. CHARLTON BASTIAN.

31. Paraplegia dependent on Idea.—

NATURE AND ÆTIOLOGY.—This is a form of paralysis, of purely 'functional' type, occasionally occurring in neurotic impressionable persons, and yet not dependent upon any ordinary hysterical condition. Attention was first called to such cases by Russell Reynolds, who cited among others a typical instance in which a young lady, while attending to a paraplegic father, amid the additional anxieties consequent upon straitened circumstances and the fatigues incident to teaching in order to obtain the bare necessities of life, became at last, under the influence of long-continued strain, together with an abiding fear (inspired by actual physical weakness) that she herself was becoming paralysed, reduced *de facto* to this condition, as the final outcome of a slowly increasing weakness.

PATHOLOGY.—Such a condition may occur quite independently of hysteria, and be just as free from anything like conscious simulation or desire to exaggerate. We cannot say positively that the state is induced by what is called 'inhibition,' or by definite vascular spasms such as are supposed to form one of the pathological bases of the class of so-called 'reflex' paralyses, and yet both these modifying influences over the functional activity of the spinal cord *may* be in part operative when imagination, continuously excited in some one direction, has a tendency to pervert the functional activity of this portion of the nervous system.

The same conditions that exist as more lasting states in these cases probably exist temporarily, under the influence of suggestion, in hypnotised persons. See MAGNETISM, ANIMAL.

SYMPTOMS.—There is a paralysis of motion in the lower extremities, more or less complete, often partial, and generally without implication of sensibility. There is unabated control over the bladder and rectum.

Reynolds pointed out that, while such patients may be wholly incapable, when bidden, of lifting a foot from the bed, they often find themselves able to turn or sit up without any assistance. And in slighter cases, though they may be unable to stand for a moment, such patients may yet be able to move the legs in any direction while in the recumbent position.

DIAGNOSIS.—The character of the paralysis, and its limitation in range, is thought to be of importance. But still more important is the establishment of the fact of the pre-existence of long-continued fears or fancies (in a person of delicate or neurotic temperament), of such a nature as to be in accordance with the patient's now-present condition, combined with the absence of all signs positively indicative of any structural defect in the spinal cord.

When such a condition exists (as it may) as a mere complication of an actually existing structural disease, the diagnosis becomes either impossible or extremely difficult. It is, in fact, only possible after prolonged observation and experience as to the course of the symptoms.

PROGNOSIS.—The prognosis is extremely good if the nature of the malady be divined, and a right course of treatment adopted. Under such circumstances, an almost complete cure may easily be brought about in a week or ten days; but, failing this recognition, the morbid condition may, it is said, under ordinary treatment, persist for an almost unlimited period.

TREATMENT.—The practitioner must inspire the patient with confidence that the malady is curable, and surround her (or him) with cheerful, hope-inspiring attendants and influences. At the same time, with the view of supporting her confidence (if for no other reason), the muscles of the apparently paralysed limbs should be faradised daily, or recourse should be had to frictions or massage combined with passive movements. He must make the patient attempt to stand or walk, with the necessary support; administer opiates, or bromide of potassium with chloral hydrate, to procure sleep, if necessary; and carefully seek to restore the patient's general health and nutrition. In this class of cases, especially, it would seem probable that the influence of 'suggestion,' if hypnotism could be induced, might be capable of producing an almost immediate cure. **H. CHARLTON BASTIAN.**

32. *Neurasthenia Spinalis.* — **SYNON.** : Functional Nervous Weakness of the Spinal Cord.

NATURE AND ÆTIOLOGY.—Under this name, descriptions have been given of a combination of symptoms not infrequently met with in males as well as females, but more especially in the latter. They are supposed to represent a condition of extreme nervous debility, coming on obscurely, or at all events not as a sequel of some previous severe illness or shock. Still the symptoms met with often approximate closely to those pertaining to a state of convalescence from some serious febrile illness; and are not at all unlike some of those which may follow concussion of the spinal cord.

Such symptoms, when occurring independently, are most prone to show themselves in those who are naturally of a neurotic temperament. They may be excited by over-fatigue of various kinds, especially when this has been coupled with disturbed sleep for some time. Prolonged exercise or mental overwork may have been the particular exciting cause of fatigue; though perhaps much more frequently this is to be found in sexual excesses (of a natural or unnatural order), either extending in the form of habitual indulgence over a considerable period, or as more isolated but marked excesses. At other times, symptoms of neurasthenia spinalis set in after influenza, or without obvious provocatives of any kind.

PATHOLOGY.—Concerning the actual cause of spinal neurasthenia little or nothing can be said. Sometimes there may be the co-existence of distinct cerebral symptoms of an analogous type; though on other occasions the symptoms are more purely spinal. This malady is perhaps capable of being induced by mere altered molecular states and actions of the tissue-elements of the spinal cord. A kind of

persistent condition of fatigue exists. Although some may imagine the existence in these cases of a more than usually anæmic condition of the spinal cord, of this, as a fact, there is no evidence. To speculate upon other modes in which such a set of symptoms might be brought about would, in the present state of our knowledge, be of little service. There is, however, the possibility that this morbid condition may be due in the main to a functional disease of the cerebellum—especially if the views of Rolando and others, as to the functions of this great organ, should prove correct even in part.

SYMPTOMS.—A feeling of utter weakness and prostration, induced by even the smallest amount of muscular exertion, is the central symptom, though this is usually associated with coldness and more or less numbness of the extremities. The knee-jerks are commonly much exaggerated, and when the tendons are struck there is generally more or less starting in other parts of the body. Pains, too, may be felt in the muscles of the limbs and in some parts of the back, though there is commonly no tenderness over any part of the spine. These symptoms may be unusually distinct after any activity of the genital function, and they may then be associated with extreme wakefulness, or sometimes with protracted inability to sleep. Occasionally, and especially when this latter symptom is not present, the patients may present a florid and fairly healthy appearance, strangely at variance with the extreme debility complained of.

DIALOGUS.—The points of greatest importance are the existence of extreme weakness, with no evidence of anything like actual paralysis, or indeed of any symptoms which would indicate an actual structural disease of the spinal cord. This being so, and diabetes being also eliminated, we may oftentimes (and especially where the existence of one or other of the above-mentioned exciting causes has been established) pretty confidently conclude that we have to deal with what is here named '*neurasthenia spinalis*.'

PROGNOSIS.—A relief of this condition is ultimately to be looked for under the influence of rest and suitable treatment; but in regard to the rapidity with which any such amelioration of the patient's symptoms is to be brought about, great differences exist in different cases. Weeks, months, or even years may be required before a natural amount of vigour is restored.

TREATMENT.—Rest, especially in the direction of previous excesses, is the first and indispensable requisite. Every effort should be used to obtain regular and sound sleep. The action of these potent restoratives should be supplemented by a generous and easily assimilable diet, together with a moderate amount of stimulants. Hypophosphites of the alkalis with iron and small doses of strychnine (which may be conveniently given in the form of a syrup) often prove decidedly beneficial. An abundance of fresh air is desirable, and especially that of elevated and bracing situations. Daily frictions and massage, aided by stimulating saline baths, may also prove to be of much use; while in the more severe cases a complete course of Weir-Mitchell treatment is indicated (p. 1073).

H. CHARLTON BASTIAN.

33. *Toxic Spinal Paralysis.*—Under this name it will be right to refer to a class of cases of paraplegia produced by poisons of various kinds. It

constitutes a somewhat heterogeneous group, concerning which our knowledge is still very defective.

Of the toxic agents taken into the body, and capable of entailing a paraplegia, some are minerals such as arsenic and lead; others are of vegetable origin, such as aconitine, conine, veratrine, prussic acid, ergot, and alcohol; while others again are of animal origin. In the majority of cases, their action as 'causes' is not sufficiently potent to lead to paralysis as anything like an invariable effect. They need the concurrence of other favouring circumstances, probably in the main intrinsic; but under the combination of conditions thus resulting a paraplegia may be induced. It is only in this attenuated sense that the above-mentioned poisons are to be regarded as 'causes' of paraplegia. They ought perhaps, from this point of view, to be considered as predisposing rather than as exciting, and in no case as proximate, causes of paraplegia.

Moreover, investigations that have been made during the last few years have shown that these various poisons act more powerfully upon the peripheral nerves than upon the spinal cord itself. So that cases of paralysis due to lead, arsenic, or alcohol, may be in the main occasioned by changes in the peripheral nerves (*see* NEURITIS, MULTIPLE), although some changes in the spinal cord may also co-exist, which vary in their nature in different cases. They mostly take the form of atrophy of the ganglion-cells in the anterior cornua, with some amount of surrounding sclerosis, though occasionally minute foci of softening may be met with.

Besides the more specific effects of lead in producing the above-mentioned changes in the peripheral nerves and spinal cord, it commonly induces a condition of lowered vitality which favours the development of degenerative conditions in the spinal cord. In such cases it can generally only be considered as one among other determining conditions, tending to bring about some form of paralysis. In this way it has seemed to the writer to be occasionally one of the concurrent causes in the production of primary lateral sclerosis and of progressive muscular atrophy.

These considerations will help to account for the fitful and irregular manner in which arsenic, lead, or alcohol (and probably to a similar extent other toxic substances) give rise to *paraplegic* symptoms in those who have taken them to excess. Thus, according to Tanquerel des Planches, out of 200 cases of lead-poisoning, in only fifteen did the paralysis implicate the lower extremities; and in only one of these did it occur as a distinct paraplegia. This case might, therefore, have been a coincidence rather than a definite result of the taking of lead. Again, in regard to arsenic, it is true that in certain cases Orfila observed paraplegic conditions in dogs which had taken large quantities of this drug; but such symptoms dependent upon actual disease of the spinal cord would seem to be met with only occasionally as a result of acute arsenical poisoning in man, and with equal rarity in those who habitually consume large quantities of this substance. On the other hand, the recent epidemic of multiple peripheral neuritis in the North of England, caused by the consumption of beer contaminated with arsenic, has abundantly demonstrated its capacity for the production of paralysis by causing neuritis—especially when taken in association with alcohol. *See* pp. 1077, 1078, and 1109.

The notion was advanced by Moxon that a certain class of poisons, which own the common property of being 'depressants of the circulation,' have a tendency to paralyse the hind-legs rather than the fore-legs of animals. In this group are included aconitine, conine, and possibly also veratrine, chloral hydrate, and prussic acid. He was of opinion that these drugs act by causing further impediments 'to the exceedingly and peculiarly difficult blood-supply of the caudal end of the spinal cord.' It should be borne in mind that extreme feebleness of blood-current is of itself a common cause predisposing to the occurrence of thrombosis both in arteries and in veins, and that such a condition may intervene in some of these cases of poisoning, and lead to the development of paraplegia. This would enable us to account for the otherwise inexplicable fact of the maintenance of the paralysis long after other effects of the poison have passed away.

PROGNOSIS AND TREATMENT.—The prognosis in this class of cases is generally good. Often, indeed, the mere cessation from the consumption of the poison, aided by favourable conditions for the maintenance of the general health, suffices to restore the patient to health. In the more severe cases, however, the treatment has to be prolonged, and we must avail ourselves of all the local measures indicated in the article NEURITIS, MULTIPLE, in order to bring about a very gradual restoration of the patient's strength.

H. CHARLTON BASTIAN.

SPINE, Disease and Curvatures of.—

SYNON.: Fr. *Maladies et Courbures du Rachis*; Ger. *Krankheiten und Krümmungen des Rückgrates*.

The structures composing the vertebral column are subject to disease such as is met with in other parts of the body where similar structures exist. In this article will be described tubercular caries, by far the most common affection of the spine, syphilitic disease, acute osteo-mylitis, tumours of the bones, and lateral anterior and posterior curvature. Angular curvature, which is merely a symptom of tuberculous, or more rarely of syphilitic or malignant destruction, of the bodies of the vertebrae, is described under TUBERCULAR CARIES.

Caries of the Spine.—SYNON.: Pott's Disease; Fr. *Mal vertébral de Pott*; Ger. *Die Pottische Krankheit*.

DEFINITION.—A destructive disease of one or more of the bodies of the vertebrae and their intervertebral cartilages, frequently leading to angular deformity of the spine in consequence of the bodies of the vertebrae above and below the seat of the disease falling together.

ÆTIOLOGY.—Spinal caries is nearly always of tubercular origin. It is occasionally due to acute osteomyelitis or the breaking down of a syphilitic gumma. The disease may occur at any age, but is most common in childhood. It may be confined to one vertebra or may spread to the neighbouring vertebrae, or several vertebrae may be simultaneously affected. The onset can frequently be traced to a slight strain or other injury of the vertebral column. The tubercle-bacillus, as in tuberculosis of other bones, commonly affects the actively growing and vascular bone beneath the epiphysal discs or, in the case of adults, the deeper or osteogenetic layers of the periosteum covering the anterior portion of the

vertebral bodies. In rare instances the periosteum of the posterior part of the bodies is affected. As the result of the bacillary invasion, granulation-tissue is formed and the bodies of the affected vertebrae and the neighbouring intervertebral discs are gradually destroyed in the way described under tuberculosis of bone (p. 168). At this stage the disease may cease and the granulation-tissue undergo ossification, causing ankylosis of adjacent vertebrae without any angular deformity. More commonly, however, the granulation-tissue, having destroyed the osseous trabeculae, caseates and breaks down, forming a tubercular abscess. If the process has been very acute a large portion of the cancellous tissue may die *en masse*, forming sequestra (*caries necrotica*). In any of these cases angular deformity may be the result, since, partly by its own weight and partly by the dragging of the abdominal muscles, the upper portion of the spine thus undermined falls forward at the seat of the disease, and forms an angle with the lower portion. In consequence of the patient's efforts to hold himself upright the normal lumbar and cervical curves, when the disease occurs in the dorsal region—the common situation—will be greatly increased, the angular projection being thus thrown backwards and the well-known 'hump-back' produced. Should an abscess have formed, its contents may undergo changes similar to those occurring in other regions (p. 9). Thus it may dry up leaving a caseous mass, or it may extend down the spine on one or both sides of the anterior common ligament, or more rarely make its way into the spinal canal. In the cervical region the abscess usually points at the back of the pharynx or at the side of the neck; in the lower dorsal and lumbar regions it either makes its way posteriorly between the last rib and crest of the ilium as a lumbar abscess, or it follows the course of the psoas muscle, forming an iliac or psoas abscess (see PHARYNX; and PSOAS ABSCESS). Occasionally and especially in the upper dorsal region it may take a circuitous course, for example, tracking along a rib towards the sternum or between the abdominal muscles, when it may open at the umbilicus, or may enter the pelvis, pass through the great sciatic notch, and point in the gluteal region, or may track down by the side of the rectum, forming an ischio-rectal abscess. When the disease begins or extends posteriorly, a tuberculous collection may form beneath the posterior common ligament; the inflammation may then involve the dura mater, setting up a pachymeningitis; in either instance a temporary or permanent paralysis may ensue from pressure on the cord. The anterior motor column being nearer to the seat of the disease, paralysis of motion is much more common than that of sensation. In rare instances the cord itself may become involved in the inflammation and undergo softening leading to permanent paraplegia.

SYMPTOMS.—In the earlier stages of spinal caries the symptoms are often obscure and an absolute diagnosis may be impossible. By the time an angular projection has formed, the disease is obvious, but to wait for this is to nullify the advantage of an early diagnosis, namely, the prevention, by judicious treatment, of any deformity. Pain on movement and pain on pressure over the spines of the vertebrae, although not conclusive signs, are of material value when taken in conjunction with rigidity of certain portions of the spine due to muscular contraction calculated to prevent movement

and consequently pain at the diseased spot. The presence of *pain* may be detected by percussing or pressing on the head, on the shoulders, on the head of the rib or over the diseased spot, or it may be elicited by certain movements of the body. It may be felt at the diseased spot or may be referred along the course of the spinal nerves to various regions according to the situation of the disease. Pain on motion may be elicited by asking the patient to stoop, hyper-extend the spine, rotate and bend the body suddenly from side to side, or to rise on tiptoe and suddenly come down on the heels. If a patient can jump without pain from a chair or low stool he is almost certainly free from caries of the spine. For the detection of *rigidity* the patient may be put through certain movements, or the apices of the spinous processes may be dotted with an aniline pencil while he is in the prone position, and a note taken whether these marks are approximated when he stands upright. Rigidity is an early sign in the cervical region, moderately early in the dorsal region, and late in the lumbar.

In the *upper cervical region* a constrained and fixed position of the head always exists in the early stages of the disease, and the patient, finding a difficulty in keeping the head erect, acquires a habit of supporting the chin upon the hands with the elbows resting on a table or chair. The neck is held rigidly. The patient, if asked to look round, turns his whole body rather than his neck. When the occipito atlantal joint is affected, the rigidity may be detected by the inability to nod the head; when the atlanto-axial, to turn the head from side to side; and when in the next succeeding vertebrae, to hyper-extend the neck. The pain is increased by bending the neck forwards and rolling the head from side to side, but is relieved by supporting the chin with the hand. The pain radiates along the course of the sub-occipital, great occipital, and great auricular and descending branches of the cervical nerves, giving rise to occipital headache and pain in the lower part of the neck and upper part of the chest.

In the *lower cervical and upper dorsal region* there are no very distinctive symptoms, but pain or tingling may be felt in the shoulders, arms, and even fingers, being reflected along the nerves given off from the brachial plexus. In children there is sometimes a troublesome cough, which has been attributed to reflex irritation of the recurrent laryngeal nerve. Some rigidity of the muscles in the posterior triangle may be detected.

In the *mid-dorsal region* the absence of symptoms in the early stages is most marked owing to the comparative immobility of this portion of the spine and the absence of any muscular attachments of the bodies of the vertebrae. Local pain and pain on percussion are sometimes present. The pain may be felt along the course of the intercostal nerves or over the sternum. The patient moves about slowly and cautiously, and generally sits with his arms extended and his hands resting on a chair to relieve the dorsal vertebrae of the superincumbent weight and to assist breathing; or walks about supporting the spine by placing his hands on various portions of furniture. If a child, he soon gets tired of play and lies about on the floor.

In the *lower dorsal and upper lumbar region* there may be pain in performing the various movements in which the psoas muscle is brought into play, such as stooping in drawing on stockings or

lacing boots, lifting even a light weight from the ground, going up and down stairs, rising suddenly from the horizontal to the sitting or standing position, and in turning suddenly from the back on to the abdomen while lying down. If asked to pick up anything from the floor the child does not bend his back; he places his hand upon his knee to support the spine and reaches the ground by bending his legs while holding his back straight. If asked to turn round he rotates the whole body, not the back. The pain may be transmitted along the lower intercostal nerves to the umbilicus, and the child complain of stomach-ache (pain on both sides of the abdomen is most characteristic of spinal caries), or it may be transmitted along the course of some of the nerves coming off from the lumbar enlargement to the front of the thighs or even to the knee or foot by the long saphenous nerve.

DIAGNOSIS.—In the early stages caries must be diagnosed from rheumatism, neuralgia, and lumbago. The history of former attacks of a like nature, and a careful consideration of the signs above given, will usually serve to distinguish them. Hysteria may simulate caries, but the absence of rigidity, the complaint of pain at different spots at different times, the effect of pressure in producing squirming movements instead of rigidity, the presence of other signs of hysteria, the evident absence of suffering on watching the face at the time that much pain is said to be felt, are the points to be attended to. Careful percussion and auscultation of the chest and abdomen will exclude aneurysm. From a gumma or malignant disease leading to breaking down of the vertebral bodies, tubercular caries cannot at first be diagnosed, as all three give rise to the same symptoms, but the presence of other signs of syphilis, congenital or acquired, will point to a gummatous origin. The age of the patient, the history or presence of a primary carcinoma or sarcoma in other regions will raise a suspicion of malignant disease; while rapidly increasing pain and paralysis, in spite of rest, wasting, and later, perhaps, evident swelling at the seat of the disease will soon clear away the difficulty. *See also* PSOAS ABSCESS.

In the later stages, when an angular projection of one or more of the spinous processes has taken place, the diagnosis as a rule is evident. It should not be forgotten, however, that the disease may run its course, even to the production of paralysis or the formation of an abscess without any angular projection. Conversely the normal prominence of the spinous processes of the seventh cervical, first dorsal, eighth and ninth dorsal, and lower dorsal and upper lumbar vertebræ may be exaggerated. The projection, when occurring in the lower cervical and upper dorsal vertebræ, may be due to a natural conformation and family peculiarity, as we see in some short-necked and round-shouldered persons; it is sometimes accompanied by local pain on pressure or percussion, the pain extending along the shoulders and down the arms, thus simulating to some extent cervical caries. A projection of the lower dorsal and upper lumbar vertebræ is not uncommon in girls, and when combined with back-ache, muscular debility, and neuro-mimesis may be mistaken for spinal caries, especially when through the rubbing of the clothes a callosity of the skin or an inflamed and tender bursa has formed over the prominent spine. In such cases, however, the tenderness and swelling will be quite superficial and

the spine mobile. In rickets, again, the kyphotic curve may be distinguished from the angular projection of caries by the projection being more uniform and involving several vertebræ instead of being sharp and angular, and localised to one vertebra, as is usually the case in caries. The kyphotic curve of rickets, moreover, disappears more or less completely when the child is held up by its arms or extended across the nurse's knees in the prone position; and he does not resist or cry on making these manipulations. In caries, on the other hand, the projection does not disappear, and the lumbar spine if affected will become rigid on pulling the legs, the manipulation evidently giving pain. In the rare cases in which the spinal caries depends upon a gumma in the vertebræ there will be other evidence of syphilis, congenital or acquired, which will set the diagnosis at rest.

COURSE, DURATION, AND TERMINATIONS.—Like other tuberculososes, tubercular caries of the spine usually runs an insidious course. Within a period of from six to nine months the angular curvature is generally produced. If the case proceeds favourably without external abscess or paralysis, sound bony ankylosis takes place in about three years. When abscess or paralysis occurs the period of recumbency has frequently to be prolonged to five or more years. Paralysis under complete recumbency usually passes off in about two years. Should death occur, it may be due to septic absorption, and hectic or lardaceous disease from a neglected spinal abscess; to paralysis due to pachymeningitis and softening of the cord; or to dissemination of the tubercle to the lungs, brain, or peritoneum.

If the case is neglected, especially when the disease is in the cervical or upper dorsal region, some weakness of the lower limbs is noticed with increase of the knee-jerk and possibly ankle-clonus; while, later, complete loss of motion may ensue. Sensation, however, is rarely affected, nor is the bladder or rectum usually involved.

PROGNOSIS.—When the disease has been diagnosed early, and the patient can be placed absolutely recumbent under the best hygienic conditions, perfect recovery may be hoped for without any angular deformity, paralysis, or abscess. When angular deformity has already occurred a good recovery may still be obtained under judicious treatment, but the angular projection will be permanent unless the risky process of forcible or mechanical straightening is undertaken. The same with regard to paralysis—this will usually completely disappear after a long period of absolute rest. For the prognosis when abscess has occurred *see* PSOAS ABSCESS.

TREATMENT.—The *local treatment* in the earlier stages is directed towards keeping the diseased vertebræ at rest, and in removing the superincumbent weight of the spine from the diseased spot. These objects are best attained by absolute recumbency combined in some cases with fixation of the spine by some form of mechanical contrivance, or in other cases by extension and counter-extension of the spine. The patient may be in the supine or in the prone position, either on a firm mattress or on an ordinary bedstead with a low pillow, or on a special spinal couch. The supine position is, as a rule, the more comfortable. He should on no account be allowed to raise himself. In the case of a child it may be necessary to apply a strap across the

chest and around the arms. For the fixation of the spine during the period of recumbency the writer has largely used, especially in children, what is known as a double Thomas's splint. The splint is placed next the skin so as not to require removal while the child is washed and dressed. It not only fixes the spine and takes off the weight of the head and upper limbs, but also fixes the lower limbs, and thus prevents the psoas muscles from dragging on the lumbar vertebrae. In this apparatus the patient can be carried about, and as the acute stage passes off, the upper end can be gradually lifted up so that the patient can lie in a slanting position and see what is going on around him.

When the disease is in the upper cervical region during the period of recumbency, which is here absolutely essential in the acute stages, no pillow whatever should be employed; the head should be immovably fixed by sandbags, and should never be raised for feeding or any other purpose, to avoid the risk of the spinal ligaments giving way, and of the upper vertebrae slipping forward on the lower and so compressing the spinal cord and possibly causing paralysis or even sudden death. In place of sand-bags the head may be fixed to the double Thomas's splint by suitably adjusted straps, or a cervical collar may be applied. In some cases of disease of the cervical and upper dorsal vertebrae extension of the head may be employed in conjunction with absolute recumbency, the extension being applied by means of a weight and pulley fixed to the end of the bedstead or spinal couch. Absolute recumbency when properly carried out offers the best prospect of preventing serious angular deformity and paralysis or abscess-formation. Roughly speaking, this position should be maintained for six to twelve months. When the acute symptoms have subsided, a spinal support or poroplastic felt jacket or plaster-of-Paris case should be applied till the vertebrae have become consolidated, the patient in the meantime being allowed to take a gradually increasing amount of exercise, though at first being kept recumbent (with the apparatus on) the greater part of the day. Very numerous varieties of spinal supports have been invented. Of these the best, perhaps, consists of a pelvic plate which fits over the sacrum and neighbouring parts of the iliac crests, and two upright steels moulded to the shape of the back on each side of the spine, and ending above in a scapula-plate, from which straps are carried under the axilla and over the shoulders back again to the plate. This form of apparatus possesses the advantage that the chest is left free, and the movements of respiration are not confined. It is somewhat heavy, however, and a little difficult to keep properly adjusted. The poroplastic felt jacket is made of porous felt impregnated with certain gums. The jacket is made to measure, and when about to be applied is put in a steam oven to soften the gums. While hot it is moulded to the figure. On cooling, it retains its shape. During its application the patient is gently suspended by a pulley-apparatus fixed by suitable straps to the head and under the axilla, the heels barely touching the floor.

A plaster-of-Paris case is applied either with the patient suspended or in the recumbent position in a hammock-apparatus. A skin-fitting vest is first put on and marked with a pencil at the line of the axilla to indicate the upper limit of the jacket. Plaster-of-Paris bandages are next wound round

and round the trunk till a sufficient thickness is obtained, perforated strips of tin being inserted vertically between the layers of the bandage to further strengthen it. When finished the case should reach from just below the pencil line to the crest of the ilium, but should not reach to the great trochanter and pubes. A folded silk handkerchief is placed over the abdomen during the application, and removed afterwards so as to ensure a space for abdominal respiration. When the plaster case is dry it may be sawn down the front, carefully stretched open and removed, and the fronts edged with leather and perforated with eyelet holes, so that it can be worn laced up and taken off from time to time for purposes of cleanliness.

During the last few years forcible straightening of the spine when angular curvature has occurred has been reintroduced by Calot, and has been extensively practised. Extension is made on the arms and legs, and direct pressure at the same time applied to the prominent vertebrae; a plaster of Paris or poroplastic jacket is then applied. The effect of this treatment is, of course, to tear asunder the approximated vertebrae, leaving a gap which can at the best be only very slowly filled up. The method is not unattended by risk, abscess, paralysis and even death having followed its use. There is always the further chance of a relapse from the vertebrae again falling together as soon as the patient gets about. In place of forcible extension, Taylor of Baltimore recommends mechanical extension of the spine by means of an instrument which he calls a kyphotone, and claims that in this way in suitable cases the hump can be made to disappear without the risks attending forcible extension.

Where paralysis has occurred in consequence of compression of the cord by inflammatory effusions or tuberculous collections, laminectomy may in some instances be successful in removing the source of pressure, but as a rule the paralysis passes off if the patient is kept perfectly rigid and recumbent for a sufficiently long period. The indications for laminectomy may be said roughly to be persistent paralysis in spite of recumbency and fixation of the spine, impairment of sensation as well as of motion, contractures or rigidity of the muscles of the lower limb, implication of the bladder or rectum, intractable cystitis, secondary chest-troubles, and severe pain. The operation should not be undertaken when there is evidence of general tuberculosis or extensive spinal meningitis.

It may sometimes be possible to evacuate tuberculous collections or remove a sequestrum by working towards the front of the vertebrae through a suitable incision. Thus in the neck the disease may be reached by an incision made along the line of the sterno-mastoid; in the dorsal region the affected vertebrae may be exposed by resecting the necks of several ribs and working backwards behind the pleura; in the lumbar region the incision is made vertically over the transverse processes, and the dissection carried down between the lumbar muscles towards the bodies of the vertebrae.

Acute osteo-myelitis of the spine is an acute infective inflammation attacking any portion of the vertebrae.

For a general account of this affection see *OSTEO-MYELITIS*, p. 166. All that need be said here is that suppuration always takes place. The pus may make its way forwards into the pharynx (retro-

pharyngeal abscess), thorax or abdomen (mediastinal and psoas abscess), backwards into the cervical, dorsal or lumbar region, or into the vertebral canal, giving rise to inflammation of the membranes and cord. The general symptoms are those of osteomyelitis elsewhere. The local symptoms are pain, tenderness, and later abscess-formation about the affected vertebrae. The sudden onset and acute course distinguish it from tubercular caries. The treatment consists in recumbency and fomentations to relieve pain. It is apt to terminate in septicæmia and pyæmia. Hence, as soon as there is local evidence of pus-formation free incisions should be made.

Osteo-arthritis.—**SYNON.**: Rheumatoid arthritis.

PATHOLOGY.—Osteo-arthritis may be met with in the spine after middle life, and, as in other structures, ultimately leads to absorption of the intervertebral cartilages, the production of osteophytes upon the vertebral bodies, ossification of the ligaments, and destruction of the interarticular joints, thus leading to complete bony ankylosis of the spine.

SYMPTOMS.—The patient has a stooping gait owing to the backward curvature, and kyphosis of the spine, which is rigid and immovable; and complains of pain in the back, which is worse at night and in damp weather and moist climates. Should the articulations of the ribs with the vertebrae become affected, the movements of the chest are impeded, the breathing becomes abdominal, and pulmonary symptoms supervene. The treatment is that for osteo-arthritis in other situations.

W. J. WALSHAM.

SPINE, Curvatures of.—Four forms of curvature of the spine are described: (1) lateral curvature or scoliosis; (2) posterior curvature or kyphosis; (3) anterior curvature or lordosis; and (4) angular curvature or spondylitis, which is a sequel of tuberculosis, or more rarely of syphilis or malignant disease.

In the normal spine the thoracic or dorsal curve, which has its convexity backwards to increase the capacity of the chest, depends upon the shape of the bodies of the vertebrae, while the lumbar and cervical curves, which are convex forwards to compensate for the backward thoracic curve, depend upon the shape of the intervertebral cartilages. Lateral curvature is due primarily to one-sided compression of the intervertebral cartilages; kyphotic and lordotic curves primarily to compression of the posterior or anterior part respectively of the intervertebral cartilages; and angular curvature to various destruction of the bodies of the vertebrae whereby the vertebrae above fall forwards on to the vertebrae below and the projecting spinous processes produce the angular projection.

1. Lateral Curvature of the Spine.
SYNON.: Scoliosis; Fr. *Scoliose*; Ger. *Seitliche Rückgratsverkrümmung*.

DEFINITION.—A deformity in which the bodies of the vertebrae deviate laterally, and at the same time undergo rotation on their vertical axes.

ÆTIOLOGY.—The causes of lateral curvature are local and constitutional; these are generally combined. The local cause of lateral curvature may be said to be any mechanical condition that induces a long-continued unequal compression of the intervertebral cartilages and bodies of the

vertebrae. In the majority of cases these mechanical conditions are associated with sedentary habits, rickets, muscular debility, relaxation of the ligaments, and a softened state of the bones, the spine being thus rendered less resistant to injurious mechanical pressure. Indeed the constitutional conditions may be the chief factors, and it may be difficult to trace the deformity to any special mechanical cause. When there is no evidence of any muscular weakness, the curvature is generally confined to the lumbar region and dependent upon obliquity of the pelvis; in these cases it rarely assumes the grave proportions met with where debilitating influences are important factors. Lateral curvature is more common in girls than in boys, and frequently commences during a period of rapid growth or of convalescence from some illness. It can frequently be traced through two or three generations, and may occur in several members of the same family. Very rarely it is congenital and dependent on malformation of the bodies of the vertebrae.

The mechanical causes may be classed as follows: (1) Permanent or habitual obliquity of the pelvis due, for example, to inequality of the length of the legs, knock-knee, flat-foot, congenital dislocation of the hip, standing on one leg, or sitting cross-legged; (2) A one-sided position of the body such as was assumed in the old-fashioned method of writing, or when sitting for long periods at low flat-topped desks and on stools without backs; or such as is entailed by employments necessitating the carrying of heavy weights in one hand, or the use of one arm, as in book-folding, feather-curling, ironing, violin-playing, and carrying heavy children; (3) Contraction of the sternomastoid in congenital wry-neck; (4) Unilateral paralysis of the spinal muscles due to poliomyelitis.

ANATOMICAL CHARACTERS.—As the result of the long-continued unequal compression the cartilages, and later to a less degree the bones, become wedge-shaped and the spine consequently assumes a lateral curve. While, however, a curve is thus being produced, say, in the dorsal region with its convexity to the right, a secondary compensating curve is also being produced in the lumbar region, and to a less extent in the cervical, with the convexity to the left, in order to maintain the equilibrium of the body. Coincidentally with these changes the vertebrae undergo rotation on their vertical axes, so that while the anterior surface of the body is directed towards the convexity of the curve the spinous processes are directed towards the concavity, the transverse process on the convex side being carried backwards, and the transverse process on the concave side forwards. Hence in addition to the lateral deviation forming the so-called primary and secondary or compensating curves there is in the later stages a general rotation of the vertebrae upon themselves, giving the spine a spirally-twisted appearance. In severe cases this rotation may extend to a quarter of a circle in the centre of the curve but diminishes from this point to the two extremities. The amount of rotation of the bodies of the vertebrae does not always accord with the amount of lateral deviation of the spinous processes; indeed there is always much greater internal rotation of the bodies than is apparent from the deviation of the spinous processes externally. In the dorsal region the ribs necessarily follow the transverse processes;

hence in a dorsal curvature with the convexity to the right the ribs on the convex side are carried backwards, thus forming at first a slight projection and later a distinct hump, while the ribs on the concave side are carried forwards, producing a prominence of the corresponding breast. As the result the sternum becomes very oblique, and its lower extremity projects.

SYMPTOMS.—Back-ache, feeling of weakness in the lower part of the spine, malaise, anæmia, inability to hold the spine erect, or a stooping gait, may occasionally draw attention to the condition, but in many cases patients suffer no inconvenience whatever, and attention is first called to the spine by the dressmaker or mother who notices that the shoulder or hip is growing out. In the early stages there may be no lateral deviation of the apices of the spinous processes, although considerable rotation of the vertebræ has occurred; while conversely in quickly-growing girls with muscular debility and ligamentous relaxation there may be marked deviation without rotation, and the slight curvature that exists can be made to disappear completely on suspension or the prone position. These, however, may be regarded as cases of weak spine or incipient curvature rather than as cases of true lateral curvature. To detect true lateral curvature, evidence of rotation should be sought. The back should be fully exposed as low as the iliac crest, and in the case of children all the clothes should be removed. The patient without shoes, with the heels together, the knees straight and the hands raised above the head as if about to dive, should bend the body forwards till the fingers approach or touch the toes. If rotation has occurred it may then be detected by a slight backward projection of the ribs in the dorsal region or prominence of the erector spinæ in the lumbar region; whereas in cases of merely weak spine the lateral deviation of the apices of the spinous processes will have disappeared, and the back be symmetrical. Some want of symmetry due to very slight rotation may also be detected by placing the patient in a sitting posture and then looking down the back from above.

In severer cases the signs are unmistakable. In the more common forms a well-marked curve with its convexity to the right is seen in the dorsal region, and a slighter and shorter curve with its convexity to the left in the lumbar region. The right shoulder is generally elevated, and the angle of the right scapula is prominent owing to the backward rotation of the ribs which follow their vertebræ on the convexity of the curve. There is also apparent prominence of the right iliac crest owing to the muscles being carried away from it by the forward rotation of the lumbar transverse process; while the lumbar muscles on the left side form a prominent ridge over the backwardly rotated lumbar transverse processes on the convexity of the lumbar curve. In other cases the compensating curves may be so slight that there is apparently a long single curve only with its convexity either to the right or to the left; while in other cases again, instead of the dorsal curve having its convexity to the right and the lumbar its convexity to the left, the opposite condition may exist.

DIAGNOSIS.—Lateral curvature may have to be diagnosed from hysteria and from the lateral deviation which sometimes occurs in spinal caries. In hysteria, although the curve may appear severe, if

the patient is made to assume the diving posture and bend the body forwards, as the fingers approach the feet it will gradually disappear. An hysterical curve will also disappear during sleep and anæsthesia. In the lateral deviation that may occur in spinal caries there is generally some angular projection as well, and rigidity of the spine at the seat of disease. Pain may also be present in the course of the nerves leaving the intervertebral foramina of the affected vertebræ; or may be elicited on applying the tests for pain and rigidity described under spinal caries (p. 1566).

PROGNOSIS.—In the early stages where there is no rotation, a complete cure may be obtained, but when rotation has once occurred, although the general appearance of the figure may be improved by strengthening the muscles that hold the spine erect, the pain relieved, and the curve prevented from getting worse, the removal of the rotation, and consequent complete cure of the curve, is impossible. In those rare cases depending upon spinal paralysis or severe contraction of the chest following empyema, little or nothing can be done to improve the deformity.

TREATMENT.—This may be discussed under the heads of (1) Removal of the cause; (2) Posture; (3) Exercises and massage; (4) Rest; (5) Reduction of rigidity; and (6) Mechanical supports.

1. *Removal of the cause.*—In the majority of cases this will consist in the correction of faulty habits in sitting and standing, and in improving the general health. In other cases, where the curvature depends upon some structural defect, it is necessary that this should, if possible, be removed or corrected. Again, when the curvature depends on wry-neck, the sterno-mastoid should be divided; when upon rickets, constitutional remedies for this disease should be employed. The avoidance of all faulty positions in sitting and writing is most important. Occupations necessitating stooping should be given up. The patient should be forbidden to stand on one leg or sit cross-legged. While in class he should stand at attention. The one-sided position with the spine twisted and the arm on the table assumed in the old sloping method of writing should be given up, and vertical or back-hand writing taught instead, the patient sitting upright and square the while. He should not be permitted to sit at a flat-topped desk on a stool or bench without a back. The height of the desk should be capable of being regulated and the slope adjusted to the proper angle according as the patient is writing (15° to 20°) or reading (40°). The stool should have a high slightly sloping back, so moulded as to correspond to the normal outline of the body. It should be provided with a foot-rest fixed at a proper angle for the feet. A similar stool should be used at meals and during music-lessons. Older patients should use a properly shaped reclining chair or couch with a movable back, and while reading should not be allowed to hold the book with one hand, but have it supported at a proper angle on a book-rest. To prevent stooping while reading short-sight should be corrected by glasses, and all articles of dress should be quite loose across the chest so as to allow of the shoulders being freely thrown back. The effects of the one-sided position of women during horse-exercise should be neutralised by riding alternately on the off and near side, while young girls should ride boy-fashion. Long violin-practice should be forbidden; and such games as tennis should be

played with the right and left hand alternately. Whenever necessary the general health should be improved by abundant outdoor exercise, games of all kinds—tennis, hockey, cricket, skipping, sculling (not rowing), swimming, and horse-exercise, with the reservations stated above. A cold or tepid bath should be taken every morning. Exercise, however, should always stop short of fatigue; and the patient, if weakly or growing rapidly, should, after taking exercise, lie absolutely flat on the back for half an hour to an hour. Early hours and country-life or residence by the sea are, of course, desirable. Tonics, and in some cases cod-liver oil and arsenic, are generally indicated, while a prolonged course of some mild astringent preparation of iron is frequently most beneficial.

2. *Posture*.—The constant assumption of a good posture is imperative. At first the patient should be placed in the posture in which the curve is obliterated, or is least noticeable. It is generally necessary to so arrange two mirrors that the patient may see her own back. At first the correct posture can only be maintained for a few minutes, but as the muscular tone is gradually improved it will become habitual.

3. *Exercises and massage*.—Exercises for strengthening the muscular system in general and the spinal muscles in particular should be employed. For the first purpose, drilling, dancing, and the ordinary gymnastic exercises are all of service, as are also the exercises performed with the Sandow's and Whiteley's apparatus. The patient may beneficially make use of the latter for five to ten minutes daily after the course of special exercises has been completed. The special exercises should be carried out by a properly trained nurse under the occasional supervision of the surgeon. Put broadly, the exercises employed are modifications more or less of the so-called Swedish and Danish systems. The objects aimed at are not only the general improvement of the spinal muscles, but the special strengthening of such of the spinal and other muscles as tend to hold the spine in the corrected position (*see* MASSAGE). The resistance exerted by the exerciser is better than that of any weight or elastic tension, since it is more sympathetic and can be better regulated to the strength of the patient, and more readily be brought to bear on the muscles it is desired to improve. Moreover, the properly trained exerciser, sees that the right movements are executed, whereas the patient, if left to the use of mere weights and cords or in the hands of an unskilful exerciser, may bring into play such movements as increase rather than improve the curvature. Special attention during the course should be given to those exercises which tend to increase the respiratory capacity of the chest. The exercises should be employed once, or, in some cases, twice daily, and be continued from three to six months. Each sitting should occupy about three-quarters of an hour. After the exercises general massage of the muscles of the back is frequently very beneficial. There are now a number of efficient nurses, who have been well trained in properly carrying out these exercises, but the occasional supervision of the surgeon is desirable. Early cases can be completely cured if the treatment is thoroughly carried out, and especially if the patient can be made to take an intelligent interest in her own cure. Even when there is considerable rotation patients will still be improved both in their bodily health and general appearance,

while the asymmetry of the back may be easily concealed by the dressmaker.

4. *Rest*.—The prolonged rest formerly prescribed for lateral curvature is objectionable from two points of view. Firstly it produces wasting and atrophy of the muscles of the back; and, secondly, it is apt to engender in the patient a condition of chronic invalidism. A judicious amount of rest is however advisable, not only in lateral curvature but for all growing girls; since, when the spinal muscles are fatigued, positions are assumed in which the weight is supported by the passive structures, the ligaments and fibro-cartilages, and the forces which produce the lateral curvature come into play. After exercise, the fatigue of the morning and afternoon lessons, &c., it is desirable that the patient, if a girl, should have from half an hour to one hour, never longer, absolute rest in the recumbent position, and this rest may be repeated once or twice according to the length of the rest-interval and the general stamina of the patient.

5. *Removal of rigidity*.—In some advanced cases of lateral curvature the spine is rigidly held in the deformed position, which cannot be improved by any amount of manipulation by the surgeon. Until this rigidity has been to some extent overcome, it is useless to recommend the patient to hold himself in a posture he is unable to assume or be manipulated into, and it is folly to endeavour to exercise muscles whose points of attachments are immovably fixed. To overcome this rigidity the writer has found the so-called weight treatment of considerable service. The patient is placed near the wall, with the body in the horizontal position parallel to the wall, the hands or elbows according to his height resting on a chair. A broad bandage fixed to a staple on the wall is passed across the patient's back, and to the free end of the bandage a weight is attached. The staple is fixed at such a height that the bandage while passing across the back does not touch the apices of the spinous processes, nor the ribs on the concave side of the curve, but embraces the projection caused by the backwardly rotated ribs on the convex side. When sufficient weight is applied the ribs are pressed on and so carried forwards. A large water-can answers admirably, as the weight can be regulated by increasing or lessening the quantity of water. In some cases a counter-weight may be applied in a similar way to the lumbar curvature at the same time.

The weight treatment should be used cautiously, the weight being at first applied for a few minutes only, and then for longer periods up to ten minutes or a quarter of an hour according to the strength of the patient. Massage and passive manipulations will also be of assistance. As soon as the rigidity has been overcome the treatment by posture and exercises may be begun.

6. *Mechanical supports*.—These should never be employed in early and slight cases, nor as a general rule in advanced cases. They have practically no influence in correcting rotation; they are cumbersome and heavy, and tend to induce wasting and atrophy of the muscles. In those cases in which the curvature depends on spinal paralysis a support is, as a rule, essential; it is moreover almost a necessity for the poorer class of patients met with in the out-patient room. To tell a girl entirely dependent on her own exertions in some such trade as flower-making, book-binding, and the like to hold herself in a good position and to take a long

course of exercises is useless and cruel. For such patients a support must, however unwillingly, be prescribed: It will probably prevent the curvature getting worse, it will relieve the pains in the back, and it will enable her to follow her employment in comparative comfort. But she should be given to understand that she cannot expect in this way to be cured. She should be urged to attend once or twice a week at a hospital for a systematic course of exercises, and to snatch a few minutes daily for the practice of them.

Spinal braces are objectionable if worn all day. When, however, they are worn for an hour or so at a time as a reminder to the patient, who as soon as she feels them become tight knows that she is lapsing from the erect posture, they are of considerable service; but it should be clearly understood that she is not to trust to the brace for holding herself upright, but to regard it as a monitor of each relapse to her former stoop.

Kyphosis (SYNON.: Posterior Curvature) is a general curving of the spine, with its convexity backwards, and is an exaggeration of the normal backward dorsal curve. In infants it may be the result of weakness or general debility, or of long nursing in the upright position. In slightly older children it is generally due to the yielding of the softened bones as a result of rickets. In adolescents it is usually caused by muscular debility and relaxation of the ligaments, slouching habits in sitting or standing. In girls it is a frequent precursor of the more serious lateral curvature of the spine. In adult life it may be traced to occupations necessitating constant stooping, and is familiar in the round shoulders of the farm-labourer. In the old it is frequently the result of osteo-arthritis. A history of an hereditary tendency to round shoulders can frequently be obtained.

TREATMENT.—In all cases where possible the cause should be removed. In infants recumbency is indicated; in adolescents the avoidance of stooping habits and constant assumption of correct postures, and gymnastic exercises, should be insisted upon. In adults in whom the kyphotic curve is confirmed, and osseous changes have occurred, and in the subjects of osteo-arthritis, little or nothing can be done.

Lordosis (SYNON.: Anterior Curvature or Saddle-back) is a curvature of the spine with its convexity forwards, and is an exaggeration of the normal forward lumbar curve. It should be regarded as a symptom rather than as a disease, in that the curvature is formed to compensate for the loss of equilibrium in the spinal column when from any cause its antero-posterior curves have been disturbed. Thus it is met with in rickets, hip-disease, coxa vara, congenital or unreduced dislocation of the hip or ankylosis of the hip—conditions in which, owing to the femur being fixed in the position of partial flexion at the hip, the pelvis is tilted forwards when the affected leg is brought down parallel with its fellow. Lordosis is also met with as a compensating curve in the angular deformity of Pott's disease and in kyphosis, also in enlargement of the abdomen as from pregnancy, ovarian dropsy, &c., to restore the erect position. It also occurs in pseudo-hypertrophic paralysis, to compensate for the tendency of the spine to fall forward, owing to the weakness of the spinal muscles.

Angular Curvature.—See CARIES, p. 1565.
W. J. WALSHAM.

SPIRRILLUM (dim. of *spira*, a twist, a curl).—*See* BACTERIA.

SPIROCHÆTE.—*See* BACTERIA.

SPIROMETER (*spiro*, I breathe; and *μέτρον*, a measure).—SYNON.: Fr. *Spiromètre*; Ger. *Spirometer*.

DEFINITION.—An instrument for measuring the vital capacity of the chest.

DESCRIPTION.—The object of the several instruments that have been designed for this purpose is to measure the total amount of air expelled from the chest by the deepest expiration following upon the deepest inspiration.

The instrument designed by Hutchinson consisted of a mouth-piece and tube communicating with a gasometer of registered and graduated capacity, into which the patient breathed. Various modifications of Hutchinson's instrument have been devised.

A convenient and accurate spirometer, which works on the principle of the anemometer, was introduced by Lowne. The advantage of this instrument is its portability.

RESULTS.—According to Hutchinson, the vital capacity varies according to *height, weight, age, and disease*.

1. *Height.*—There is an increase of 8 cub. in. in vital capacity for every inch in height between 5 ft. and 6 ft. Thus the vital capacity of a healthy person at 5 ft. to 5 ft. 1 in. being 174 cub. in., at 5 ft. 4 in. it would be $174 + 32 = 206$ cub. in.; at 5 ft. 8 in., 238; &c.

2. *Weight.*—Excess in body-weight is associated with diminished capacity, in the proportion of about 1 cub. in. per lb. excess.

3. *Age.*—From thirty to sixty years the vital capacity decreases nearly $1\frac{1}{2}$ cub. in. per year.

4. *Disease.*—The spirometer furnishes a very accurate standard of health or of the extent of disease, as regards the chest, the vital capacity in lung-disease diminishing from 10 to 70 per cent.

R. DOUGLAS POWELL.

SPITTING OF BLOOD.—*See* p. 620.

SPLEEN, Diseases of.—SYNON.: Fr. *Maladies de la Rate*; Ger. *Krankheiten der Milz*.

GENERAL REMARKS.—Although certain affections have been, and still are, described under the heading of diseases of the spleen, it is doubtful if, with the exception of the results of traumatism, and perhaps one form of enlargement, there is one single disease affecting the spleen which is not secondary to, or at least coincident with, disease elsewhere in the body, such disease being almost invariably of a kind in which the blood is deeply affected. This fact has become more and more recognised of late years, so that diseases of the spleen described as such have grown less and less in number, the various disordered conditions of the organ being for the most part classed under *malaria, anaemia, leucocythæmia*, and other diseases in which it is variously affected. The diseases in which it is common to find the spleen enlarged are numerous, and in nearly all these the splenic affection is distinctly secondary, the only possible exception being 'splenic anaemia,' in which it seems that it may perhaps be primary; in 'splenic (or spleno-medullary) leucocythæmia' it would appear that the splenic affection is probably secondary to the marrow-

changes. Uncertainty as to the relation of these splenic affections to the anæmias must prevail until more is known of the physiology of the spleen as concerned with the formation and destruction of blood-corpuscles, and the condition of the blood generally. At present the one point apparently settled is that the spleen is intimately concerned with hæmolysis, or destruction of red corpuscles. Numerous cases of removal of the spleen, both when more or less diseased and when apparently healthy, have been now recorded, and it seems that the loss of this organ can be borne without other than occasional temporary impairment of health. Removal of diseased or enlarged spleens has been followed by no symptoms, and a similar result has followed in some cases the removal of spleens for traumatic rupture; but in two cases reported by Pitts and Ballance, of removal of healthy spleens for rupture, the operation was followed by extreme anæmia, a daily rise of temperature of 1° to 3° F., increased frequency of pulse, enlargement of external lymphatics, diminution of red corpuscles in blood, with increase in leucocytes and hæmoglobin, all of which symptoms gradually passed off. According to Rolleston, when the spleen becomes diseased some sort of compensatory action as regards its functions is apparently set up, possibly in the bone-marrow, and the more complete this compensation the less is the spleen missed; hence the absence of symptoms after removal of enlarged spleens, their presence after removal of healthy spleens for rupture, and their absence in many instances of removal of spleens for rupture, when, as is often the case, this accident has occurred to a spleen the subject of old-standing disease.

The spleen, from the nature of its structure, is capable of accommodating at times a very large amount of blood, and is very susceptible to hyperæmia. It varies considerably in size in health; thus its bulk increases for some hours after taking food, while digestion is going on, after which it lessens again. A peculiarity of the spleen that may be mentioned here is that in many cases of infectious disease dependent on micro-organisms, such as anthrax, enteric fever, and plague, these organisms are present in large numbers in the blood of the spleen, though they be found with difficulty, or perhaps at times not at all, in the general systemic blood. In cases of malarial infection, also, the splenic blood contains the parasite in large numbers, and also quantities of pigment and *débris* of broken-down parasites. As regards these points, the question has been raised as to whether the spleen may not exercise some protective influence over the blood.

VARIETIES.—The diseased conditions of the spleen will be noticed in the following order: (1) acute inflammation; (2) the various forms of enlargement of the organ, both such as may be primary and those that are certainly secondary to, or dependent on, other diseases; (3) other splenic affections, malformations, and anomalies; (4) rupture.

1. Acute Inflammation.—**SYNON.** : *Splenitis*. Acute hyperæmia of the spleen is common in certain forms of fever, but it is extremely doubtful if this condition ever proceeds to a general inflammation of the spleen; it is doubtful, also, if any general inflammation of the organ is ever caused traumatically, inflammation from violence being more likely to occur in isolated spots in consequence of laceration

of the structure of the gland and extravasation of blood, i.e. of slight degrees of rupture. Acute inflammation is not by any means common, but, when it occurs, it is in the great majority of cases the result of embolism, such embolism in a branch of the splenic artery resulting in an 'infarct' (see **EMBOLISM**). Splenic infarcts are usually of the red variety, though they may ultimately become pale as they shrink and disappear. In their later stages they are surrounded with a dense whitish layer of cicatricial tissue. Septic infarction leads to abscess-formation, and if suppurating infarcts be numerous and near one another, the resulting foci may coalesce, and a large abscess be formed. Splenic emboli are apt to occur in valvular disease of the heart, in chorea, in infective endocarditis, in pyæmia and septicæmia, in typhoid and other fevers, and in any case in which thrombi may form in the blood; and it is obvious that, according to their origin, they may be innocent or infective. Inflammation of either kind may be accompanied by hyperæmia of the organ generally, which may thus be enlarged; or the peritoneal covering of the gland may be affected, leading to adhesions to neighbouring parts.

Inflammation of the spleen may go on to suppuration without any marked local symptoms, and the evidences of such inflammation are far more frequently seen on the *post-mortem* table than diagnosed during life. Local symptoms consist mainly of pain in the region of the spleen, with some tenderness, especially if local peritonitis is present, and perhaps some enlargement of the organ. Suppuration may be indicated by shivering and other constitutional signs of that process; it does not cause any local symptoms unless the abscess is large and near the surface, and the spleen adherent to the abdominal wall, in which case there may be swelling, tenderness, pain, and even local œdema and fluctuation.

2. Enlargements.—The enlargements of this organ will be described according to the several diseases in which they occur.

(a) *In splenic anæmia.*—In this affection, sometimes called *primary splenomegaly*, it is probable that the splenic disease is primary; the anæmia is progressive and is characterised by considerable diminution in the number of the red-corpuscles (which, however, rarely fall below 50 per cent. of their normal quantity), by great diminution of hæmoglobin, and by a lower colour-index ($\cdot 5$) than any other form of anæmia; there is no increase in the number of leucocytes. The spleen is greatly enlarged, though not to the extent often met with in splenic leucocythæmia; it is tender; and the patient is subject to attacks of pain in the region of the gland. The spleen may weigh from two to eight pounds, and contains enormous numbers of large nucleated cells enclosing blood-corpuscles; there is general fibrosis of the organ, the capsule is firm, and it and the trabeculæ are thickened; the pulp appears to be diminished in quantity, and the Malpighian bodies are small and atrophied; there may be peritoneal adhesions. There is often some irregularity of temperature, but no enlargement of lymphatic glands. Hemorrhage is infrequent and the stomach is the commonest source. The disease is generally fatal in three years.

(b) *In splenic or spleno-medullary leucocythæmia.* In this affection the spleen is generally greatly enlarged. See p. 866.

(c) *In malaria.*—In acute malarial disease the

spleen is enlarged from hyperæmia ; in cases which end fatally the substance is found to be diffult, dark, and full of pigmented elements and *débris* of parasites. In chronic malarial disease, or malarial cachexia, the spleen is often very much enlarged ; the capsule and trabeculæ are thickened, the consequence probably of constant hyperæmia, but the pulp is at the same time increased, and hence the organ is soft and friable. Spleens thus enlarged, which are very common among Asiatic races, and probably in malarious countries generally, are very liable to rupture under slight violence. See MALARIAL DISEASE.

(d) *In amyloid disease.*—In this disease the spleen only shares with other organs in the effects of a general affection (see AMYLOID DISEASE). A spleen affected with amyloid disease is uniformly enlarged, hard, smooth on the surface, and painless. It is inclined to be globular in shape. No ascites or other evidence of pressure on the portal vein or bile-ducts occurs unless the disease is complicated by some other condition.

(e) *Under other conditions.*—The spleen is temporarily enlarged from hyperæmia during the course of certain fevers, especially of enteric fever and plague ; in such cases the enlargement subsides with recovery from the fever. It is also nearly always enlarged, though not to any very great extent, in lymphadenoma, and occasionally in idiopathic or pernicious anæmia. In the former disease the Malpighian bodies are enlarged and yellowish, exhibiting the proliferation of lymphoid cells characteristic of the disease ; in idiopathic anæmia iron is found deposited in the spleen, and it is possible that the organ plays an accessory part in the destruction of red blood-corpuscles in this disease. Enlargement of the spleen also takes place in consequence of general congestion of the portal system, notably in cirrhosis of the liver, and to a less degree in valvular disease of the heart ; it also may be due to malignant disease which is usually secondary.

The only subjective symptoms associated with enlargements of the spleen are occasional pain in the side with some tenderness ; and, if the spleen be very large, a feeling of weight in the left side of the abdomen, and inconvenience from increased size in that region. For the physical signs of enlargement of the spleen see PHYSICAL EXAMINATION, and accompanying plates.

3. *Miscellaneous affections.*—*Tuberculosis* may affect the spleen—so far as is known, always secondarily to other organs—and the appearances presented may be either of the ‘miliary’ or ‘caseous’ type. The spleen is said to be often enlarged in *syphilis*, but it is rare to find gummata in this gland. New-growths and hydatid cysts have been described as occasionally found in the spleen, but both these conditions are excessively rare, and malignant disease is probably always secondary. The chief anomalies of the spleen are those known as ‘wandering spleen’ and ‘supernumerary spleens’ ; the latter condition is simply an anatomical variation, and possesses no pathological interest, the former may occasionally cause trouble in much the same way as movable kidney, and may sometimes justify surgical measures for its relief.

4. *Rupture.*—In England rupture of the spleen only happens from injuries similar to those which cause rupture of other internal organs, but in Asiatic (and probably in all malarious) countries, where the possession of an enlarged spleen with a friable pulp

is common among natives, this accident is of common occurrence, and has led to trials for manslaughter in cases in which no serious injury was intended. The possibility of this accident having occurred should always be borne in mind in cases of sudden death following any slight tussle. Death generally follows rapidly on the injury, but this is not always the case : in two cases which came under the observation of the writer an injury was followed by intense pain and collapse, from which temporary recovery took place, to be followed by sudden collapse and death about three days after. In both these cases *post-mortem* examination showed a torn spleen enclosed in a torn distended capsule, the whole appearance reminding one of a placenta in a bag of membranes ; the first violence had ruptured the spleen, but not the capsule, into which hæmorrhage had taken place, distending it greatly ; subsequently the capsule, possibly from some sudden movement of the patient, had given way, and the mass of fluid and clotted blood had been suddenly discharged into the peritoneal cavity, causing collapse and death. The symptoms of rupture of the spleen are pain, collapse, and signs of internal hæmorrhage.

TREATMENT.—The treatment of splenic diseases resolves itself for the most part into the treatment of the accompanying conditions. In acute inflammation pain may be relieved by hot applications, or if great active hyperæmia be suspected, by leeches. In the rare event of it being possible to localise suppuration in the spleen, and to determine adhesion of the organ to the abdominal wall, it would be right to evacuate the pus, but indiscriminate exploratory puncture is to be deprecated, from fear of hæmorrhage. In pure splenic anæmia no satisfactory treatment has been found ; it has been stated that removal of the spleen has done good in this affection, and, if so, this would seem to indicate that the splenic condition is primary. In the splenic affection consequent on malarial poisoning the enlargement is often very obstinate ; it is best treated by measures which tend to improve the general health and combat the malarial cachexia. Iron and quinine, or more especially arsenic, will be found of service, with an occasional dose of Carlsbad salts ; locally, tincture or solution of iodine may be employed, or a piece of lint about four inches square spread with the ointment of red iodide of mercury may be applied and kept on for four or six hours ; this last remedy is often very useful, but it requires a little care, as if left on too long it is apt to blister the skin ; in any case the irritant effect is more lasting than that of a mustard plaster. Flannel cholera-belts should be worn in cases of malarial spleen. For rupture of the spleen the treatment is laparotomy and removal, as speedily as possible, of the ruptured gland ; several successful cases of this operation have now been reported. See LEUCOCYTHÆMIA.

SPUTUM.—SYNON.: Fr. *Crachats*; Ger. *Auswurf*; *Sputum*.—This article deals with the diagnostic indications afforded by a microscopical examination of the sputum, and with the requisite methods of preparation. The pathological constituents of the sputum to which definite diagnostic importance can be attributed are comparatively few in number. These will be considered under the following heads: (1) Micro-organisms; (2) Elastic tissue; (3) Curschmann's spirals.

No special description will be devoted to the rare instances in which hooklets derived from hydatid cysts in the lung, or portions of laryngeal or pulmonary new-growths, may be discovered in the expectoration, inasmuch as these structures require no special preparation for their identification.

THE COLLECTION OF SPECIMENS OF SPUTUM FOR EXAMINATION.—The early morning expectoration, representing the gradual accumulation formed during the hours of sleep, is the most likely to contain a mixture of the secretions of the respiratory tract, and is therefore the most suitable for examination; moreover, the sputum expelled at this time is less likely to contain particles of food. It is often important that the specimen should be as free as possible from contamination with the saprophytic micro-organisms of the buccal cavity; consequently the patient should be directed to rinse the mouth out thoroughly, using sterile water (e.g. water that has been boiled and allowed to cool), three or four times in succession before expectorating. The sputum is then coughed up from the lungs, and expectorated into a clean wide-mouthed glass bottle or other suitable vessel, which must not contain any disinfectant solution whatever.

1. Micro-Organisms.—*Tubercle-bacillus*.—As a preliminary to microscopical examination the sputum should be poured out into a flat glass dish, and search made for yellowish, i.e. purulent, streaks and spots (a process which is facilitated by placing a piece of black paper under the dish); where the sputum is more or less opaque throughout, the thickest and most curdy parts are to be selected. A small selected portion of the sputum is now transferred to a clean cover-slip by the aid of a stout platinum rod, or a piece of copper wire having one end beaten out to form a small spatula, spread out in a thin film, and allowed to dry thoroughly in the air. In the case of thin watery sputum, a second or even a third film may be spread over the first. The cover-glass, film upwards, is now passed rapidly three or four times through the flame of a spirit-lamp or Bunsen's burner; this coagulates the albuminous matter and fixes the film firmly to the glass. The film is now ready for staining, a process which is most conveniently effected by the Ziehl-Neelsen method. This method depends on the fact that the tubercle-bacillus, probably by reason of the wax that enters so largely into its composition, is extremely difficult to stain with aniline dyes as ordinarily used, but having once taken up the stain, is equally reluctant to part with it to decolourising reagents. This peculiarity the tubercle-bacillus shares with several other organisms, such as the bacillus of leprosy, the smegma-bacillus and the Timothy-grass bacillus.

The following reagents are needed:

(A) Carbol-fuchsin. This is prepared by dissolving 1 gramme of basic fuchsin in 15 cc. of absolute alcohol, and making up to 100 cc. with a 5-per-cent. solution of carbolic acid.

(B) Alcohol—preferably rectified spirit, although methylated spirit will answer the purpose.

(C) A 25-per-cent. solution of sulphuric acid.

(D) Methylene blue—a 1-per-cent. watery solution.

Method of staining.—(1) Warm some of the carbol-fuchsin (A) in a watch-glass over the naked flame or on a sand-bath, until steam commences to rise; float the cover-slip preparation, film downwards, on the surface of the fluid, and keep gently steaming for 5–10 minutes.

(2) Remove the cover-slip from the stain and wash in water.

(3) Wash with alcohol (B) until no more colour is discharged.

(4) Place in sulphuric acid (C) for one or two seconds, then immediately wash in water. If the film is 'red,' it must be again immersed in the acid, then washed in water. The film should now be of a light pink colour.

(5) Counterstain with methylene blue (D) for 10 to 20 seconds.

(6) Wash in water, blot off the excess of water with blotting-paper, complete the drying by holding the cover-slip between thumb and forefinger over the flame, and mount in a solution of Canada balsam in xylol.

For the recognition of the tubercle-bacilli, a magnifying power of 250 to 300 is sufficient in most cases, if the illumination be brilliant. Abbé's sub-stage condenser greatly facilitates the detection of the bacilli; and in all doubtful cases, where the microbes are scanty, the combination of Abbé's condenser with a $\frac{1}{2}$ -inch oil-immersion lens is indispensable. With the method of staining above described, the bacilli appear as delicate crimson rods, in length from one-quarter to one-half the

FIG. 1.—Tubercle-Bacilli in Sputum. $\times 550$.
The bacilli are seen as dark rods, lying amid threads of mucus and a few pus-corpuscles.

diameter of a human red blood-corpuscle. The rods may present a uniform bright-red appearance, the staining may be unequal, or the microbes may present a beaded appearance resembling a string of red granules. Very little clinical importance can be attributed to these morphological differences, although the moniliform appearance is indicative of young actively multiplying tubercle-bacilli. Various other bacilli and micrococci contained in the sputum, as well as the nuclei of cells and filaments of mucin, take the blue stain, contrasting sharply with the red tubercle-bacilli.

SIGNIFICANCE.—The discovery of tubercle-bacilli in the sputum is a decisive proof of the existence of tubercular disease of some part of the respiratory system. In cases of tuberculosis of the air-passages, bacilli are discharged from the surface of the ulceration; but the number derived from this source is insignificant as compared with the quantities that come from cavities in the lungs. If we exclude the extremely rare cases of primary tubercular ulceration of the main air-passages, it may be affirmed that a large number of bacilli in the sputum is a certain sign of pulmonary excavation. The size of the cavity or cavities is immaterial, but free communication between a vomica and a bronchus is a necessary condition.

The number of the bacilli is no certain index of the severity or extent of the disease, and may be said to be largely a question of discharge. In some acute pneumonic forms of tuberculosis the microbes may for a time be very scanty, whereas in cases of the most chronic and limited disease the sputum may teem with tubercle-bacilli. It has been asserted that where tubercular ulceration of the larynx exists the number of bacilli is always large. This statement is incorrect, as numerous observations have convinced the writer. Complete and permanent disappearance of the bacilli from the sputum is a most favourable sign; but, on the other hand, persistent expectoration of these micro-organisms is not incompatible with a favourable and chronic course of the disease.

Actinomycosis.—In the rare instances in which this disease attacks the respiratory system, the characteristic ray-shaped organisms may be discharged in the expectoration. These appear as minute yellowish granules visible to the naked eye in the purulent discharge. When a drop of the pus is examined without any staining, the rosettes of clubs can readily be recognised with a moderately high power. If dried cover-glass preparations be stained by Gram's method, combined with rubine or eosine as a counter-stain, the mycelial threads and clubs may be demonstrated. The presence of the ray-fungus is pathognomonic of actinomycosis. See ACTINOMYCOSIS.

Pneumonia.—Among the various micro-organisms that may be found in the sputum of croupous pneumonia, contaminated as it usually is in its passage through the mouth, the *Diplococcus pneumoniae* of Fränkel is the most important numerically in a large percentage of the cases. Occasionally its place is taken by the short pneumobacillus of Friedländer, or by the convoluted chains of the *Streptococcus pyogenes longus*. The *Diplococcus pneumoniae* and the pneumobacillus are characterised by the possession of distinct capsules, which may be demonstrated microscopically by the use of MacConkey's capsule-stain. This is prepared by dissolving 0.5 gramme of Dahlia and 1.5 gramme of Methyl Green (oo crystals) in 100 cc. distilled water, adding 10 cc. of a saturated alcoholic solution of basic fuchsin, and making up to 200 cc. by the addition of distilled water. In specimens of pneumonic sputum stained by this mixture, the capsules appear as delicate magenta-coloured halos surrounding the more darkly stained bacteria. These organisms may be stained by any of the anilin dyes, and of the three above-mentioned forms, the pneumobacillus is alone decolourised by Gram's method. See also p. 132.

As similar microbes are sometimes met with in

other diseases, such as bronchitis, and occasionally in healthy saliva, no definite diagnostic significance can be attributed to them when occurring without any other indications of disease.

Influenza.—The sputum should be carefully examined for small semi-solid yellowish-green masses: in these the specific bacillus of influenza can usually be demonstrated by staining film-preparations for long periods with very weak solutions of fuchsin; 1 cc. of a saturated alcoholic solution of basic fuchsin in 10 cc. of distilled water makes a suitable strength, and the preparation should be subjected to its action for a period of two or three hours. The influenza-bacillus then appears as a minute bacillus, in length about equal to one fifth the diameter of a red blood-disc, often staining most deeply at the two extremities, and so resembling a diplococcus; usually situated within or in the neighbourhood of pus-cells. The bacillus is decolourised by Gram's method.

The presence of the *Bacillus influenzae* in the sputum may be looked upon as pathognomonic of the disease, and as it makes its appearance within about twelve hours of the onset of an attack, the examination of the sputum is often of great assistance in diagnosing between influenza and pneumonia.

2. Elastic Tissue.—In destructive pulmonary disease of all kinds, portions of the elastic framework of the lungs are from time to time expectorated, and can be recognised with the microscope. In some cases the elastic tissue may be detected without any special preparation. The sputum is poured out into a flat glass dish, and some of the most opaque parts are selected and transferred to a glass slide; a cover-glass is then pressed lightly on the sputum, and the specimen can be at once examined.

But for general use Fenwick's solvent method is much more satisfactory. Equal quantities of the sputum and a solution of caustic soda (twenty grains to the ounce) are boiled for a few minutes until the mixture becomes liquefied. It is important not to continue the boiling too long, as the elastic fibres themselves ultimately become much altered in ap-

FIG. 2.—Elastic tissue of the lung in Sputum. $\times 550$.

pearance. The fluid is now set aside for two to twelve hours in a tall conical glass, to allow the elastic tissue to sink to the bottom; or, better still, placed in the centrifugal machine, in a conical test-tube, and run at a fairly high rate of speed for some minutes. A drop of the sediment is then withdrawn with a pipette, and examined with the microscope in the usual way. A magnifying power of 90 to 100 diameters is sufficient in most cases; but when the fibres are isolated or much broken up, a higher power may be required. In the latter case difficulties are apt to arise from the fact that the sputum

commonly contains adventitious fibres closely resembling elastic tissue. In some cases the curled-up ends and branching fibres may serve to distinguish the elastic tissue of the lung; but unless some trace of the characteristic alveolar arrangement be recognisable, it is unwise to hazard a positive diagnosis.

SIGNIFICANCE.—The discovery of elastic tissue in the expectoration may be regarded as definite evidence of destructive disease of some portion of the respiratory tract. With rare exceptions the elastic fibres come from the lung, though at times they may be derived from the larynx or bronchi, in which case no alveolar grouping will be found. Tuberculosis, by far the commonest ulcerative disease of the lung, may generally be suspected when elastic tissue is found in the sputum; but in non-tubercular destructive affections the same discovery may be made. Hence elastic fibres do not possess the pathognomonic significance of the tubercle-bacilli. In acutely progressing excavation large groups of alveoli are often expectorated; whereas in cases of chronic disease the fibres are usually more isolated, and are not uncommonly encrusted with lime-salts.

In the sputum of pulmonary gangrene the elastic fibres are generally scanty or ill-defined, and sometimes cannot be recognised at all. It has been suggested that this is due to the presence of a ferment in the gangrenous secretion, which dissolves the lung-tissue.

3. **Curschmann's Spirals.**—In the sputum expelled towards the close of an asthmatic attack small gelatinous sago-like lumps of mucus are generally present. If these masses be gently pressed out between a cover-glass and a glass slide certain spiral structures may commonly be recognised. The spirals vary much in size, often being visible to the naked eye, whereas at other times they can only be discovered with the help of the microscope. These structures consist of gelatinous threads of a mucoid substance, coiled in the form of a corkscrew. In many cases a central bright wavy or twisted thread occupies the hollow of the coil. Von Jaksch believes the central fibre to be chemically allied to fibrin, the spiral coil being composed of mucin.

SIGNIFICANCE.—These spirals are to be regarded as casts of the bronchioles. Curschmann considers that they are the result of an exudative bronchiolitis, and are causally related to the paroxysms of asthma. The spirals are not pathognomonic of asthma, as they are occasionally found in the sputum of bronchitis and croupous pneumonia. But, as von Jaksch suggests, their presence in a case of asthma of doubtful nature would stamp the bronchial nature of the attack. Charcot-Leyden crystals (p. 272) are often found adhering to the spirals, and sometimes seem to develop after the sputum has been allowed to stand for some hours. Von Jaksch believes that the crystals are products of chemical decomposition of mucin.

PERCY KIDD.

SQUINTING.—See STRABISMUS.

STAGNATION OF BLOOD.—Local arrest of the circulation. See CIRCULATION, Disorders of; and INFLAMMATION.

STAMMERING.—**DEFINITION.**—The word 'stammering' has been used by some writers in its broadest sense so as to include several different

forms of defective articulation, such as inability (congenital or acquired) to pronounce certain letters or combinations of letters, the tendency to hesitate or stumble in utterance, or to transpose letters or syllables, &c. It is better, however, to restrict its use to imply a spasmodic affection of the organs concerned in speech, in virtue of which the enunciation of words becomes suddenly checked, and a painful pause ensues, usually marked either by a prolongation, or a repetition in rapid sequence, of the particular literal sound at which the check arises. By several writers the word 'stuttering' is used as synonymous, but it is better to confine the use of the term 'stuttering,' as will be pointed out later, to one clinical variety of stammering which it is well to employ as the general descriptive title.

ÆTIOLOGY.—Stammering is to some extent hereditary, although in many cases no such connection can be traced. It is very frequently imitative, e.g. children may learn it from a companion—a point of considerable importance as regards its preventive treatment. The defect rarely shows itself before the age of four or five years. Usually it comes on from this time up to the period of puberty, but it may originate at any age. It is a curious fact that men stammer in much larger proportion than women.

DESCRIPTION.—The varieties of stammering are so numerous that anything like a complete consideration of them here would be impossible. It should be noted, however, that there are two great groups of stammerers: (1) those whose peculiarity consists in an attempt to overcome their difficulty in articulation by a series of fitfully and rapidly recurring repetitions of the letter at which they have come to grief, a condition to which the term 'stuttering' is best restricted; and (2) those who 'silently stick' at the difficult letter, which is not audibly produced for some seconds, although the patient may be making violent and even visible spasmodic attempts to enunciate it. Both classes of patients thus 'stammer'; the first 'stutters,' the second 'silently sticks.' As one writer has put it, the stutterer in trying to say such a word as 'top' enunciates a series of small 't's' in rapid succession, thus 't-t-t-top,' while a patient of the other class silently builds up a great big T! The clinical picture of each type is so familiar that little further description is called for, varying degrees of severity being met with. In his attempts to overcome difficult letters the patient may make such spasmodic efforts at ejaculation that he becomes quite flushed or even purple in the face, while still oftener an 'overflow' of muscular energy takes place to other groups of muscles, leading to *involuntary* twitchings of the lips, eyebrows, or eyelids, &c., or even violent jerking of the head and neck in severe cases. This condition should be clearly distinguished from another in which the patient finds his difficulty lessened if he *voluntarily* throws some other muscles into action—e.g. by stamping with one or both feet, tapping the fingers, clenching the hand, &c.—the outlet of muscular energy appearing thus to lessen the obstruction to his articulation. Sometimes it will be found that patients have been taught this as a method of overcoming their difficulty; in other cases the stammerer has learnt it by experience.

In by far the greater proportion of cases the consonants, and especially the 'explosive' consonants, are the chief stumbling-blocks of stammerers, only a very small proportion finding a difficulty with

vowels. Consideration of this part of the subject will come in more fittingly, however, when the treatment is taken up.

PATHOLOGY.—Stammering being essentially a functional disorder, a definite pathology is scarcely to be expected. Attempts have been made at times to associate its occurrence with various conditions present in the glottis, tongue, &c.; but there is little doubt that the condition is inherently due to a *faulty working* of a complex mechanism rather than any *defect of structure*. It should be borne in mind that in the enunciation of words a threefold mechanism is at work—(a) a current of air must be regularly supplied by the lungs; (b) phonation is effected by the laryngeal mechanism; while (c) articulation is obtained by the coaptation and separation of the lips, teeth, tongue, palate, &c. A form of stammering has been described in which the primary fault is said to lie in the respiratory mechanism, but this is so rare that for all practical purposes stammering may be considered as arising essentially from a *want of the proper harmony between the functions of phonation and articulation*. To illustrate this no better example could be got than that used in his work on ‘The Disorders of Speech,’ by Professor Wyllie, who points out that in violin-playing, in order to ensure the production of the proper musical sounds, the two mechanisms of the ‘bow-hand’ *producing* the sound and the ‘string-hand’ *modifying* the same must work in complete harmony. No overaction on the part of the ‘string-hand’ can ever make up for a failure on the part of the ‘bow-hand’ to perform its function. This overaction on the part of one of the co-ordinated mechanisms concerned in the enunciation of words is the essential error of the stammerer.

TREATMENT.—This—the most important portion of the subject—is unfortunately too often dealt with inadequately, or in merely vague general terms. And yet the necessity for treatment, and the satisfactory results that may be obtained, are such that an endeavour should always be made to remedy the defect. It is not sufficient to give merely general instructions to the patient as to speaking slowly and from a full chest, &c. He must be taught how to surmount his individual difficulties. The first essential is that the stammerer be made clearly to understand the double nature of the process in speaking, the equal need for *phonation* as well as *articulation*; and Wyllie’s example of the violinist’s combined working of two mechanisms harmoniously can scarcely fail to be understood by even young patients. It should then be explained to the pupil that his difficulty arises essentially from a failure to allot the *due proportion* to phonation and articulation respectively in his enunciation of words; and a reference to the fact (which he has probably discovered for himself) that stammering seldom, if ever, occurs in *singing*, will impress this more firmly on his memory. The teacher should then demonstrate to him that certain letters of the alphabet have no ‘voice’ in themselves, and that any attempt to insert ‘voice’ into such will only lead to an aggravation of the patient’s trouble. Similarly, if he tries to pronounce any of those letters which *normally* contain voice without allowing phonation to have its proper share along with articulation in their enunciation, stammering will again result. It is therefore with a view to making such points perfectly clear to pupils that Wyllie has drawn up what he terms a ‘Physiological Alphabet,’ which is here

reproduced by his kind sanction from his work on ‘The Disorders of Speech.’

A Physiological Alphabet (Wyllie).

I. VOWELS.

Y—IEAOU—W.

These should be pronounced in the Latin manner, as—
ēē, eh, ah, oh, oo; Y and W, though consonants, are given here for reasons in the text.

II. CONSONANTS.

	Voiceless Oral	Voiced Oral	Voiced Nasal Resonants
Labials (1st stop-position)	P (W)	B W	M
Labio-Dentals	F	V	
Linguo-Dentals	Th ¹ S	Th ² Z	
Anterior Linguo-Palatals (2nd stop-position)	Sh T (L)	Zh D L R	N
Posterior Linguo-Palatals (3rd stop-position)	K H or Ch	G Y (R)	Ng

The voiceless W and the voiceless L have been given in brackets, the former being now almost confined to Scotland, the latter being peculiar to Wales. The uvular (burring) R is also in brackets.

In it this all-important distinction between ‘voiceless’ and ‘voiced’ letters is emphasised, the vertical columns showing a complete list of the consonants grouped according to definite principles. The vowels, of course, are essentially ‘voiced.’ The letters W and Y are placed by Wyllie along with the vowels as being more closely allied to them than to consonants for reasons fully given in his work referred to. It is sufficient here to explain that since an *initial* W is really phonetically equivalent (as Wyllie says) ‘to a tight oo,’ such words as ‘will’ ‘wet’ should really be pronounced as if they began with a vowel, e.g. ‘ōoill,’ ‘ōoet.’ Similarly, an *initial* Y (as in ‘you’) is phonetically equivalent to ēē, and must be treated as a ‘voiced’ letter by the stammerer, who will be surprised at the ease with which such words as ‘Will you’ can be produced, if he pronounces them as if they were spelt ‘ōoill ēeou’; for the *initial* Y, pronounced *voicelessly* as ‘yeh,’ is an extremely common difficulty with stammerers. [The horizontal divisions of the table are not of the same importance from the stammerer’s point of view, but are given here as the table is reproduced from Wyllie’s work.]

The essential principle, then, of the equal importance of phonation with articulation in the enunciation of words having been made perfectly clear to the pupil, all that is required is that the teacher should go seriatim through the letters of the ordinary alphabet, and explain how and why they come to be arranged as shown in Wyllie’s table. It is not necessary here to do more than indicate a few of the points there shown. Thus, it is quite evident that if P (which is merely a ‘voiceless’

labial with an *explosive* character *silently* prepared for its enunciation) has 'voice' added to it, the letter B is produced; and similarly D and G ('hard') are the 'voiced' equivalents of T and K (or C 'hard'). The distinction between the *voiceless* 'th' of 'thin' and the *voiced* 'th' of 'thee' must also be made clear to the patient.

When the pupil has thoroughly grasped the inherent difference between the two groups of consonants, he should be taught that the essential principle that he has to remember in working out his own cure is this: that all letters possessing 'voice' should have their full vocal element given them, or even more than their normal quantity of 'voice'; while those letters which are themselves 'voiceless' are to be touched off as lightly as possible, the attention of the pupil being directed rather to the 'voiced' letter that precedes or follows the 'voiceless' consonant. Thus in saying, e.g., '*Big Peter made no sound,*' the stammerer is to emphasise the letters italicised—the lips are merely to be apposed for the formation of the 'P,' but no *sound* is attempted to be produced, the '-eter' merely acquires the *explosive* character of the voiceless 'P.' The fact that the nasal resonants (m and n) are both 'voiced' consonants should be clearly demonstrated, for the attempt to pronounce *voicelessly* all words commencing with these consonants is one of the commonest errors of stammerers.

Before summing up the various points in treatment, it may be well to refer to a few of the specially common difficulties of stammerers, and indicate briefly how best to surmount these. Words commencing with 'wh' often give rise to very great trouble owing to the patient trying to pronounce these *voicelessly*. If he will bear in mind the fact that 'w' is really a vowel (i.e. voiced), and further grasp the fact, which is clearly brought out by Wyllie, that phonetically the 'h' precedes the 'w' (so that the physiological spelling becomes 'hw'), he will discover that the enunciation of such words as 'when,' 'whether,' becomes quite easy, provided they are produced as if they were spelt (phonetically) 'hōoen,' 'hōoether.'

A similar difficulty often occurs with words commencing with 'sw,' which the stammerer usually attempts to utter *voicelessly*. Here, again, the 'voiced' oo of the 'w' must be given its full value, so that words such as 'swim' become phonetically 'sōoim.'

Lastly, the pupil should be made to understand clearly that all words in which the initial letter is J or (soft) G must really be pronounced by him as if they began with a (fully-voiced) D, e.g., 'Jew' is phonetically equivalent to 'Dzhōo.' J and (soft) G are thus really compound letter-sounds, the real *initial* of which is D.

In conclusion, then, the treatment aimed at is as follows. The pupil must be made to understand thoroughly the essential difference between phonation and articulation in speaking, and that it is worse than useless to attempt to make up for deficiency in vocalisation by overaction in articulation. He must practise speaking in a full ringing voice, and in troublesome cases it is sometimes useful to practise 'intoning' his lessons, so as to emphasise the value of the musical element in speech. He should then be taught the 'Physiological Alphabet,' and in connection therewith the following illustrative sentences (reproduced by Prof. Wyllie's kind sanction) will be found most useful, since they bring

out clearly the essential physiological distinctions between the groups of consonants:—

A. *Initials that contain voice.* [In pronouncing these the voice must be thrown boldly into the initial.]

1. 'Even ancient elves are awed over oozing.'
2. 'We visit the Zulus like ramblers yearly.'
3. 'My nephew.'
4. 'Best gold dust.'

B. *Initials that do not contain voice.* [These must be touched off lightly and the voice be promptly brought out in the succeeding vowel or voiced consonant.]

1. 'Far shores seem thinly hazy.'
2. 'Two poor comrades.'

The pupil should be enjoined to practise reading aloud daily for at least ten minutes, commencing always with the above set of sentences; and he should be encouraged further to draw up for himself (and practise the repetition of) other illustrative sentences, not only those containing initial consonants of *similar* character, but also those of *dissimilar* nature, so that he may readily acquire the habit of distinguishing between the *voiceless* and *voiced* consonants. Once he has mastered the principles upon which the treatment depends, all that is necessary is for him to notice in reading or speaking any letters that occasion him particular difficulty, so that he may learn from his teacher (if he has been unable to discover for himself from the 'alphabet') how such letters are to be enunciated. Lastly, he should learn to take inspirations at short intervals so that he may always have ample breath to enable him to give the full vocal element to all those letters requiring it, and he should make it a constant practice to speak or read (as Wyllie says) 'with voice, making music with the voice, and listening to it as he speaks.'

H. GRAHAM LANGWILL.

STANDARDISATION—Standardisation is the name given to the process by which certain official preparations are made to contain a definite and uniform amount of the alkaloid or active principle of the vegetable drug from which they are extracted.

To obtain the requisite strength, stronger percolates, containing a known quantity of active principle, are diluted with alcohol; or, again, to obtain extracts of proper strength and consistence, stronger and weaker extracts may be mixed, and stronger extracts may be diluted with distilled water or with milk-sugar as may be necessary. The Aqua Laurocerasi, mentioned below, has its strength adjusted either by the addition of hydrocyanic acid or by dilution of the distillate with distilled water. The details of the procedures required in each individual instance are given fully in the British Pharmacopœia under each preparation.

The following are the standardised preparations according to the last revision of the British Pharmacopœia in 1898. It will be noted that 1 per cent. equals 1 grain in 110 minims, or according to the metric system 1 gramme in 100 cubic centimetres:—

Extractum Belladonnæ Alcoholicum, containing 1 per cent. of the alkaloids of Belladonna-root.

Extractum Belladonnæ Liquidum, containing 0.75 per cent. of the alkaloids of Belladonna-root.

Tinctura Belladonnæ, containing not less than 0.048 per cent. nor more than 0.052 per cent. of the alkaloids of Belladonna-root.

Emplastrum Belladonnæ, containing 0·5 per cent. of the alkaloids of Belladonna-root.

Linimentum Belladonnæ, containing 0·375 per cent. of the alkaloids of Belladonna-root.

Unguentum Belladonnæ, containing 0·6 per cent. of the alkaloids of Belladonna-root.

Extractum Cinchonæ Liquidum, containing 5 per cent. of the alkaloids of Red Cinchona Bark.

Tinctura Cinchonæ, containing 1 per cent. of alkaloids of Red Cinchona Bark.

Tinctura Cinchonæ Composita, containing 0·5 per cent. of alkaloids.

Acetum Ipecacuanhæ, containing 0·1 per cent. of alkaloids.

Extractum Ipecacuanhæ Liquidum, containing from 2·0 to 2·25 per cent. of alkaloids.

Vinum Ipecacuanhæ, containing 0·1 per cent. of alkaloids.

Tinctura Jalapæ, containing 1·5 per cent. of Jalap Resin.

Aqua Laurocerasi, containing 0·1 per cent. of Hydrocyanic Acid.

Extractum Nucis Vomiceæ, containing 5 per cent. of Strychnine.

Extractum Nucis Vomiceæ Liquidum, containing 1·5 per cent. of Strychnine.

Tinctura Nucis Vomiceæ, containing 0·25 per cent. of Strychnine.

Extractum Opii, containing 20 per cent. of Morphine.

Extractum Opii Liquidum, containing 0·75 per cent. of Morphine.

Tinctura Opii, containing 0·75 per cent. of Morphine.

FREDERICK WILLCOCKS.

STAPHYLOMA (σταφυλή, a bunch of grapes).
 SYNON.: Fr. *Staphylôme*; Ger. *Staphylom*.—This word was applied by old writers, in the jargon which was once supposed to be scientific, to any limited protrusion of the tunics of the eyeball. It was first used to denote the protrusion which occurs in the circum-corneal sclerotic zone, as a consequence of localised inflammation of this region. The tissue affected by the inflammation in such a case becomes softened, yields to the intra-ocular tension, and projects; but being restrained by bands of lymph, or by thicker portions of its own structure, from projecting uniformly, the prominence becomes more or less sacculated; and the most prominent portions, being thinner than the rest, and permitting the dark pigment of the interior of the eye to show through, present an appearance which may be compared to that of a miniature bunch of purple grapes—a real or fancied resemblance from which the term ‘staphyloma’ was derived. This form has more recently been termed *staphyloma of the sclerotic*, to distinguish it from *staphyloma of the cornea*, which is the protrusion left when the corneal tissue has been destroyed by ulceration, either wholly or in part, and the resulting cicatrix, formed of iris-tissue coated over by lymph, yields to the pressure of the fluids within the eye and becomes prominent. Corneal staphyloma is described as either partial or complete, according to the amount of cornea which is replaced by cicatrix.

Staphyloma posticum is a phrase applied to that protrusion of a circumscribed portion of the sclerotic, in the immediate vicinity of the optic nerve, which occurs in some cases of myopia; and which, by increasing the elongation of the eyeball, increases also

the degree of the short sight. It would be highly desirable to abandon the term ‘staphyloma,’ in favour of ‘protrusion,’ with such appended words as might serve to indicate the place and nature of the change. See EYE, AND ITS APPENDAGES, Diseases of.

R. BRUDENELL CARTER.

STARVATION (Sax. *steorfan*, to perish).—This term is generally applied either to deprivation of food, or to the series of phenomena to which such want gives rise. The word is often used synonymously with *fasting*, which, however, may be more accurately applied to voluntary starvation. See FASTING.

STASIS (ἵσταμι, I stop).—Local arrest of the circulation. See INFLAMMATION.

STATISTICS, MEDICAL.—See MORBIDITY; MORTALITY; PERIODICITY IN DISEASE; PUBLIC HEALTH; and VITAL STATISTICS.

STEARRHŒA.—SYNON.: Seborrhœa; Steatorrhœa; Fr. *Stéarrhée*; *Séborrhée*; Ger. *Talgdrüsenausschwitzung*.

Stearrhœa is an affection of the skin which is met with in an idiopathic form, but more often as an attendant on other skin-diseases, such as folliculitis, acne, gutta rosea, and lupus.

DESCRIPTION.—Two varieties of this disease are described: (1) *Stearrhœa sicca*; and (2) *Stearrhœa oleosa*.

1. *Stearrhœa sicca*.—This form is usually associated with folliculitis, and constitutes common pityriasis capitis, or dandruff of the scalp. A similar affection is often met with as a ringed eruption on the back between the shoulder-blades, and on a corresponding part of the chest. This eruption is a variety of follicular inflammation involving the sebaceous glands as well as the follicles, in which stearrhœa is a constant feature; it is very often associated with stearrhœa capitis, so that it is impossible to dissociate the two diseases.

Stearrhœa sicca is usually met with on the scalp and eyebrows, and in adults is characterised by the formation of dirty-white or yellowish scales. The outermost of these become dry and fall off as a scurf. At the same time the hairs are shed, and those which replace them are imperfectly developed, so that partial baldness is caused. In uncomplicated stearrhœa there is no inflammation of the skin, and little itching; but it generally happens that the affection is associated with folliculitis, and then itching becomes a troublesome feature. This condition of the scalp is commonly known as *pityriasis capitis* or *alopecia furfuracea*, in which the skin becomes covered with great quantities of fine, pearly-white, glistening scales, which are constantly shed and fall upon the shoulders, giving the appearance of the hair having been powdered. There is, in fact, an excessive desquamation of cuticle; and when the hairs participate in the changes, as they often do, the vertex becomes bald. The degree of itching depends on the amount of folliculitis present. Stearrhœa capitis may be mistaken for dry eczema or psoriasis; but these diseases are rarely limited to the hairy part of the scalp, and the changes in the skin are much more marked.

2. *Stearrhœa oleosa*.—This variety of the disease is usually confined to the face, and is a very common complication of acne rosacea. It consists of an excessive secretion of sebum, which is changed

in character into an oily fluid. This oil is poured out on the surface of the skin, and gives it a shiny appearance. When dabbed with a piece of blotting-paper, the fluid is absorbed and its greasy nature at once becomes evident. From the ready adhesion of dust, the skin assumes a dirty look which is very characteristic. This affection is especially prevalent in spirit-drinkers.

TREATMENT.—The treatment of stearrhœa is chiefly local, and consists, in the first instance, in removing any crusts which may have formed from the accumulation of sebum. These should first be softened by a thorough application of oil, and then well washed with hot water and soap. The subsequent treatment consists in the daily use of the white precipitate, or nitrate, or red oxide of mercury ointment, well diluted with vaseline. At the same time the skin should occasionally be washed with a lotion containing soft soap or a little borax and ether. Before any local treatment is adopted, it should be carefully explained to patients that the process of rubbing off the crusts is always attended by the removal of a large number of loose hairs, otherwise they are apt to think that the loss of hair is caused by the treatment rather than by the disease.

ROBERT LIVEING.

STEATOMA (στέαρ, fat; and the termination *oma*, adopted to indicate a tumour).—**SYNON.**: Fr. *Stéatome*; Ger. *Steatom*.—A sebaceous cyst. See CYSTS.

STEATOZOON (στέαρ, fat or sebum; and ζῶον, an animal).—A synonym for the *Acarus folliculorum*. See ACARUS.

STEEL-GRINDER'S PHTHISIS.—See PNEUMOCONIOSES.

STELLWAG'S SIGN.—A widening of the palpebral fissure occurring in many cases of exophthalmic goitre, bearing no constant relation to the exophthalmos, and due partly to retraction of the upper eyelid.

STENOSIS (στενῶω, I constrict).—A constriction, narrowing, or stricture of an opening or a tube; for instance, *mitral* or *aortic stenosis*, in the heart; and *stenosis of the œsophagus*.

STERCORACEOUS (stercus, dung).—Fæcal; a term generally applied to vomited matter when it presents the characters of feces. See VOMIT: Examination of Vomited Matters.

STERILITY IN THE FEMALE.—**SYNON.**: Barrenness; Fr. *Stérilité*; Ger. *Unfruchtbarkeit*.

DEFINITION.—Want of the power of reproduction in the female.

FREQUENCY.—In the general community the proportion of childless marriages seems to be about 1 in 8 or 8·5; among members of the peerage 1 in 6·11. Whether Kehler be correct in estimating that the husband is in fault in at least one-fourth of the cases of *sterilitas matrimonii* remains to be proved. Doubtless he is nearer the truth than those who attribute the sterility in nine cases out of ten to some fault in the wife, because while the comparatively rare cases of male impotence are readily enough recognised, and also the rarer cases of *aspermatis*m, the cases of *azoöspermatis*m, where

an azoic semen is ejaculated, are for the most part altogether overlooked. The possibility that the cause of the childlessness may be found in the male must, therefore, always be borne in mind. See IMPOTENCY; and STERILITY IN THE MALE.

ÆTIOLOGY.—For generation the essential product in the female is the ovum; and in her reproductive apparatus we find (i.) *oviparous organs* for its production; (ii.) *oviducts* for its transmission; (iii.) an *ovigerent organ* or nest in which the ovum is hatched; and (iv.) *copulative organs* for the reception of the semen, the spermatozoa of which constitute the essential contribution of the male. In a married woman in whom the generative function is in abeyance, the sterility may be either primitive or acquired. In the former case we have to do with a female who has never borne a child; in the latter the woman may have borne one or more children, but has for some years ceased to conceive. In either case we search for the fault in one or more of these four planes of her sexual apparatus.

I. Faults in the Ovaries.—The ova are developed in the ovaries, and the conditions which interfere with ovulation—that is, the regular ripening of an ovisac, and the discharge of an ovum—diminish or destroy the possibility of conception. Such conditions are found in:—

(1) *Absence or imperfect development.*—Cases of absence or defective development of the ovaries are rarely met with, except in women in whom the rest of the sexual apparatus is also anomalous.

(2) *Displacements.*—One or both ovaries may be found displaced. Instead of lying at the level of the pelvic brim, they have fallen into the pouch of Douglas. In this position, though the ripening and dehiscence of the ovisacs may be duly taking place, the discharged ova are not received into the free extremity of the Fallopian tube. The displaced ovary, moreover, is extremely likely to be the seat of some degree of inflammation.

(3) *Inflammation.*—Oöphoritis, acute or chronic, lessens the conceptive power in various ways. It may lead, first, to destruction of the follicles, so that no ova are produced; secondly, to condensation of the stroma, so that the regular ripening of the ovisacs is impeded; thirdly, to deposits on the surface, which prevent the dehiscence of the ovisacs; or, fourthly, to adhesions of the ovary in situations which hinder the entrance of the discharged ova into the oviducts.

(4) *Degenerations.*—The neoplastic degenerations to which the ovaries are most liable are the cystic; and all the varieties of cystomata, as well as the fibromata, the sarcomata, and the carcinomata, are commonly attended by sterility. Where both ovaries are affected the sterility is absolute, from the complete loss of function in the organs; and even where only one is affected, the disturbance in the relations of the pelvic organs, caused by the growing mass, is likely to prevent impregnation. See OVARIES, Diseases of.

II. Faults in the Oviducts.—The Fallopian tubes or oviducts serve not only for the reception of the discharged ova, and their transmission downwards to the uterus; they may serve also for the upward transit of the spermatozoa. Lawson Tait maintained that the entrance of spermatozoa into the tubes is pathological; but most authorities are of opinion that in them the male and female elements come into union.

(1) *Absence*.—Defective development of the Fallopian tubes is usually associated with other abnormalities of the sexual apparatus, especially with rudimentary conditions of the uterus.

(2) *Inflammation*.—Inflammatory changes may be found affecting either the external serous covering, or the internal mucous lining. In the former case sterility results from adhesions, which lead to displacements of the free extremities, so that they are not in a position to receive the ova discharged on the bursting of an ovisac; or from bands which constrict the tubes, and so occlude their canal. In the latter, changes in the secretion may prejudice the vitality of the spermatozoa or ova; or the thickenings, polypoidal or other, may obstruct the canal; or complete atresia may be produced, and their permeability be thus entirely lost. See FALLOPIAN TUBES, Diseases of.

(3) *Degenerations*.—The tubes are rarely enough the seat of neoplasms; but when such do develop in their walls, occlusion of their canal and consequent loss of function may ensue.

III. *Faults of the Uterus*.—In the process of reproduction, the uterus serves as the receptacle or nest, in which the fertilised ovum is carried during the period of incubation. In its proliferating mucous membrane the chorionic villi take root; through its expanded blood-vessels the foetal blood is brought into relation with the maternal; its walls grow in correspondence with the increase in size of the ovum; and its largely developed muscular fibres are the main agents in the expulsion of the ovum when it is finally hatched. It plays such an important part in the female economy that the name of it is often used as synonymous with the sexual apparatus; and some of its morbid conditions are among the commonest causes of sterility.

(1) *Defective development*.—First, the uterus may be absent altogether, or represented merely by a fibrous nodule. Secondly, it may be small, having undergone arrest at some stage of its growth, and remaining infantile, juvenile, or adolescent. Thirdly, it may be *bicornuous*—retaining the trace of its original duplicity by the presence of a septum running through the body alone, or running through both body and cervix, perhaps through the vaginal canal as well. Fourthly, it may be *unicornuous*—only one of the halves of the organ having been developed, while the other tube may be obliterated, or attached as a rudimentary by-horn to the better-developed tube. Fifthly, a more frequent malformation is found in a *conical* form of the cervix, which is not infrequently complicated with, sixthly, *narrowness of the os*. This last condition may exist by itself, forming a well-recognised cause of sterility, and furnishing some of the cases in which a most satisfactory cure can be accomplished.

(2) *Displacements*.—First, *descent* of the uterus is found as the predominant morbid condition in some cases of acquired sterility, but this is more frequently associated with the deviations anteriorly or posteriorly. Of these, secondly, the *antrorsions*, flexion and version, are very frequent among women who have never conceived at all; thirdly, the *retroversions*, flexion and version, are more common in women who have given birth to one or more children, and have subsequently remained sterile. The flexions, in particular, form a very clearly recognisable and often remediable cause of sterility.

(3) *Changes in size*.—The retrogressive changes which occur in the uterus after labour sometimes go

on morbidly, and in one group of cases leave the organ in a condition of (1) *super-involution*. The uterus may be reduced to a little tube which only admits the sound for half an inch. Even when the degree of super-involution is less, and the uterus still measures two and a quarter inches in length, it is apt to cause amenorrhoea and sterility. In another group of cases the uterus remains hypertrophied in a condition of (2) *sub-involution*, which is inimical to conception; and when conception does take place in such a uterus, abortion is liable to occur.

(4) *Inflammation*.—Among the commonest causes of sterility must be ranked the inflammatory changes to which the uterus is so liable, whether the process have affected mainly the external, middle, or internal coat; and in many of the cases where some other condition tending to sterility is present, inflammatory changes come in to increase the difficulty, and to cloud the prospects of recovery. First, *perimetritis* is usually only an element of a more general pelvic peritonitis, which often leaves behind it fixations and displacements of the uterus, preventing conception or promoting early abortion. Secondly, *mesometritis*, leading to thickening of the walls of the organ, produces an expansion of its cavity and disturbance of its function. It is rarely possible to dissociate this from, thirdly, *endometritis*, which is attended also by dilatation of the cavity, but which is further mischievous from the deleterious influence of its abnormal secretions on the life and progress of the spermatozoa, and from the difficulty with which a fertilised ovum gets healthily engrafted on its surface. Moreover, in certain cases of long standing, some of the uterine orifices may become more or less occluded, a result which is more especially apt to ensue in the external orifice when caustics have been applied to the cervical canal.

(5) *Degenerations*.—First, *myomata*, or fibroid tumours, are found in a considerable proportion of barren women. Whether sub-peritoneal, intramural, or sub-mucous, they interfere in many ways with conception, and give a proclivity to miscarriages or dangerous labours when conception has occurred. Secondly, *sarcomata* have usually their seat in the uterine cavity, and seem to be an absolute bar to impregnation. Thirdly, *carcinomata* have been sometimes met with in the pregnant uterus; but these are commonly seated in the cervix, and it is usually only in an early stage of the mischief that conception can occur. See UTERUS, Diseases of.

IV. *Faults in the External Organs*.—In various ways the organs which serve for the reception of the spermatic fluid may be so affected that their copulative function is disturbed or destroyed, and the patient remains sterile.

(1) *Malformations*.—Occlusions of the labia are rare; but the vaginal canal may be impervious, firstly, from abnormal conditions of the *hymen*; secondly, from *atresia* in some part of its course; or, thirdly, from complete *absence*. It will even be found that in certain cases where the rest of the generative apparatus seems to be well-developed, a preternatural *shortness* of the canal exists in some sterile women, from whom the semen escapes immediately after it is thrown into the cavity.

(2) *Injuries*.—The injurious influences of a bad labour on the reproductive power of a woman may be found, first, in an undue *patency* of the canal, usually from extensive rupture of the perinæum; secondly, more frequently from *atresia*, partial or

complete; or, thirdly, from *fistulous* formations, leading to communication with the neighbouring cavities.

(3) *Inflammation*.—In its acute stages, inflammation of the pudenda and vagina produces, first, *dyspareunia*; in its more chronic forms it may be productive of, secondly, *unhealthy discharges*, which endanger the vitality of the spermatozoa; or it may lead, thirdly, to *occlusions* of the labia, or of the vaginal orifice or canal. Partly of inflammatory origin is the condition, fourthly, of *vaginismus*, which is not an uncommon cause of impossibility of connection.

(4) *Degenerations*.—The various neoplasms occur with rarity in the vaginal canal; but in the pudenda—sometimes from their bulk, sometimes from their sensitiveness—they interfere with connection, as in cases of elephantiasis labiorum or of urethral carcinoma. *See* VAGINA, Diseases of.

DIAGNOSIS AND PROGNOSIS.—Investigation into a case of sterility may require us to satisfy ourselves as to the fertilising powers of the male, and the due fulfilment of the marital function. Occasionally some concurrent disturbance in the functions of the sexual apparatus of the female, or of the neighbouring organs, may enable us to make a close guess at the cause of her barrenness; but we can only arrive at a true conclusion by a careful physical examination, having in view such causes as we have given. Some of the conditions, as, for example, the more pronounced malformations, or imperfect development, make us regard a woman as hopelessly sterile; others, such as uterine flexions and stenosis, some vaginal occlusions, and injuries and tenderness, we may undertake to treat with good hope of fruitful result.

TREATMENT.—In commencing the treatment of any case, we must bear in mind that morbid conditions may be present in more than one of the planes of the sexual system, and that we must begin with the removal of the obstacle that lies nearest the surface. Urethral caruncles and other sensitive structures in the vulva must be cut off or cauterised. Contractions of the vaginal orifice or canal must be stretched; and where there is complete atresia an aperture must be formed and kept patulous. Stenosis of the uterine orifices may be overcome by temporary dilatation by means of graduated bougies introduced under chloroform, or with a tupelo-tent, which the writer has more than once seen followed by impregnation. Where such dilatation fails, the os may be dilated more permanently, by tearing it with an instrument like a pair of long dressing-forceps, the blades of which are forced apart after it has been passed into the cervix; or by dividing the cervix at both sides, or in one or other lip, with a hysterotomy; or the orifice and canal may be dilated by means of graduated bougies. The deviations of the uterus must be rectified: versions, after replacement, being usually retained by some modification of Hodge's pessary, flexions demanding in addition the use of an intra-uterine stem. The stem-pessary of zinc and copper, introduced into the interior, is the best means of stimulating to its full function the imperfectly developed uterus, and the uterus which has withered from super-involution. Morbid conditions in the interior of the uterus require direct applications to its cavity. And as in a large proportion of the cases some inflammatory mischief complicates the other morbid condition, it is often helpful to the cure to make the patient use hot

douches and baths, and the internal remedies which tend to remove the effects of inflammatory action. It is to the beneficial influence which the waters of Ems, Aix, Kissingen, and other spas exert on chronic metritis that their reputation for curing sterility is mainly due. In cases where the natural method of getting spermatozoa brought into relation with the ova has failed, success is said to have followed the introduction of seminal fluid by means of a fine syringe and tube into the cavity of the uterus—a line of treatment legitimate, it may be, but only to be adopted in quite exceptional circumstances.

ALEXANDER RUSSELL SIMPSON.

STERILITY IN THE MALE.—SYNON.: Fr. *Stérité chez l'homme*; Ger. *Unfruchtbarkeit des Mannes*.

DESCRIPTION.—By sterility is meant an inability to procreate. This condition must not be confused with impotence, which is an inability to perform sexual intercourse. A perfectly impotent man is necessarily sterile, but a sterile man may be able to perform the sexual act. The condition may result from widely differing causes.

1. *Abnormalities of the Genitals*.—(a) In those cases in which both testicles are undescended or are otherwise misplaced, these organs remain small, undergoing no increase in size at the time of puberty; moreover, they do not form spermatozoa. The writer has examined a number of testicles removed by operation in this class of case, and has found them wholly destitute of spermatozoa. In these cases the patient is sterile but not generally impotent, and the fluid emitted in coition is destitute of spermatozoa (*azoospermism*). Cryptorchies are sometimes reputed to have procreated children; but it is remarkable that as yet no case has been found in which a retained testicle has been fully proved to be capable of secreting a fertilising fluid.

TREATMENT.—All cases of undescended or misplaced testicle should be operated upon as soon as possible. If the testicles are brought well down into the ill-developed scrotum before puberty they enlarge at that period, and may attain the ordinary size. As a rule, although they do not enlarge to the full extent, they grow into useful organs, sterility thus being avoided. An additional reason for operation is that the majority of these cases also suffer from herniæ.

(b) In epispadias or hypospadias, in hermaphrodites, and in many other cases of malformation of the penis, the semen is not properly introduced into the vagina, and sterility results. *See* PENIS, Diseases of.

2. *Obstruction to the emission of Semen*. In double acute epididymitis the inflammatory exudation occludes the canal of each epididymis. This condition may be only temporary, but if a fibrous nodule remain in the globus minor on each side, the ducts will be occluded, and the sterility be permanent. The treatment of epididymitis should be continued until the inflammatory exudation is quite absorbed and no induration left. Other causes of obstruction and sterility are tubercular disease and gumma of the epididymis, disease of the vas deferens, or pressure upon these ducts from without, and the removal of the epididymes or portions of the vasa deferentia. Three other common causes of sterility are stricture of the urethra, enlarged prostate and severe phimosis. A severe stricture of the urethra obstructs the flow of

semen during erection, the semen passing back into the bladder. An enlarged prostate and any disease of or operation upon the prostate may occlude the ejaculatory ducts. In phimosis of a severe type the semen may collect in the prepuce. In perineal fistulæ the semen may escape through these canals.

3. **Diseases of the Testicles.**—By interference with the functions these may prevent the formation of spermatozoa. In double orchitis after mumps the testicles sometimes atrophy and become sterile.

4. **Aspermatism.**—Even though there be no obstruction or lack of secretion the ejaculation of semen does not always follow coitus, even in persons who are subject to nocturnal emissions. This appears to arise from defective sensibility of the glans penis. In one case of non-ejaculation the nerves proceeding to the glans apparently had been destroyed by ulceration and cicatrization; in some cases the surface of the glans is converted into a mass of scar-tissue which contains no nerve-fibres. Loss of the glans penis by operation or from ulceration may thus cause sterility, although the writer has seen a case in which efficient and fertile intercourse was possible after amputation of the penis, leaving only a small stump.

5. **AzoöspERMATISM.**—A few cases have been recorded of healthy, well-formed male adults, apparently capable of normal coition, who yet proved sterile. Repeated microscopical examination of the semen has demonstrated the absence of spermatozoa. No explanation of this condition has as yet been discovered.

TREATMENT.—If any of those conditions which are amenable to surgical assistance be present they should be treated according to general principles. Phimosis, retained testicle, stricture of the urethra, hydrocele, hernia, &c., should be at once subjected to an operation for their radical cure.

A question as to the advisability of marriage may arise. Proved sterility is a legal disqualification; and even if this point be not raised, it will accord with the experience of most practitioners, that for such men to marry is usually unwise.

CHARLES GIBBS.

STERNUTATORIES (*sternuo*, I sneeze).—**SYNON.**: Errhines; Fr. *Sternutatoires*; Ger. *Niesmittel*.

Drugs which cause sneezing, and produce an increased secretion from the mucous membrane of the nose. The principal sternutatories are Tobacco-snuff, Veratrum album, Euphorbium, and Ipecacuanha.

STERTOR (*sterto*, I snore).—**SYNON.**: Fr. *Sterteur*; *Ronflement*; Ger. *Schnarchen*; *Röcheln*.

DEFINITION.—A term commonly applied to sounds in the throat resembling snoring, which occur in the apoplectic and like conditions. The writer considers the name should be extended to other sounds formed in any part of the respiratory passages or mouth by the movements of the air, under similar circumstances.

VARIETIES.—Several varieties of stertor may be recognised, as follows:—

1. **Nasal.**—Nasal stertor arises from approximation of the alæ nasi towards the septum by the ingoing air, as in the act of sniffing.

2. **Buccal.**—This form of stertor is due to vibrations of the lips, and puffings and flappings of the cheeks, during inspiration or expiration.

3. **Palatal.**—This arises from vibrations of the soft palate, whether the breath passes through the mouth or the nose.

4. **Pharyngeal.**—Pharyngeal stertor is caused by the lolling back of the base of the tongue into close contact with the posterior wall of the pharynx.

5. **Laryngeal.**—This variety is referable to vibrations of the chordæ vocales.

6. **Mucous.**—Mucous stertor is a term which may be given to the bubbling of air through mucus in the trachea or larger air-tubes.

ÆTIOLOGY.—One or more of the varieties of stertor, in varying degrees of intensity, may occur in any of the following morbid conditions, namely: Suffocation; apoplexy; epilepsy; convulsions in children; the death-agony; fractures of the skull, and concussion of the brain; bronchitis—particularly in old subjects, sudden œdema of the lungs, and large hæmorrhages into the lungs; great exhaustion; chloroform-poisoning, drunkenness, and opium-poisoning; drowning, and all conditions in which mucus or other fluid is present in the lungs; and all forms of sopor, whether natural or the result of accident or disease.

DESCRIPTION.—The general phenomena of stertor are those of suffocation.

A patient may be found lying in a state of complete unconsciousness, with a congested, turgid, and expressionless face; usually dilated and fixed pupils; insensitive conjunctivæ; a hot and perspiring skin; throbbing arteries; a full and bounding pulse; and, lastly, noisy breathing, the direct result of mechanical interference with the passage of air into or out of the lungs, whether arising from contractions of the orifices, and vibrations of the soft parts of the nose, lips, cheeks, palate, pharynx, or larynx, or from mucus or fluids in the trachea and bronchial tubes. When the obstruction to the breathing is only slight, but long-continued, the face may be of a dusky pallor, and there is an entire absence of turgidity and congestion.

PATHOLOGY.—The noise in stertor depends on the vibration of certain parts just enumerated. The primary disease causes partial paralysis or spasm of the muscles contained in these parts, and this factor, together with the position of the patient, causes the paralysed or rigid structures to occupy positions interfering with the passage of air into and from the lungs. Thus is produced a double result. In the first place, the air passing over the affected parts throws them into vibration, and thus gives rise to the characteristic sounds, and in the second the obstruction to respiration produces the characteristic symptoms of asphyxia, which may be sometimes so great as to be fatal in itself. The congested and turgid face, the noisy breathing, the râles in the chest, the throbbing arteries, and the full and bounding pulse, are signs of suffocation. Directly the impediments to respiration are removed, all is quiet in apoplexy, and the practitioner is enabled to judge of the real state of the case—which side is paralysed, whether the nerves are losing or recovering their power, and what evidences exist as to greater or less interference with the functions of organic life.

TREATMENT.—In stertor, as in strangulation, we must proceed at once to remove the impediment to free respiration.

Nasal stertor.—This may be relieved by pressing upwards the tip of the nose, or by keeping the nares open by the handle of a common salt-spoon.

Laryngeal stertor.—In apoplexy this never appears dangerous enough to warrant tracheotomy, which alone would remove it.

Buccal, pharyngeal, palatal, and mucous stertor.

—These varieties of stertor are readily treated by placing the patient comfortably on one side, and affording support by well-arranged pillows. In this position the buccal and palatal stertor, if any remain, will be too feeble an impediment to require further attention. The tongue drops to the side of the pharynx and leaves plenty of room for the in-going air. The mucus or fluid, too, whether resulting from these or other forms of stertor, drains away into the lowermost lung, thus preventing the formation of large foam-vesicles in the trachea (the 'death-rattles'), which are always dangerous respiratory impediments. Care should be taken to keep the neck rather straight, as, if the chin be brought too near the sternum, the thyroid cartilage presses upwards and backwards, and pushes the base of the tongue towards the back of the pharynx. In the management of mucous stertor it must be observed that, after a time, varying from one day to three or four, the lower lung becomes filled with mucus, though the patient is still breathing quite placidly. If at this stage the patient be turned over on the other side, the mucus begins travelling across the trachea into the opposite lung; is caught on its passage by the in-going air; and is whipped into foam, which at once blocks up the larger air-tubes of the only lung that can work, and so instant distress and danger result. If the life of the patient be not at once destroyed, still the additional shock reduces very much the chances of ultimate recovery. Under these circumstances change of position should always be tentative, and time for some return of nerve-vigour should be allowed before it is attempted. This warning applies with equal force to all cases where mucus or fluid obstructs the air-passages, as in drowning, hæmoptysis, and bronchitis. In drowning, it may be remarked that the water on entering the lungs becomes quickly insapissated with mucus, forming a milky foam, which can only be slowly evacuated by the application of Dr. Marshall Hall's or other process of artificial respiration. See ARTIFICIAL RESPIRATION; and RESUSCITATION.

ROBERT L. BOWLES.

STETHOGRAPH (στήθος, the chest; and γράφω, I write).—An instrument for recording the movements of the chest.

STETHOMETER (στήθος, the chest; and μέτρον, a measure).—SYNON.: Fr. *Stéthomètre*; Ger. *Stethometer*.—An instrument for measuring the mobility of the chest, and of its several parts, during respiration.

STETHOSCOPE (στήθος, the chest; and σκοπέω, I examine).—SYNON.: Fr. *Stéthoscope*; Ger. *Stethoscop*.

DEFINITION.—An instrument employed as a medium for the conduction of sound, between the ear and the chest or other parts, in auscultation.

DESCRIPTION.—Stethoscopes are of various patterns. They are often made of a thin, cylindrical piece of wood, perforated throughout its length, which is of about 6 inches to 8 inches; expanded at one end to a somewhat trumpet-like extremity, for convenient application to the chest; and at the other end provided with a nearly flat, broad surface,

to which the ear can be comfortably applied. Some practitioners prefer a solid stethoscope—that is, one in which there is no central canal. Such was Laennec's original instrument. Others prefer the stethoscope to be made of metal; others, again, of vulcanite. An instrument made of cedar-wood, with a perforation of about $\frac{1}{8}$ inch in diameter, a chest-piece about $1\frac{1}{2}$ inch in diameter, and a slightly concave ear-piece $2\frac{1}{2}$ inches to $2\frac{3}{4}$ inches in diameter, is perhaps the best adapted for auscultation.

Most auscultators at the present day use the *binaural stethoscope*, which consists of a short hollow chest-piece, of an elongated conical shape, from which two flexible tubes extend, terminating in metal tubes tipped with ivory, to fill the meatus of the ear on each side. This instrument has some advantages. It can be more readily applied to different parts of the chest without the observer being obliged to adopt constrained postures; and by occupying both ears while the chest-piece is applied, it excludes extraneous sounds, and considerably intensifies the chest-sounds. One disadvantage is, that sounds produced in the mouth and throat of the patient, which would be recognised by the disengaged ear of an observer using the ordinary stethoscope, are apt to be mistaken for modified pulmonary sounds. Again, with the aid of the rigid stethoscope impulses of various kinds, cardiac or aneurysmal, not recognisable on ordinary palpation, are very appreciable by the ear, which might escape attention with the binaural instrument.

The *differential stethoscope*, which is a binaural stethoscope having the tube connected with each ear attached to a separate chest-piece, is useful in some cases of heart-disease, and for simultaneously comparing the two sides of the chest—provided the two ears of the observer are of equal auscultatory power. Finally, some practitioners prefer a single flexible tube, with an ear-piece fitting into the meatus, and a chest-piece. It has been attempted to apply the telephone, and even the microphone, to stethoscopy, but as yet without success.

R. DOUGLAS POWELL.

STHENIC (σθένος, strength).—This term is applied, first, to individuals when they are vigorous and strong; and, secondly, to inflammatory diseases, when they assume an active character, such as *sthenic pneumonia*, as distinguished from *asthenic*.

STIFF-NECK.—A popular name for muscular torticollis. See RHEUMATISM, MUSCULAR.

STIMULANTS (*stimulo*, I excite).—SYNON.: Excitants.

DEFINITION.—Any agent which increases the function of a tissue or of an organ.

The term is fast disappearing from therapeutics since pharmacology is steadily demonstrating the way in which remedies exert their action upon the body.

Used in the general sense as above defined, it includes nearly all the remedial agents in the pharmacopœia if we exclude the class Sedatives or Depressants. A very objectionable employment of the term is made in circumscribing its use as a synonym for alcohol and its preparations.

Nevertheless there are some therapeutic groups where the term is still admissible in the present state of our knowledge, and these may be briefly enumerated.

1. *Local Stimulants*, or more correctly *External Stimulants*, include the long list of agents which are employed as counter-irritants, rubefacients, vesicants, pustulants, irritants, and even caustics. These the reader will find discussed under the heading Counter-irritants.

2. *General Stimulants*.—This is a most misleading term, and if employed at all should be used as a synonym for *Cerebral Stimulants*. These are drugs which increase the activity of the brain either by their stimulation of the cerebral cells or by their power of increasing the vascular supply. The excitation of the mental functions may be so great as to cause marked exhilaration or even delirium, and since the most typical members of this group of drugs are the narcotics, when the action of the drugs is pushed, sleep or depression of the mental faculties to the extent of coma occurs.

The agents generally employed as cerebral stimulants are alcohol, tea, coffee, coca (*Erythroxylum coca*), opium, absinth, and Indian hemp. Belladonna, hyoscyamus, camphor, and ether are also powerful excitants of the cerebrum. Of course the most important of all these is alcohol, and its use in disease is one of the most serious problems that can be placed before the physician, but it must be clearly recognised that alcohol as a remedial agent in fever should not be prescribed as a cerebral or general stimulant, but as a food and as a cardiac stimulant. See ALCOHOL.

3. *Cardiac Stimulants*.—This group is of great therapeutic importance, and comprises those drugs which notably augment the force of the ventricular contractions, and at the same time markedly increase the frequency of the pulse. In theory and in practice they must be carefully distinguished from cardiac *tonics* which in a slower and more lasting manner also increase the power of the ventricle, but at the same time diminish the number of its contractions. The action of cardiac stimulants is utilised in emergencies as in threatening failure of the circulation from shock, injury, mental emotions, or from the effects of the depressing poisons elaborated during fever. These drugs act upon the heart through its nerve-supply, directly, and also by reflex action on the sensory filaments of the vagus distributed to the stomach. Ammonia acts in this manner, while at the same time it powerfully stimulates the vaso-motor centre in the medulla. The chief cardiac stimulants are alcohol in all its forms, free ammonia and its preparations, heat, camphor, turpentine, ether, nearly all the aromatic or essential oils, chloroform in small doses, and strychnine.

The indication for the use of alcohol in fevers should be sought for mainly in the condition of the heart and circulation as evidenced by the force of the ventricular contractions, the frequency of the pulse, and the heat of the extremities. At the same time its value as a food (the greater part of a medicinal dose is burned up as fuel in the system) and its power of retarding metabolism must not be lost sight of. In desperate emergencies ammonia must be relied upon, applied to the nostrils or injected directly into the veins or swallowed in combination with alcohol.

4. *Vascular Stimulants*.—Though the previous group is often spoken of as 'vascular stimulants,' this term should be strictly confined to those drugs which stimulate the retarded circulation by their action in causing dilatation of the blood-vessels, as

amyl nitrite, nitroglycerin, ethyl nitrite, sweet spirit of nitre, sodium nitrite, and to some extent alcohol—especially if administered hot—and some of the sudorifics.

5. *Spinal Stimulants* are agents which notably increase the functional activity of the spinal cord. They act mainly by stimulating the large ganglion-cells in the anterior cornua. The most powerful are strychnine, brucine, thebaine, and ammonia. A host of drugs in certain definite doses also affect the cornua similarly, but are never employed for this purpose: among these are ergot, nicotine, ether, opium, gelseminine, and even chloroform. The indications for the exhibition of spinal stimulants are seldom clearly marked save in the case of paralysis, hemiplegia, or polio-myelitis anterior acuta after all inflammatory action has subsided.

6. *Gastric Stimulants* include those drugs which act in the opposite way to gastric sedatives, but the term is misleading as it includes all the gastric tonics, the local emetics, and nearly all the substances which if applied to the skin would cause irritation (*External Stimulants*), all aromatics, and alcohol in small undiluted doses, and the various spices, sauces, liqueurs and small dishes which enter into the Russian Zarkuiska or into the Branwinsbrod of the Swedes.

7. *Intestinal Stimulants* also include the long list of so-called carminatives and the various cathartics and laxatives which the reader will find described under PURGATIVES.

8. *Hepatic Stimulants* are drugs which increase the functional activity of the liver so far as the manufacture of bile is concerned, and after their administration the amount of this fluid is always augmented. They are sometimes called cholagogues, but must be distinguished from indirect cholagogues or so-called cholagogue purgatives which simply lead to the expulsion of the bile from the body by irritating the upper part of the small intestine, which causes the hepatic secretion to be expelled before it has had time for its absorption, as in the case of calomel and podophyllum. Many of the hepatic stimulants are also purgatives, but their direct cholagogue or hepatic excitant action is destroyed or suspended when they are administered in purgative doses. They are indicated in all sluggish conditions of the liver where there is reason to believe that the secretion of bile is deficient or where the physician wishes to raise the pressure of the bile in the ducts, as in cases of mild obstruction like catarrhal jaundice. The following are the more important hepatic stimulants: dilute nitric and nitro-hydrochloric acids, ipecacuanha, sodium salicylate, sulphate, benzoate, phosphate and tartrate, aloes, rhubarb, podophyllum-resin, iridin, euonymin, leptandrin, colocynth, colchicin, baptisin, corrosive sublimate, jalap, scammony, and some arsenious compounds. It is very doubtful if calomel has any direct cholagogue action. By the administration of small doses of any of the above hepatic stimulants, followed by one large dose of a cholagogue purgative like calomel, podophyllum-resin, Glauber's or Rochelle salt, very large amounts of bile may be removed from the system.

9. *Renal Stimulants*.—This group should include all the diuretics or drugs which increase the amount of the urinary secretion, but for practical purposes it is best to use it as a synonym for the stimulating diuretics. These are drugs which act

locally or directly upon the kidneys or renal cells without markedly raising the general blood-pressure. The most important members of the group are: Broom, buchu, copaiba, turpentine, caffeine, juniper, gin, calomel, urea, potassium-salts, uva ursi, nitrites, &c. Their use is limited for the most part to the treatment of diseased conditions of the bladder and urethra, or as agents for the relief of dropsy or anasarca where the kidneys are sound. In exerting their diuretic effects the urine is so altered in its chemical composition that most of these agents act as vesical sedatives and allay irritability of the bladder and urethra, or counteract the dangerous evils of the cystitis which accompanies obstructed flow, as in the senile enlargement of the prostate gland.

WILLIAM WHITLA.

STING: STINGING PLANTS AND ANIMALS.—SYNON.: Fr. *Aiguillon*; Ger. *Stachel*.

DEFINITION.—A sting is an abnormal sensation, partly painful, and partly itching in character, usually caused by the introduction beneath the skin of some poison of animal or vegetable origin. Either increment of the sensation may predominate; the stung surface may be simply painful and tender, or the itching may be intense, and lead to considerable scratching for its relief.

In the widest acceptance of the word, the effect produced by the application to the skin of such substances as mustard, cantharides, strong carbolic acid, and the like, may be denominated as stinging; but here it is proposed to consider only the wounds inflicted by stinging plants and animals. The subject of venomous animals is separately discussed. See **VENOMOUS ANIMALS**.

ETIOLOGY.—The severity of the sensation and of the local constitutional effects of stinging depends, not only on the quality and quantity of the irritant, but also on individual susceptibility; in some persons the effect may be extremely mild and transient, in others severe symptoms may ensue. In respect to the peculiar susceptibility of the person attacked, the greatest difference is observable among individuals, and even in the same person at different times. In many of the recorded fatal cases, the victim had been previously stung and had suffered severely. There seems, however, reason to believe that the system becomes more resistant to the effects after repeated stings, as is seen to be the case among bee-keepers, and those continually exposed to mosquitoes. Some variation in the virulence of the poison, whether of animal or plant, occurs with the season of the year.

Stinging Plants.—These are almost entirely limited to the order *Urticaceæ*, of which the following species are the most important: *U. urens*, *U. dioica* (British), *U. crenulata*, *U. stimulans* (Indian), *U. ferax* (New Zealand), *U. gigas* (New South Wales), which forms lofty trees, and *U. urentissima* (Java). A few species of the order Malpighiaceæ also possess stinging properties.

In the nettles the urticating organs consist of unicellular hairs tapering towards the free end, each of which terminates in a bent knob, and, swelling out at the attached extremity, is received into a cup-shaped depression of a cellular pedicle. The acrid fluid, the nature of which has not been determined, but is supposed to be an acid similar to malic or acetic acid, is regarded as being secreted by the pedicle and stored in the stinging hair, from which

it escapes into the integument when the brittle knobbed tip is broken off by contact. The hairs in the Malpighiads are peltate and not tapering.

Stinging Animals.—Urticating organs, known as *trichocysts*, *cnide*, or *thread-cells*, similar in function only to the stinging cells of nettles, are found in many animals, such as the Infusoria, some Annelida, and several Nudibranchiate mollusca. They are, however, best developed and most characteristic in the Cœlenterata, of which the jelly-fishes or sea-nettles are the best known. These organs consist of cells, containing an acrid fluid, and prolonged into a long filament which presents numerous modifications of barbs and serrations. The filament is usually spirally coiled within the cell, from which it is everted on contact, conveying the fluid into the surface that it penetrates. Great variety exists in the form, size, and disposition of these organs; in many of the Actinozoa or sea-anemones they are arranged in rope-like clusters, enclosed in fine tubes, within the body-cavity.

The power of stinging is possessed very generally by members of the articulate sub-kingdom, such as spiders and scorpions among the Arachnida; bees, wasps, mosquitoes, gnats, and ants among the Insecta. The bite of the flea or bug produces itching rather than a sting. In all cases of true stinging an irritant fluid, thought to be of the nature of formic acid, is introduced beneath the skin by some penetrating organ, which may be connected with the mouth or with the terminal segment of the abdomen, and is in some animals—as bees, but less frequently wasps—torn out and left in the wound when the sting is inflicted.

EFFECTS.—The introduction of the poison of a stinging vegetable or animal is followed, either immediately or within a very short time, by erythema of the affected part, the surface being red, swollen, and exhibiting all degrees of pain and tenderness. If a mucous membrane, as of the mouth, be the seat of the wound, the swelling is intense, the tongue cannot be protruded, and swallowing becomes difficult or even impossible. Nor are the results limited to the locality of the sting, the erythema often spreading to a considerable extent, from the hands or face, which are obviously the most frequent starting-point, to the arms, neck, and trunk, sometimes presenting the appearance of a scarlatiniform or urticarial eruption. Associated with the local manifestations, general symptoms, often of a most severe and even fatal character, have been known to occur. Well-authenticated cases of death from the stings of bees, wasps, scorpions, and even some species of tropical nettles, have been placed on record. In the majority of such cases the poison has brought on a state of syncope; severe prostration, pallor, and pulselessness being the most general symptoms; and death has been known to occur within a quarter of an hour, or from that to a few hours. Other cases, especially of scorpion-stings, are characterised by excitement and some delirium; and tetanic spasms even sufficient to cause death have been not infrequently known to follow the stings of bees, wasps, and spiders (see **TARANTISM**). When the case does not prove fatal, recovery is generally rapid and the patient is quite well in a day or two; but this is not always so, and the effects of some nettles, for example, *Urtica urentissima*, the Devil's Leaf of Java, are said to last for years.

TREATMENT.—(a) *Local.*—Innumerable applications have been suggested as specifics in cases of

stinging. Their efficacy, without doubt, depends mainly upon their being applied to the seat of the sting quickly after infliction. The *modus operandi* of many is quite empirical, but others would seem to decompose the irritating material, and so prevent or arrest its effects. Among those most generally resorted to are alkalis, such as liquor ammoniæ or strong solutions of bicarbonate of sodium or potassium; and it is probable that many popular remedies, such as soap, the 'blue-bag,' &c., depend for their effect upon the alkali they contain. Concentrated solutions or even the pure crystals of alum, and tartaric or other vegetable acids, often afford distinct relief if rubbed in at the site of the sting. The bruised leaves of plants such as the dock, or the juice of a raw onion, applied similarly, will act in the same way. For the more serious stings of tropical plants and animals, more potent remedies are necessary, such as the application of lint soaked in chloroform and laid over the wound; poultices of ipecacuanha, or preferably an extract of the same drug made by mixing equal parts of powdered ipecacuanha, rectified spirit, and ether; or rubbing the part with hydrate of chloral—pure, or liquefied by mixture with camphor, in the proportion of three parts of the former to one of the latter. Menthol-camphor will also relieve the pain and irritation; carbolic oil (1 in 20), or even subcutaneous injections of carbolic acid, have been used. The aromatic oils of pennyroyal, lavender, cloves, or cinnamon smeared over the hands and face, are most effective in preventing the attack of mosquitoes, gnats, &c., and often give relief when applied to the stung part.

In the case of bee-stings it is important to search for and remove any parts of the penetrating organ which may have been left in the wound.

(b) *General*.—When symptoms of prostration or collapse are produced, stimulation with brandy, ammonia, or ether is an absolute necessity, and one or other of these should be administered without stint, as recovery undoubtedly depends on counteracting the cardiac depression.

W. H. ALLCHIN.

STITCH.—A sharp catching pain in the side, generally associated with pleurisy, pleurodynia, or intercostal neuralgia. See PLEURA, Diseases of.

STOKES-ADAMS DISEASE. — See ANGINA PECTORIS; and BRADYCARDIA.

STOMACH, Diseases of.—The diseases of the stomach will be considered in the following order:

- Clinical Examination of, p. 1588.
- Atrophy and Degeneration of Glands of, p. 1592.
- Cirrrosis of, p. 1593.
- Concretions in, p. 1594.
- Congenital Pyloric Hypertrophy of, p. 1594.
- Dilatation of, p. 1595.
- Functional Disorders of, p. 1597.
- Inflammation of, p. 1602.
- Malposition of, p. 1607.
- Morbid Growths of, p. 1608.
- Neuroses of, p. 1612.
- Perforation of, and its Results, p. 1619.
- Ulceration of, p. 1621.

The following articles on cognate subjects appear in alphabetical order in other parts of the Dictionary: ABDOMEN; ALIMENT; ANTACIDS; APPETITE; CARMINATIVES; DIET; DIGES-

TION; EMETICS; EPIGASTRIC PAIN; FLATULENCE; FOOD, POISONOUS; FORCIBLE FEEDING; HÆMORRHAGE; LAVAGE; NAUSEANTS; PAIN IN VISCERAL DISEASE; PEPTONISED FOOD; PERSONAL HEALTH; PHYSICAL EXAMINATION; STIMULANTS; VOMITING.

STOMACH, Clinical Examination of the. The subject will be considered under the headings of (1) *Physical Examination*; and (2) *Examination of the Functions*.

1. **Physical Examination**.—The shape and relations of the stomach are shown on p. 1242. Its average capacity is from 35 oz. to 40 oz.; a capacity of three pints is to be considered as pathological.

Physical examination of the abdomen gives no sign when the stomach is normal and undistended. After a large meal, more especially with much liquid, the organ forms, in some cases, a distinct mass in the epigastric region, the borders of which, however, cannot be defined. The peristaltic movements of the healthy organ are never visible, nor can they be rendered visible by manipulation. Succussion of the normal stomach produces no splashing. As digestion proceeds and finishes, the organ empties itself, and the prominence of the epigastrium disappears.

In disease, a physical examination must be directed to determining the size, both before meals and after meals, as well as alterations in position of the organ.

The body of the enlarged stomach sometimes forms a globular tumour in the front of the abdomen. It may be situated in the epigastrium, or in the umbilical region, as in cases of gastroptosis. Palpation of the tumour reveals an elastic mass, of which the upper edge cannot be defined; although in some cases the greater curvature may be felt as a transverse line of resistance below the umbilicus. Visible peristalsis may be observed in this tumour, either spontaneous, or elicited by friction with the palm of the hand. The wave of contraction passes downwards from the left hypochondrium towards the umbilicus, and in the course of its progress, which is slow, the tumour may appear divided into two or more globular masses. Visible peristalsis, in the position and of the character above stated, indicates dilatation of the stomach secondary to stenosis of the pylorus or duodenum. It is only evident when the stomach is distended with gas or liquid, or both.

A succussion-splash may be brought out by palpation, either below the left hypochondrium, on a level with the umbilicus or to the left of the umbilicus. The succussion-splash may be absent in cases of dilated stomach, when the organ is empty and flabby. When present, it shows the presence of dilatation of the organ, but it is no guide to the degree of dilatation, since it may be obtained in cases of myasthenia, with only slight dilatation, as well as in cases of great dilatation, due to pyloric obstruction. In cases of myasthenia (atony), the occurrence of this physical sign in relation to the meals is of importance. It is usually absent before meals, and is observed best from two to three hours after a meal. In advanced cases of dilatation of the stomach it is often constantly present, but the stomach may be so distended that no splash can be obtained. The sign is elicited by placing the left hand to the right of the umbilicus, and the other to the left, slightly below. A sudden jerk of the right

hand will cause the splashing, which may be elicited by the patient himself if he suddenly contracts the diaphragm.

Pulsation in the epigastrium may be present in dilatation of the stomach, and, if the organ is full of liquid, a systolic epigastric thrill may be felt. The sign is, however, of no great importance.

Percussion by itself is of no value in the diagnosis of stomach-conditions. A tympanitic note is obtained over the enlarged stomach distended with gas, but neither the size of the organ nor the existence of dilatation can be diagnosed by this means, inasmuch as the transverse colon, when distended with gas, may occupy the epigastrium, pushing the stomach upwards. In normal conditions, a tympanitic stomach-note is not obtained in the axillary region. When the stomach is dilated and distended with gas, a tympanitic note is obtained in the left axillary region, backwards as far as the posterior axillary line, and upwards as far as the fourth rib, and over this area a bell-sound may frequently be heard by auscultatory percussion. The presence of a tympanitic note in the axillary region is usually only a temporary condition. A permanent stomach-note may, in some cases, be present in this region, as when the fundus of the stomach is adherent to the diaphragm, and is dragged upwards by chronic disease of the left lung and pleura, as in some cases of pulmonary tuberculosis. The presence of gas in the stomach is a great aid to the diagnosis of its size, and, for the purposes of diagnosis, it may be necessary to distend the stomach artificially. This may be done, either by pumping in air through a stomach-tube, or more readily by making the patient drink fifteen to thirty grains of citric acid dissolved in half a tumbler of water, and, immediately afterwards, the same amount of bicarbonate of sodium dissolved in a similar amount of water. The carbonic acid evolved distends the organ and facilitates examination.

Auscultation is of no value by itself in the recognition of enlargement of the stomach. The splashing of fluid may be heard, and if the patient be given some water (2 or 3 oz.) to drink, the liquid may be heard to fall into a dilated stomach distended with gas, with a characteristic sound. This is not a sign, however, of much value.

More is learnt by a combination of auscultation and percussion, that is, by placing the end of the stethoscope over the stomach-area, below the left hypochondrium, and either percussing or tapping with two coins in radial lines below the stethoscope. If the stomach contains gas, the area over which the percussion is heard, or the bell-sound, gives a very fair idea of the size of the organ. By this means, too, in many cases, as when the sound is obtained from the axillary region, distension of the colon may be distinguished from dilatation of the stomach.

Examination for Tumours of the Stomach.—The commonest tumour of the stomach is situated at the pylorus, and, in not a few cases, this can be recognised through the abdominal wall. The tumour may be fixed behind the liver, and only appear below the edge, or it may be felt as an indefinite thickening to the right, and above the umbilicus. In cases where the pyloric tumour is freely movable, it may be from time to time detected, even if the patient is lying on the back, but a useful method of examination, in such cases, is to palpate the abdo-

men with the patient lying on the left side, with the knees drawn up. The movable tumour then tends to fall downwards and to the left, and can readily be felt. A stomach distended with liquid or gas may push the tumour up behind the liver, so that emptying the organ may be of value in the examination. The first segment of the right rectus muscle is frequently a bar to a recognition of tumours in the upper part of the abdomen. Sometimes patience and a little manipulation will overcome this difficulty, but, in other cases, it is necessary to give the patient an anæsthetic in order to make a complete examination. Tumours of the cardiac end are sometimes felt below the left hypochondrium, and the contracted stomach, in diffuse carcinoma, may be felt as a pyriform, or oval tumour, across the epigastrium.

Internal Examination of the Stomach.—Distension of the stomach artificially with gas has already been described as an aid to the diagnosis of the size of the stomach by external examination. The amount of liquid which the stomach can contain is also a valuable aid in the diagnosis. This is, in some cases, simply gauged by the large amounts of liquid matter (over three pints) which the patient will bring up at one time; but, in other cases, it has to be determined by putting liquid into the stomach and regaining it. This is done through a soft stomach-tube, with a syphon-arrangement. Water, which has been boiled, is slowly added through the funnel, to the amount of three or four pints, the amount being gauged by the sensations of the patient, any attempt at vomiting or sensation of great abdominal distension being an indication to stop the filling. The liquid must now be syphoned off, and it may be found that more is obtained than was put into the stomach, making the total capacity of the stomach over three pints. All the liquid cannot be regained by syphoning, but most of it can be made to return by placing the patient on the left side, and expressing the contents of the stomach by manipulation of the abdomen from right to left. In some cases of hour-glass stomach where physical signs show a dilated organ, much less liquid may be obtained by syphonage than was put in. This occurrence suggests the diagnosis of hour-glass contraction.

Electric illumination of the stomach by means of the electrophane is not of great value in the diagnosis of the size of the stomach, as this can usually be detected by other means. It does, however, show the size of the organ, and may prove of value in the diagnosis of unusual conditions, such as hour-glass contraction.

2. Examination of the Functions.—The functions of the stomach are divided into (1) the movements; (2) the absorption of its contents; and (3) the chemical processes occurring in its interior.

In some cases it is necessary to determine the capabilities of the stomach by means of a test-meal. It is not of much value obtaining the gastric juice by artificial means, such as the injection of ice-cold water into the stomach, inasmuch as what is required to be known is the activity of the stomach during the digestion of a meal. Ewald's test-breakfast consists of 35 grms. of bread and one-third of a litre of water; it is of value in determining whether the gastric juice is secreted in response to the stimulus of food, but it is not of much value in determining the prolonged activity of the functions of the organ. A better meal is one consisting of about 5 oz. of beefsteak, 2 to 3 oz. of bread, and

half a tumblerful of water at the end of the meal. The patient is allowed to rest after the meal, and, in four to five hours, a portion of the stomach-contents is removed; this shows disintegration of the muscle-fibres, and the presence of hydrochloric acid and peptones. In six or seven hours the digestion ought to be completed. Such a test is of importance in certain cases of prolonged indigestion of food, where there is great diminution of function of the stomach (see p. 1600). It may also be of service in early cases of carcinoma of the stomach, for the determination of the amount of hydrochloric and organic acids present, as well as in neuroses of the organ.

(1) *Test for the Mechanical Power of the Stomach.* The test-meal serves as a guide to the mechanical power of the stomach, but other methods have been devised, none of which are of much value. (a) *Salol-test.* Salol is decomposed by the pancreatic juice into salicylic acid and carbolic acid. The salicylic acid is excreted in the urine, and can be recognised by the reddish-violet colour produced by the addition of a solution of ferric chloride. To test the mechanical power of the stomach fifteen grains of salol are given in a gelatine capsule, just after the mid-day meal. In healthy individuals, the salicylic-acid reaction appears in the urine in thirty to ninety minutes. Delay in the reaction has been ascribed to diminution of the mechanical power of the stomach, or to stenosis, owing to the drug not being expelled through the pylorus. It is evident that, for the test to be of any value, it is necessary to suppose that the pancreas, the intestinal mucous membrane, and the kidney are performing their functions in a normal manner. (b) *Oil-test.* It has also been attempted to test the mechanical power by means of 100 grammes of oil, placed in the stomach through the tube. In two hours the stomach is washed out, and the residue of oil estimated. Seventy to eighty per cent. of the oil ought to be discharged into the duodenum in two hours under normal conditions. This is not a method, however, which is applicable clinically.

(2) *Testing the Absorptive Power of the Stomach.* This has been attempted by means of iodide of potassium, three grains of which are given in a gelatine capsule, three ounces of water being drunk afterwards. The iodide can be detected in the saliva in about ten minutes, by adding a little fuming nitric acid, which sets free the iodine, which may be dissolved in chloroform, or turned blue by the addition of starch. The delay in absorption was found to be great in dilatation and carcinoma of the stomach, but less in chronic catarrh and in ulcer. The fallacy of the method, however, is that it is only a test for the absorption of iodide of potassium, which undergoes but little change during its passage through the mucous membrane. It is not a test of the absorption of proteids or sugar by the stomach, as these substances undergo a transformation while passing through the mucous membrane; their method of absorption being totally different from that of iodide of potassium.

It may be affirmed that not much advantage clinically is obtained by these methods of testing either the mechanical power or the absorptive capacity of the stomach. Diminution of absorption is seen in the retention of liquid in the organ; diminution of mechanical power is shown by dilatation. The best method of determining alteration in these functions is by means of a test-meal.

(3) *Examination of the Stomach-Contents and of Vomited Matters.*—The examination of these liquids frequently gives very valuable information regarding the process of digestion in the diseased stomach. The presence of undigested food long after a meal has been taken shows deficiency in function of the organ, and may indicate some degree of obstruction in the pylorus or duodenum. A diminished quantity of hydrochloric acid is an indication of diminution of function, and the determination of this diminution is important in gastric catarrh, in atrophy of the glands, and in cancer. An increase in acidity, due to hydrochloric acid, is a sign of irritation of the stomach, and occurs in functional disorder, in some cases of ulcer, in some cases of non-malignant obstruction of the pylorus, and in obstruction of the duodenum. The presence of mucus indicates irritation or catarrh; the presence of pus indicates an abscess in the walls of the stomach, or one perforating the coats from outside. The presence of blood indicates either a local condition, such as gastric catarrh, ulcer, or carcinoma, or cirrhosis of the liver, or a general condition, such as occurs in the profound anæmias, and in some specific febrile disorders. The presence of a large amount of organic acids (lactic, butyric, acetic), as well as that of micro-organisms, shows bacterial decomposition of the stomach-contents, the most frequent causes of which are prolonged gastric catarrh and obstruction of the pylorus.

The stomach-contents must be examined for: (a) the presence of undigested food; (b) the presence of micro-organisms; (c) the presence of mucus, pus, and blood, and fragments of new-growth; (d) the total degree of acidity; (e) the character of the free acids present (hydrochloric, lactic, butyric, acetic); (f) the presence of the products of digestion (albumoses and peptone); (g) the presence of pepsin and the curdling ferment. The methods which will be described are those easy of performance, and which can be done as ordinary clinical tests.

(a) *Undigested food* must be examined microscopically to determine the amount of digestion of muscle-fibre and of starch, and by dilution to determine the presence of any large masses of undigested matter. This is carried out by diluting the stomach-contents with a large amount of water in a beaker; after stirring the mixture and allowing it to settle, the supernatant liquid is poured off, and the sediment again washed, until only the largest particles are left. In this way it may be found that there are large masses of vegetable-fibre in the stomach-contents long after food has been taken, and even many days after the eating of fruit or vegetables. In such a case, their presence is suggestive of pyloric stenosis. Small fragments of new-growth may also be detected in this way.

(b) *Microscopical examination for bacteria* is, as a rule, sufficient from a clinical standpoint. Cover-glass preparations, carefully dried and stained with methylene-blue, may show the presence of bacilli and cocci, or torulæ and sarcinæ. The presence of any demonstrable number of bacteria or sarcinæ in the recently evacuated stomach-contents is a sign of bacterial fermentation in the stomach. This occurs in cases of gastric catarrh, in some of the rare cases of atrophy of the glands, but, more particularly, in pyloric and other obstruction. Bacteria are not seen in microscopical preparations of the stomach-

contents in cases of irritation of the organ due to irregularities in diet, or in cases of ulcer. In some cases where there is no bacterial fermentation, yeast-cells may be seen, especially when bread has recently been eaten, but the cells are obviously not budding; that is, they are in the resting stage.

(c) The *mucus* present in the vomit may be derived either from the bronchial tubes and pharynx, or from the stomach itself. The difference rests in the fact that mucus from the bronchial tubes and lungs is pigmented, while that secreted by the stomach is translucent and unpigmented. Only in cases of prolonged catarrhal inflammation of the stomach is pigmented mucus seen. The mucus which comes from the stomach may be tinged with blood, showing a diffuse lemon colour or streaks of red or dark blood. Mucus is found in the vomit and stomach-contents in cases of hyperchlorhydria and catarrh, and in some cases of pyloric cancer, but a large amount of mucus is found only in catarrh; most of it is not vomited, but is passed in the motions in long strings, as the stomach-mucus is not digested in any part of the alimentary tract.

Pus is to be recognised microscopically. It is frequently present in the vomited matters as mucopus, from the pharynx, bronchial tubes, or lungs. It comes from the stomach only in the rare cases of abscesses, local or diffuse, of the stomach-wall, and is, in these cases, not mixed with mucus, as is the pus from the lungs. Cover-glass preparations are best stained with methylene blue.

Blood in the vomit may come from the lungs or the stomach, and is discussed elsewhere (see p. 620). It may, however, be noted that the guaiacum- and hæmin-tests (p. 622) are quite unreliable, and that the best test for the presence of blood, especially in a case of coffee-ground vomiting, which is the only condition difficult to diagnose, is the Prussian-blue test for the presence of iron. This is easily performed by adding to some of the black sediment in a porcelain capsule a small quantity of chloride of potassium and a few drops of strong hydrochloric acid. The mixture is heated over the flame, and becomes greenish-yellow; the addition of a few drops of solution of potassium ferrocyanide (5 per cent.) causes the development of Prussian blue, if blood is present. The patient must, of course, not be taking any preparation of iron. Other dark colouring matters in vomit (such as wine or tea) are, unlike blood, soluble in alcohol.

(d) *Determination of the total degree of acidity.*—The total degree of acidity of the stomach-contents is due to acid salts, to acids in combination with the proteids, and to free acids. The free acidity may be due to hydrochloric acid alone, or to hydrochloric acid in addition to one or more organic acids (lactic, acetic, butyric), or it may be due to organic acids alone. The acid in combination with proteids is chiefly hydrochloric acid, but organic acids, to some extent, also combine with proteids. The determination of the total acidity is done as follows: A 1-per-cent. solution of phenol-phthalein is used as an indicator; it is slightly yellow, and is turned red by alkalis. The stomach-contents are shaken up in a bottle until completely broken up: 20 c.c. are taken, and 8 drops of the solution of phenol-phthalein are added. Water is then added up to 300 c.c. 150 c.c. of this mixture is placed in each of two flasks, and

to one flask decinormal solution of sodium hydrate ($\frac{N}{10}$ NaHO) is added, until a pinkish tinge appears; the acid liquid is now neutralised, and a control estimation may be made with the other flask. The decinormal solution of sodium hydrate contains four grammes of sodium hydrate to the litre. This exactly neutralises 3.65 grms. of hydrochloric acid. The acidity may be expressed in terms of hydrochloric acid. Thus, if 5 c.c. of the decinormal solution neutralises 10 c.c. of the stomach-contents, 50 c.c. would neutralise 100 c.c. of the stomach-contents. This would be equal to an acidity of 0.1825 gramme per cent. of hydrochloric acid. The total acidity is, however, not always expressed in terms of hydrochloric acid, but sometimes as a number of cubic centimetres of the sodium-hydrate solution required to neutralise 100 c.c. of the stomach-contents.

(e) *Determination of Acidity due to Hydrochloric Acid and to Organic Acids.*

Hydrochloric Acid.—Free hydrochloric acid exists in the stomach-contents in combination with proteids (albumoses, peptone), and uncombined. Hydrochloric acid also exists as chlorides. The first two forms indicate the hydrochloric acid secreted by the stomach in the gastric juice.

Colour-Tests for Free Hydrochloric Acid.—The colour-tests which have been devised show the presence only of free hydrochloric acid, namely, that which is not combined with proteids. The two chief solutions are as follows: *Gunsberg's solution*, consisting of phloroglucin 2 grms., vanillin 1 grm., absolute alcohol 30 c.c.; *Boas's solution*, consisting of 5 grms. of resorcin, with 3 grms. of cane-sugar, in 100 c.c. of weak spirit. Both these solutions are used in the same way, and give the same result. A drop is mixed with a drop of the stomach-contents, placed in a porcelain dish, and evaporated to dryness in a water-bath. If free hydrochloric acid be present, a rose-red colour is developed, due to the formation of red crystals. As little as 0.05 per cent. of hydrochloric acid may be detected in this way. These and other colour-reactions for the presence of free hydrochloric acid are, however, of no great clinical value. As soon as the hydrochloric acid is secreted, it combines with the proteids present in the food, and the colour-tests indicate only the excess of acid which is not so combined. The absence of reaction, therefore, does not indicate that the stomach secretes no hydrochloric acid; indeed, a large quantity may be secreted, and yet its presence will not be indicated by the colour-reactions. Tested in this way, some samples of stomach-contents will give the reaction, and some will not, and, if reliance is placed on the colour-reaction alone, false deductions regarding the functions of the stomach will be made. The only serviceable plan is to estimate the total amount of free hydrochloric acid, that is, both the acid which is free, and that in combination with proteids.

Method for estimating total amount of Free Hydrochloric Acid.—Several methods have been devised; the one given here is Lüttke's. The total quantity of chlorine is first estimated, and then the quantity of fixed chlorides, after the free hydrochloric acid has been driven off at a red heat. Subtracting the second result from the first gives the amount of chlorine not in combination.

The solutions used are: (1) Decinormal solution of silver nitrate, containing 16.997 grms. of pure silver nitrate, dissolved in 100 c.c. of 25-per-cent.

nitric acid; 50 c.c. of the liquor ferri persulphatis are added, and the mixture diluted with water to a litre. (2) Decinormal solution of ammonium sulphocyanide, containing 7.6 grms. of the salt to the litre. This solution, added to the solution of silver nitrate, gives in excess a reddish colour. It must be standardised against the silver solution, so that on mixing 10 c.c. of each solution a reddish colouration just appears. The analysis is carried out as follows: To 10 c.c. of the shaken gastric contents 20 c.c. of the silver solution are added. After standing for a few minutes, the mixture is diluted to 100 c.c. and filtered through a dry filter. The precipitate on the filter contains the chlorine in combination with silver, while the filtrate contains the excess of silver solution used. This excess is estimated by taking 50 c.c. of the filtrate, and adding the sulphocyanide solution until a red colour appears. The number of cubic centimetres multiplied by two equals the number of cubic centimetres of silver solution used in excess. Thus, if 5 c.c. of the sulphocyanide solution were used, the excess of silver solution = 5×2 , and the amount of silver solution used = $20 - (5 \times 2) = 10$ c.c.

The estimation of the fixed chlorides is as follows: 10 c.c. of the gastric contents are carefully evaporated to dryness in a platinum capsule; the residue is ignited until it no longer burns with a flame, and is then ground up with 100 c.c. of boiling distilled water to extract the chlorides. The liquid is filtered, and to the filtrate 10 c.c. of the silver solution is added. The excess of silver solution used must be estimated as in the first process. The amount of hydrochloric acid is determined as follows: The number of cubic centimetres of silver solution used in the second estimation is subtracted from the number obtained in the first; multiplying the difference by 0.0365 gives the weight of hydrochloric acid present in 100 c.c. of the gastric contents. Thus, if the first estimation gives 10 c.c. and the second 5 c.c., $10 - 5 = 5 \times 0.0365 = 0.1825$ gm. per cent. HCl. The whole estimation takes about an hour to perform.

Determination of the Organic Acids present.—These are usually lactic, butyric, or acetic acid, chiefly the two former. Acetic and butyric acids are volatile, while lactic acid is fixed. The total amount of organic acid present may be roughly estimated by subtracting the acidity due to free hydrochloric acid from the total acidity. The nature of the acids present is determined in the following manner: 50 or 100 c.c. of the stomach contents are shaken up with an equal volume of ether, and after standing for a time, the ether is poured off. A second and third extraction with ether is made, and the ethereal liquids allowed to evaporate in an open dish. If the residue is acid to test-paper, it may be mixed with a little warm water, and the following reactions performed.

Test for Lactic Acid.—The test-solution is made by adding one or two drops of liquor ferri perchloridi to 50 c.c. of water. The mixture is almost colourless, but, on the addition of lactic acid, becomes yellow. Another test-solution consists of one or two drops of liquor ferri perchloridi added to 30 c.c. of 1 in 60 carbolic-acid solution. The blue liquid which results is changed to a clear yellow, or greenish-yellow, by a trace of lactic acid.

Test for Butyric Acid.—This has a pungent smell like rancid butter. To the liquid to be tested add a small quantity of alcohol and two drops of strong

sulphuric acid. On heating, there is a characteristic smell of butyric ether.

Test for Acetic Acid.—Perchloride of iron gives a blood-red colour, and the nauseous pungent smell of cacodyl is developed when potash and a little arsenious acid are added to the liquid containing it, and the mixture evaporated in a test-tube.

It is important to estimate the total amount of free hydrochloric acid in the stomach-contents in cases of hyperacidity due to excessive secretion of hydrochloric acid, and in cases where there is a diminution in the secretion, more particularly in cases of gastric catarrh and in cancer of the stomach. The presence of a large amount of organic acids in the stomach-contents, or in the vomit, shows the occurrence of bacterial fermentation in the stomach. A small amount of organic acids (chiefly lactic and butyric) is derived from the food.

(f) *Determination of the presence of digestive products.*—The presence of albumoses and peptone in a liquid coming from the stomach shows that the organ is capable of secreting active gastric juice. A necessary precaution must be observed in ascertaining whether peptonised food is being taken or not. Albumoses and peptone are usually to be found in the vomited matters, unless vomiting occurs soon after food has been taken. In cases of obstruction of the lower end of the oesophagus, the regurgitated liquid, which is sometimes in large quantity, does not contain these substances, since the food has never entered the stomach, and the examination for albumoses may thus be of great importance from the point of view of diagnosis. They are tested for as follows: If the stomach-contents are very acid, they must be neutralised by sodium hydrate, and filtered. To the filtrate a trace of Fehling's solution may be added, and an excess of liquor potassae. If albumoses are present a pink colour develops (biuret reaction). See p. 35.

(g) The determination of the presence of pepsin and of the curdling ferment in the stomach-contents is not of great clinical importance.

SIDNEY MARTIN.

STOMACH, Atrophy and Degeneration of the Glands of.—Degeneration of the glands of the stomach may be secondary to inflammation, or it may be non-inflammatory. The inflammatory conditions which lead to degeneration are the ordinary forms of gastric catarrh or gastritis, as well as toxic gastritis (due to irritant poison) and bacterial gastritis. With the non-inflammatory causes a primary atrophy has been described. Fatty degeneration of the glands also occurs in some cases of cancer of the stomach; more rarely in ulcer, and it may occur in tuberculosis. The glands may also be fatty in poisoning by phosphorus and arsenic, and in some of the profound anæmias, more particularly pernicious anæmia. Amyloid degeneration of the mucous membrane of the stomach may also occur.

PATHOLOGICAL ANATOMY.—Degeneration of the glands, seen as the result of inflammation, consists, in some cases, almost solely of fatty degeneration of the secretory cells. In other cases, however, there is an increase of interstitial fibrous tissue, and the glands atrophy partly from pressure. Cysts may be formed, but these are, as a rule, not numerous: cystic formation is usually associated with some increase of interstitial tissue. The gross injury which is done to the mucous mem-

brane by irritant poisons leads to its destruction over large areas, and to an increase of interstitial tissue. In this case there is, as a rule, no universal degeneration of the glands. In some cases, especially over the pyloric portion of the stomach, the mucous membrane is in a polypoid condition (*état mamellonné*). One part of the mucous membrane may be quite normal, and adjoining it is an area smooth, thin, and atrophied, while at another part there are projections, or polypi, varying in diameter from one or two lines to a quarter or half an inch. The chief change in the mucous membrane, besides destruction of the glands, is an increase of fibrous tissue; small cysts may also be formed.

Primary atrophy of the stomach is not a common disease, and some of the cases may probably have been mistaken for inflammatory degeneration. The walls of the stomach are greatly thinned in some cases, so as to be semi-transparent, the normal appearance being a whitish-yellow opaque mucous membrane folded into rugæ. The organ is dilated, and more or less empty, and there is no *post-mortem* digestion of the mucous membrane, there being but little gastric juice secreted. Microscopically all the coats of the stomach are seen to be affected; the glands are in an advanced stage of degeneration; in many parts absent, in other parts shown only by fatty granules.

The so-called primary atrophy, therefore, is associated with fatty degeneration of the secretory cells. This is the same with the fatty degeneration which occurs in cases of cancer anywhere in the body, in cases of tuberculosis, of pernicious anæmia, and of poisoning by phosphorus and by arsenic. In these cases there is no apparent increase of interstitial fibrous tissue.

Amyloid degeneration occurs chiefly in long-standing cases of pulmonary tuberculosis and of syphilis, and in cases of prolonged suppuration. It affects the vessels of the sub-mucous and mucous coats, and the muscular fibres and the connective tissue between the glands. The glands themselves degenerate; some of the cells being hyaline, others fatty, while the nuclei have for the most part disappeared.

CONDITION OF DIGESTION.—In all cases of degeneration of glands of the stomach there is a diminished secretion of gastric juice, both of hydrochloric acid and of pepsin, and a diminished motor activity. Not only, therefore, are the chemical processes of digestion very inefficiently performed, but the stomach is unable to empty itself. Dilatation of the organ results. The absorptive processes are also deficient.

SYMPTOMS.—The symptoms referable to the stomach in degeneration of the mucous membrane vary according to whether the degeneration is due to a chronic inflammatory process, or whether it is non-inflammatory. In the former case symptoms of irritability of the organ may be present, as shown by pain and vomiting. In the latter case the symptoms of irritation are absent, and the chief sign is an inability to take food, except in a liquid or predigested form. The symptoms due to the inflammatory degeneration are discussed elsewhere. With the exception of primary atrophy other degenerations are associated with some profound disease, or some form of poisoning, as by phosphorus or arsenic, and the general disease, such as cancer, tuberculosis, or pernicious anæmia,

to a great extent masks the changes in the stomach. Primary atrophy of the stomach occurs chiefly in patients beyond middle age. Thus, of thirteen cases recorded by various observers, six were over sixty years of age, four were between the ages of thirty and fifty, and three between the ages of nineteen and thirty. In such cases there is inability to take solid food, and there is great wasting and anæmia. It cannot be considered that, in most of the cases, the mere atrophy of the mucous membrane was the cause of death. An animal or man can exist without a stomach, and in primary atrophy of the stomach there is also probably an associated degeneration of the other digestive glands, or some general disease, such as granular contracted kidney.

DIAGNOSIS AND TREATMENT.—In many cases of so-called primary atrophy a diagnosis is not made during life. The chief disease which may be mistaken for it is Addison's disease, when there is no pigmentation. The absence of fever, the great prostration, the wasting, and the feeble pulse, are points of similarity. Vomiting, however, occurs in Addison's disease, and cases without pigmentation are rare. The treatment is by means of predigested food, and by rectal injections; in these ways the patient may be enabled for a time to take a sufficiency of nourishment.

SIDNEY MARTIN.

STOMACH, Cirrhosis of the.—**SYNON.:** Hypertrophy of the Stomach-Walls; Chronic Interstitial Gastritis; *Fibrosis Ventriculi*; Sclerotic Gastritis.

Cirrhosis of the tissues forming the stomach-wall is generally one of the later results of protracted chronic gastritis. Occasionally it would appear to occur apart from any antecedent gastritic affection. The more localised hypertrophy of the muscular coat in the pyloric region of the stomach, which is associated with stenosis and simple enlargement of the pylorus, is of a somewhat similar nature, though of different origin.

When *cirrhosis ventriculi* follows chronic gastritis, in addition to hyperplasia of the connective and muscular tissues, some atrophy of the mucous membrane is often present, a legacy from the earlier lesion. Otherwise the mucous membrane may be normal.

ÆTIOLOGY.—Cirrhosis of the stomach is by no means a common disease. According to some authorities it shows a preference for men, to others for women; the weight of evidence available inclines towards its greater frequency in males. It is a disease of the middle-aged. Brinton states the average age of its occurrence as thirty-four, and that of cancer as fifty.

Its mode of causation is unknown. Alcohol, misused, has been blamed, but the disease has attacked rigid teetotallers; traumata or irritation from gastric ulcerations have been accused of causing it. Perhaps the most probable hypothesis, provided that chronic gastritis has not previously existed, is that the excessive development of fibrous and muscular tissue forms but one among many possible manifestations of a constitutional predisposition towards fibroid change; similar to the lesions which occur without evident cause in the liver, kidney, spleen, and other organs. Many of the most severe and prolonged examples of chronic gastritis fail to develop any marked degree of hyper-

trophic cirrhosis, however pronounced the atrophy produced may be; others, without adequate cause being shown to account for the difference, proceed to hypertrophic cirrhosis under apparently identical circumstances. Usually of long duration, up to fifteen years in some instances, it may run a rapid course and prove fatal in a few months. The dividing line, however, between the later stages of all types of chronic gastritis and gastric cirrhosis is often largely hypothetical, unless the term 'cirrhosis' be only applied to those cases wherein undoubted hypertrophic and cirrhotic changes, affecting rather the submucous and muscular layers than the mucosa, exist, and to all appearance exist primarily.

MORBID ANATOMY.—As in other organs, cirrhosis of the tissues of the gastric walls implies hyperplastic increase of the connective tissue, to the detriment of the muscular and glandular elements. But unlike the common accompaniment of chronic gastritis this increase invades all the coats of the stomach-wall, except the mucosa; the outer coverings are sclerosed, the inner only affected secondarily. In time the submucosa, muscular and peritoneal layers become so gravely involved that almost all power of movement is lost, followed consequently by deterioration of digestive function, degeneration of the glands, contraction of the organ, and finally invasion of the mucosa.

SYMPTOMS.—Primary cirrhosis of the stomach presents few pathognomonic symptoms. The condition is rarely diagnosed *ante mortem*. The symptoms common to chronic gastritis are also common to it with but slight variation. Chief among these may be placed epigastric pain and tenderness; emesis; diminished gastric function, accompanying, and due to, hypochlorhydria; and in the more advanced cases hypopepsia. The capacity of the organ is small, nor can it be dilated by any of the methods employed for such purpose. Appetite fails gradually. Slight hæmatemesis sometimes occurs. The symptoms are generally closely associated with the taking of food.

The physical signs present are seldom sufficiently distinct to afford definite evidence of the true nature of the disease before an advanced stage has been reached. Then, on palpating the abdomen, a tender firm mass can be detected either lying obliquely from the left hypochondrium down to the middle line, or transversely in the lower epigastrium.

DIAGNOSIS.—Cancer of the stomach *en cuirasse*, with extensive infiltration of the walls, presents so similar a clinical picture that perhaps the only appreciable point of difference between it and cirrhosis ventriculi obtains in the duration of the disease. If the tumour persists for more than three years, it is probably of simple type. Peritoneal tumours may simulate cirrhosis of the stomach, but physical examination of the gastric contents and motility suffice to distinguish them.

Foreign bodies in the stomach in large accumulation offer some faint resemblance to this condition; usually met with in the insane and neurotics, local tests readily serve to prove the true nature of the lesion.

PROGNOSIS.—A complete cure can never be looked for where cirrhosis of the stomach-walls has become established; the earlier attention is drawn to the condition, and the sooner the patient regulates his diet and habits as advised, the greater the chance will be of checking further progress of the disease, and of assuring a fairly comfortable future for him

for some years. But in some cases rapid progress of the symptoms from the date of their first recognition tells only too clearly that no favourable result can be hoped for.

TREATMENT.—As the stomach is small, and has lost much of its motile power, food must be taken in small quantities, and be in liquid form. Milk and meat-extracts or soups are best suited for administration. The state of the bowels must be carefully attended to; no stimulants allowed. Opium is often required to soothe the distress. Otherwise treatment is symptomatic.

ALEXANDER LOCKHART GILLESPIE.

STOMACH, Concretions in.—Concretions in the stomach are composed of various indigestible substances that have been swallowed, such as hair, paper, cotton, cocoa-nut fibre, &c. They chiefly occur in idiots and lunatics. In some of the cases recorded a tumour has been observed during the life of the patient, which in one case was mistaken for a floating kidney. Concretions of this kind may give rise to perforation, but more generally they set up inflammation of the mucous membrane, followed by peritonitis. See CONCRETIONS.

STOMACH, Congenital Pyloric Hypertrophy of.—This condition, the origin of which is a matter of doubt, has only been recognised within recent years. It is met with in new-born infants, and usually consists in so great a measure of hypertrophy of the coats which combine with the pyloric sphincter to form the pylorus that the passage of the gastric contents into the duodenum is almost or wholly arrested.

The victims of this abnormality generally exhibit no sign of ill-health during the first few days of life, save that the milk ingested is rather more apt to be returned in part than normally. After an interval, of variable duration, has elapsed since birth, a few days or, it may be, a few weeks, everything swallowed is rejected either at once or from half an hour to an hour afterwards; no therapeutic measures have the least effect on the vomiting; the infant gradually grows weaker and more emaciated, and finally succumbs to inanition. *Post mortem* the only constant lesions found consist of some degree of dilatation of the œsophagus, marked dilatation of the stomach, and pyloric stenosis from hypertrophy of the muscular layer in the pyloric region, including the portion which goes to form the sphincter, and of a larger or smaller extent of adjacent stomach-wall. The cardiac end of the stomach is rarely affected.

The hypertrophy of the pyloric muscular layer is often so great, as in two of John Thomson's reported cases, that after death compression of the stomach fails to force any of its contents into the duodenum, although they readily enter the dilated œsophagus. The mucous membrane of the dilated stomach seldom shows signs of more than a variable degree of congestion—no ulcers nor hypertrophy. The morbid thickening of the pyloric and adjacent gastric coats was entirely due to pure muscular hypertrophy in Thomson's and Fitz's cases, with decrease of connective tissue; the mucous and serous membranes were unaffected. In other recorded instances of this condition the submucosa has been found to be also involved, or, again, all the coats implicated. Maier has described two varieties of congenital pyloric stenosis, a funnel- and a ring-shaped, the first-named owing its shape and name

to a more extensive infiltration of the stomach-wall than the second.

DIAGNOSIS.—A diagnosis of congenital pyloric stenosis can only be arrived at by a process of exclusion combined with some degree of conjecture. The pyloric hypertrophy is seldom if ever palpable. But whenever obstinate and continuous vomiting, resisting all medicinal or dietetic treatment, persists in infants but lately born, with progressive emaciation and enfeeblement, and with scanty stools, pyloric obstruction should be suspected.

PROGNOSIS.—The prognosis is hopeless as regards ultimate recovery, unless the hypertrophied pyloric section be removed by surgical interference. A successful result after such an operation will depend greatly upon the extent to which the muscular hypertrophy has invaded the stomach-wall.

TREATMENT can only be palliative, unless it be feasible to employ surgical measures.

ALEXANDER LOCKHART GILLESPIE.

STOMACH, Dilatation of.—Grave defects in nutrition result when the stomach is dilated, owing chiefly to the diminished digestion and assimilation of the food which is taken into it. There is delay of food in the organ, extending, it may be, over months; moreover, the food may undergo bacterial fermentation, whereby it is broken up into substances not used in the nutrition of the body.

The causes of dilatation may be either organic disease or a primary weakness of the muscular coat; in other words, it may be either obstructive or non-obstructive.

1. The commonest form of obstruction occurs at the pylorus, in the form of a stricture, malignant or non-malignant. The effects of obstruction in the duodenum are similar to those of obstruction of the pylorus. Adhesions of the stomach to a neighbouring tumour may hamper its movements; but a more common external cause of dilatation is the presence of adhesions round the pylorus, or between the stomach and liver or gall-bladder, and transverse colon and spleen, or between the left pleura, diaphragm, and stomach. Such adhesions may be caused by previous tubercular peritonitis or pleurisy, or by inflammation of the gall-bladder or perihepatitis. Local adhesions are frequently the result of chronic ulcer of the stomach. Adhesions round the pylorus may lead to dilatation without obvious obstruction, predisposing to functional weakness.

2. The causes of the muscular weakness of the stomach-wall, which may end in dilatation, are chiefly two in number. The first is the excessive work thrown on the stomach by the repetition of large meals for a number of years, the dilatation showing itself chiefly towards middle age. The second and accessory cause of this form of dilatation is excessive muscular exercise. Primary weakness of the muscular wall, known as atony or myasthenia, occurs in cases of gastric insufficiency, and is associated with anæmia, and with neuroses of the stomach. It may also follow any acute febrile disease, such as pneumonia, typhoid fever, rheumatic fever, scarlet fever, and measles. With chronic gastric catarrh, dilatation is a common symptom, and is not associated with any organic change in the muscular tissue. The dilatation following weakness of the muscular wall is of varying degree. In the majority of cases it is but slight, but, beyond middle age, the stomach may be very greatly enlarged. The distending force in dilatation is mainly the

accumulation of gas in the organ, more particularly when there is bacterial fermentation of the food.

The causes of dilatation of the stomach may be classified as follows:—

(a) *Obstructive dilatation occurs in:* (1) Stenosis of the pylorus, caused by cancer, or fibroid contraction as from chronic ulcer; or congenital disease.

(2) Pressure on the duodenum by a new-growth, or stricture of the duodenum, following the healing of a duodenal ulcer.

(3) Contraction of the pylorus by adhesions and chronic peritonitis, caused by ulcer of the stomach, tubercular peritonitis or inflammation of the gall-bladder.

(4) Contraction of the cardiac end of the stomach by adhesions, resulting from a severe left-sided pleurisy, usually tubercular and associated with disease of the lung.

(5) Hour-glass contraction of the stomach, with which may be associated pyloric stenosis, or scarring of the stomach after ulcer.

(b) *Non-obstructive dilatation occurs:* (1) As a sequel to gastric irritation.

(2) In gastric insufficiency.

(3) As a result of subacute or chronic catarrh of the stomach.

PATHOLOGICAL CONDITIONS PRESENT.—There is a change in the functions of the stomach in all cases of dilatation, but of different kinds. The amount of hydrochloric acid varies according to the cause of the dilatation. Thus, there are cases of dilatation associated with hypersecretion of hydrochloric acid (*hyperchlorhydria*), and other cases associated with a diminished secretion (*hypochlorhydria*). Hyperchlorhydria and dilatation are associated in cases of gastric irritation, but they are also observed in cases of non-malignant stricture of the pylorus, in hour-glass contraction of the stomach, and in some cases where the dilatation is caused by pressure on the duodenum, even by a malignant tumour, e.g. of the pancreas. In such cases there is no bacterial fermentation of the food. Diminution of the secretion of hydrochloric acid occurs with dilatation in cases of gastric insufficiency; in gastric catarrh; and in prolonged cases of ulcer, with great scarring and deformity of the organ. It is, however, seen most markedly in cancer of the pylorus.

In hyperchlorhydria the percentage of free hydrochloric acid found is, on the average, about 0.3; in hypochlorhydria none may be found, or only a small percentage (0.05). Bacterial fermentation is apt to occur where the secretion of hydrochloric acid is deficient.

Bacterial Fermentation of Food.—There are numbers of bacteria taken into the stomach with food, but their development is hindered by the presence of hydrochloric acid in the gastric juice. The acid does not actually kill the majority of the bacteria taken with the food. The forms of bacterial fermentation occurring in the stomach are the acid fermentations and the alcoholic; both of these affecting carbohydrates. Putrefaction, in which the proteids are decomposed, is of rare occurrence in the organ.

1. *Acid Fermentation* is of three kinds: lactic-acid, butyric-acid, and acetic-acid fermentation. The *lactic-acid fermentation* is produced by the *Bacillus acidilactici*, which is the cause of sour milk, and is found in beet, cheese, and in sour grapes. It is seen as short, thick cells, usually

united in pairs. It forms spores when grown in milk. It is aerobic, and decomposes milk-sugar, cane-sugar, dextrin, and mannite, forming a large quantity of lactic acid, together with carbon dioxide. Starch is first converted into sugar. *Butyric-acid fermentation* is due to the *Bacillus butyricus*, which is found in decaying vegetable infusions, old cheese, and in milk kept a long time. It consists of actively motile, long, slender rods, and acts upon starch, dextrin, and cane-sugar, with the production of a large quantity of butyric acid, as well as carbon dioxide and hydrogen. It also transforms lactic acid into butyric acid, with the formation of the same gases. The *acetic acid* which is found in some cases of bacterial fermentation in the stomach is probably the product of fermentation by yeast. *Sarcina ventriculi* is an acid-producing micro-organism, but its exact rôle in acid-fermentation is not known (see SARCINA). *Alcoholic fermentation*, due to the yeast-fungus (*Saccharomyces ellipsoideus*), rarely occurs in the stomach-contents. The commonest forms of bacterial fermentation are the lactic- and butyric-acid fermentations. The presence of putrefactive gases in the stomach, as well as other products of putrefaction, is almost invariably due to regurgitation from the intestine. The total amount of organic acidity of the stomach-contents, due to bacterial fermentation, may be very high (0.4 to 0.6 per cent.), the acids present being chiefly lactic or butyric, in rarer cases acetic acid. The amount of lactic acid found varies between 0.15 and 0.63 per cent. The gases eructated in cases of dilated stomach consist chiefly of carbonic acid, hydrogen, and nitrogen. These are derived from the acid fermentation and from swallowed air. Marsh gas and sulphuretted hydrogen may be present, so that the gas may be inflammable. See FLATULENCE.

SYMPTOMS.—1. Obstructive Dilatation.—The cases which occur under this heading may be divided into two groups: those due to malignant disease of the pylorus, and those resulting from the non-malignant forms of stenosis, such as that due to a chronic ulcer, to congenital stenosis, or to adhesions round the stomach. In all obstructive cases great dilatation and marked bacterial fermentation may occur: this statement, however, applies more particularly to the malignant cases, for in these there is a diminution in the amount of hydrochloric acid, whereas, in the non-malignant cases, the secretion of acid is not only undiminished, but, in many cases, actually increased in quantity. The stomach-symptoms which are due to the dilatation have, as a rule, no direct reference to the ingestion of food, although there are exceptions to this. They come on in four, five, or six hours after a meal, or only towards the end of the day, or at intervals of two or three days, and are shown chiefly in epigastric distress and pain, followed by vomiting and gaseous eructations. The pain is diffused over all the region of the stomach, and is accompanied by a hot, burning sensation immediately before the act of vomiting. The ejection of the contents of the stomach gives relief. The quantity brought up may be as much as six pints, and, in cases of bacterial fermentation, is grumous in appearance, yellowish and frothy. It may contain bile, but bile is only constantly found when there is duodenal obstruction beyond the opening of the common bile-duct. Hæmatemesis may be present (see p. 620). The condition of the undigested food varies considerably,

and washing the vomited matters in the manner previously described (see p. 1590) may show the presence of masses of vegetable fibre, which have been eaten some days before, and have been unable to pass the pylorus. Flatulence, without vomiting, is frequently a severe symptom. The presence of a greatly dilated stomach affects the circulation and respiration. Dyspnoea and increased rapidity or irregularity of the pulse may be present. In cases where the dilatation occurs more or less acutely, the embarrassment of the respiration and of the cardiac action may end in death. The appetite is diminished, or lost in cases—more particularly those of cancer—where hydrochloric acid is diminished; but, in cases of dilatation with hyperchlorhydria, the appetite may be retained, or there may be hunger. Thirst is usually present, and sometimes dry-mouth (*xerostomia*). Dilatation of the stomach affects the general nutrition, so that wasting and even emaciation follow. The loss of weight is to be ascribed to the fact that the food is not only not properly digested, but is not absorbed. This is the chief explanation of the wasting, even in cases of carcinoma, as in these cases, when the obstruction is relieved, a great gain of weight takes place. The bowels are usually constipated, but bacterial fermentation may spread along the intestinal tract, resulting in the passing of loose and offensive motions. The urine is usually scanty, and contains an excess of phosphates and of ethereal hydrogen-sulphates.

2. Non-obstructive Dilatation.—This occurs in cases of chronic gastric irritation, of gastric insufficiency or atrophy of the stomach, and of gastric catarrh. In the first group of cases the dilatation is usually associated with hyperacidity; in the last two groups, with a diminished quantity of hydrochloric acid, which is most marked in gastric catarrh and atrophy.

An appreciable degree of dilatation may be present without there being any vomiting, or any of the severe symptoms associated with obstructive dilatation, so that the dilatation is only discovered on a physical examination of the patient. Such a condition of things is constantly found in cases of chronic gastric irritation, and the symptoms are those which are described under that heading (see FUNCTIONAL DISORDERS, p. 1597). If the dilatation is excessive, especially in cases of gastric catarrh, and of prolonged gastric irritation, vomiting and flatulence may be severe symptoms. The dilatation of catarrh or atrophy may be associated with bacterial fermentation, but this is not observed in cases of gastric irritation.

PHYSICAL SIGNS.—See STOMACH, Examination of.

DIAGNOSIS.—Two points have to be considered, namely, the diagnosis of the presence of a dilated stomach, and the diagnosis of the causes of dilatation.

The presence of a dilated stomach is indicated by the physical signs which have already been described, as well as by the vomiting of large quantities of liquid. A chemical and physical examination of the vomited matters is of great importance in the diagnosis. The discovery of large masses of vegetable fibre may indicate obstruction of the pylorus. The repeated presence of bile in the vomit is against the presence of pyloric stenosis. The occurrence of blood in the vomit in large quantity as a rule indicates ulcer or cancer. As has been previously stated, the hydrochloric acid may be either increased or

diminished in dilatation, and it is of great importance, in such cases, to make a quantitative estimation of the acid. It is never increased, but gradually diminishes, in cases of dilatation due to cancer of the pylorus. A similar diminution also occurs in the dilatation of gastric catarrh and of atrophy. The presence of organic acids in large quantity indicates bacterial fermentation, and this most commonly occurs in cases of malignant obstruction of the pylorus. An excess of hydrochloric acid, without an excess of organic acids, may occur in cases of obstructive dilatation, due to any cause other than malignant stricture of the pylorus. The presence of an excess of hydrochloric acid does not exclude a diagnosis of pyloric stenosis, though it is against the presence of cancer of the stomach. Obstructive dilatation is indicated by visible peristalsis of the stomach, but this may occur in some cases of subacute gastric catarrh. Its repeated occurrence, however, is in favour of stenosis.

In deciding as to the pathological cause of dilatation of the stomach, the foregoing facts have to be taken into account, as well as the history of the case. In obstructive dilatation, the prolonged duration of the case, the presence of hyperchlorhydria, and the history of hæmatemesis some years previously, is in favour of non-malignant obstruction, while the definite origin of the illness during a period of a few months, its progressive character, its association with hypochlorhydria and with bacterial fermentation, are in favour of malignant stenosis.

PROGNOSIS.—The prognosis depends on the cause. Relief may be given in cases of cancer, but no cure is possible. In the non-malignant forms of obstructive dilatation relief, more or less permanent, is given by gastro-enterostomy, or other operation. Cases of dilatation, due to gastric catarrh, gastric insufficiency, or irritation may get well with appropriate treatment. Those associated with atrophy are, as a rule, fatal.

TREATMENT.—*Obstructive Dilatation.*—This usually leads to bacterial fermentation, and relief may be given by systematic lavage of the stomach, a soft tube being used, and two, three, or more pints of liquid being employed, such as a solution of boric acid (4 drachms to the pint), of permanganate of potassium (light pink colour), of sodium bicarbonate (3 to 6 drachms to the pint), or of common salt ($1\frac{1}{2}$ drachm to the pint). The washing out is to be done daily, either morning or evening, and preferably by the syphon-arrangement (see **LAVAGE**). In the intervals of washing out, anti-fermentative remedies may be given, such as hyposulphite of sodium (10 to 15 grains), glycerine of carbolic acid (5 to 15 minims), and creosote in one-minim doses. Great relief may be given by the lavage in cases of obstructive dilatation, but greater relief is frequently given by an operation. Thus, in cases of malignant pyloric stenosis, gastro-enterostomy may give the patient many months of comfort, instead of dire distress. It is not possible to operate in all cases, owing partly to the infiltration of the stomach-walls by the growth, or to the advanced age and degenerate arteries of the patient. In cases of non-malignant stenosis, gastro-enterostomy is the proper procedure, and has been very successful in some cases. Where there are adhesions round the stomach, the freeing of these by operation is a legitimate procedure, and sometimes leads to success in the cure of the condition; but the results are not

always favourable, and new adhesions may be formed.

Non-obstructive dilatation is to be treated on other lines. Cases associated with gastric irritation or insufficiency, or with neuroses, are to be treated generally on the lines laid down in discussing functional disorders. In some cases it is advisable, when there is great epigastric distress, to wash out the stomach each day for a week or ten days. Massage of the abdomen, and especially of the stomach, with rest, is of great advantage in the treatment of these cases. The diet must be frequently varied, according to the idiosyncrasies of the case. If there is a large amount of vomiting and epigastric pain, rectal feeding is to be adopted for a time, especially in cases of catarrh, of ulcer, and of neurosis. If there is bacterial fermentation, carbohydrates must be withheld. These may be given if there is hyperchlorhydria. The diet is to consist solely of fresh and digestible food; large quantities of liquid being forbidden. Minced mutton, minced chicken, or meat-balls are usually allowable, with thin dry toast. In obstructive dilatation, when the patient recovers from the operation of gastro-enterostomy, the functions of the stomach also recover, and, in some cases, the ordinary diet may be resumed. In other cases, the greatest care has to be exercised in the diet. The medicinal treatment is to be on the lines already laid down in functional disorder; alkalis to relieve the acidity, and antispasmodics to relieve the flatulence, are the chief remedies to be given.

SIDNEY MARTIN.

STOMACH, Functional Disorders of.—By functional disorder is meant the condition of indigestion of food, which results from a change in the functions of the stomach, or in its innervation, apart from organic disorder of the organ. The changes which occur may not be of a permanent character.

The cases of functional disorder may be divided into three classes. In all food is the direct exciting cause of the symptoms of the disorder. In the first class of cases, *gastric irritation*, food plays a very important part in the ætiology of the disorder. In the second class, *gastric insufficiency*, there is a primary functional defect in the stomach, resulting from some general condition, such as anæmia, gout, acute infective disease, or old age. In the third class, *nervous dyspepsia* or *neurosis of the stomach*, the symptoms are mainly those referable to the nervous system. All these classes of cases run into each other, and may, at one time or another, exhibit very similar symptoms. A distinction can, however, be made in the majority of cases, not only from the history of the disorder, but from the symptoms present, and from the result of treatment.

Gastric Irritation.—The symptoms in gastric irritation are, in the first instance, referable to the stomach, and are the result of irritation of the organ, all the functions of the stomach being disordered. It includes by far the largest number of cases of functional disorder, and nervous dyspepsia is really only a part of gastric irritation, with a prominence of nervous symptoms. The disorder is usually primary, but it may be associated with disease elsewhere. It may last a considerable time—even years—and shows, during this time, periods of quiescence, during which digestion is fairly well performed, and periods of exacerbation, in which the symptoms are well marked, and may be almost intolerable. In some cases it leads to gastric catarrh.

ÆTIOLOGY.—It may occur at any age; in the infant fed by the wet-nurse or with the bottle, in the child, and in adult life. Sex has no influence; the more direct cause in women being excess of tea-drinking, and in men excess of food and alcohol. Those of a nervous temperament are especially prone to the disorder, inasmuch as they are more affected by periods of worry, hard work, or excitement. Heredity plays some part, as when there is the inheritance of gout, or a nervous disposition. The chief factor in the ætiology is, however, the food, and the mode of life. Insufficiency and irregularity of food, even with much exercise, lead to the disorder, but, more frequently, there is a history of an insufficiency of exercise, with an excess of food, alcohol, or tea. It is thus met with in all classes.

With regard to the food there are several factors to be considered: the arrangement of the meals, imperfect mastication, composition of the food, chemical reaction of the food, and the effect of food-accessories. A large meal ought to be followed by a period of bodily rest, and should not be followed by another large meal within five hours. Meals eaten hurriedly, or hard work directly after a meal, may lead to the disorder, as well as large meals taken just before going to bed. Imperfect mastication is a very important factor. It may be due to toughness and bad cooking of the food, to rapid eating, to pain caused by decayed teeth, or to the absence of teeth. The last two points are frequently overlooked. Frequently a deficiency of the molars in the upper or lower jaws prevents mastication, and so leads to irritation of the stomach. Excess of food in time throws too much work on the organ, which thus has no period of rest. Eventually it leads to hypersecretion and deficiency of movement. The food must contain a certain amount of proteids, fats, carbohydrates, salts, and water, in the daily diet. An excess of meat in the diet of the well-to-do, and an excess of vegetable food in that of the poorer classes, are frequent causes of gastric irritation. Both lead to hyperacidity of the stomach-contents, not only by stimulating an excessive secretion of hydrochloric acid, but also from the fact that they contain organic acids and salts; in vegetable food there is also an excess of cellulose, which acts as an irritant. Thus, fine wheaten flour contains 0.29 per cent. of cellulose by weight, whole-meal flour 1.9 per cent., barley and rice-flour about 0.5 per cent., potatoes 0.69 per cent., spinach and cauliflower about 1 per cent., and fine oatmeal 1.86 per cent. Food must not be taken too acid, and cooking is important as regards the digestibility of food. Bad cooking makes the food tough, or does not sufficiently prepare the starch for digestion. Food-accessories, such as alcoholic drinks, tea and coffee, and rich sauces, are useful in digestion, but, in excess, they act as irritants. Alcoholic drinks, especially beer, port, sherry, hock, burgundy, and claret, delay the chemical processes of digestion, and lead to an increased organic acidity of the stomach-contents. Taken in moderation with a meal, alcohol causes a slowing of the process of digestion, but, owing to the fact that it stimulates the secretion of gastric juice, it does not produce an imperfect digestion—indeed it helps the digestion of a large meal. The effect of alcohol, however, varies in different individuals. Taken in excess, or between meals, it leads directly to hypersecretion, and many cases of hyperchlorhydria are

due directly to the taking of alcohol. The excess of secretion which it causes persists even between meals.

Gastric irritation commonly exists by itself, but it is not infrequently associated with tuberculosis, chronic malaria, and convalescence from typhoid fever, scarlet fever, measles, rheumatic fever and influenza. It may be observed in ulcer of the stomach.

PATHOLOGICAL CONDITIONS.—The pathological conditions present in gastric irritation may be divided into (1) the condition of acidity of the stomach-contents; (2) the condition of the movements; and (3) the condition of digestion. During digestion there is a secretion of very acid gastric juice, which may continue after the food has left the stomach. In some instances a large excess of acid is secreted in an hour or an hour and a half after the meal, and this continues during the process of digestion. In severer cases, however, the secretion continues after the mass of food has been expelled into the duodenum, so that, during fasting, liquids removed from the stomach are acid. The degree of acidity varies, and may be 0.3 per cent. or higher in an hour after a meal. This is the acidity due to free hydrochloric acid. In normal conditions, the acidity of the stomach-contents after a meal only gradually increases in the first hour, in which time it is about 0.1 per cent.; it increases later to about 0.2 per cent., as a rule not much higher. The continued irritation of the mucous membrane by an excess of food causes an increased secretion of mucus, which may occasionally be vomited, or, more rarely, be observed in the motions. The excessive secretion of mucus is not a feature of gastric irritation, as it is in gastric catarrh.

The conditions of the movements of the organ are of two different kinds. In some instances the hyperacidity is associated with spasmodic contraction of the stomach, which is only relieved by the expulsion of the contents of the organ in the natural way or by vomiting. In some cases there is spasm of the cardia and pylorus; a spasm leads to great distress, and may result in rapid expulsion of the contents into the duodenum. In an important and very numerous class of cases the hyperacidity is associated with a weakness of the muscular coats (myasthenia, atony). Just before the food is expelled into the duodenum, the organ tends to become flaccid, and it is unable completely to empty itself. Prolongation of the myasthenic condition leads to dilatation of the organ, which may be very great. See DILATATION, p. 1595.

The congestion which occurs in gastric irritation is, like the hyperacidity, an exaggeration of the normal condition of the organ during digestion. It renders the stomach more sensitive. Observed during life, as in one case of gastro-enterostomy for hour-glass stomach, the mucous membrane was of a dusky red colour, and slightly covered with mucus.

In cases of gastric irritation there is no bacterial fermentation of the stomach-contents. The presence of an excess of hydrochloric acid prevents the growth of the bacteria. Thus the vomit will keep for a long time without undergoing decomposition.

SYMPTOMS.—The mode of onset is usually insidious. The symptoms are at first to be directly ascribed to repeated slight indiscretions in diet, or irregularity in mode of life. The disorder is characterised by periods of only slight digestive distress, intervening between acute or subacute

attacks. *Acute gastric irritation* occurs usually as the result of very large meals or of irritating food, but most frequently it is a food-debauch, and referred to as a *bilious attack*. In such cases the symptoms are not developed for, perhaps, two or more hours after the meal. A sense of fullness and discomfort is experienced in the epigastrium, accompanied by nausea, and relief is only obtained by vomiting or by washing out the stomach. An examination of the vomited matters shows hyperacidity, due chiefly to hydrochloric acid, but also to organic acids, which have been taken in with the food. Subsequently the appetite is lost for a day or two, and loose motions may be passed. Acute dilatation of the organ may result from a single large meal. A physical examination may show the prominence of the epigastrium, due to the stomach. There is, however, little or no tenderness, but manipulation may cause eructation or vomiting. The tongue is thickly coated, and lassitude, pallor, and frequently headache follow.

Chronic gastric irritation, with subacute attacks, is a more common disorder. The symptoms, which preserve their individual features in each particular case, are both general and referable to the stomach. The general symptoms are referable to the nervous system, such as headache, palpitation, drowsiness, mental depression, sleeplessness, vertigo, and hiccup. The symptoms referable to the stomach always appear in relation to the food, coming on either immediately or one or two hours after a meal, and are most marked after the principal meal of the day, and in the evening or night. A sense of weight, fullness, and oppression in the epigastric region may last until the next meal, which relieves it. So with the pain in the chest and between the shoulders. The time of onset of the pain is dependent on the degree of hyperacidity, so that, when it appears directly after a meal, it is usually in prolonged cases, where the stomach-contents are always acid. The continuance of the pain is due to the delay of food in the organ, or to the continuance of secretion of hyperacid gastric juice after the food has been expelled. In prolonged cases the pain tends to become continuous, more especially in the front of the chest, between the shoulders, and in the lower part of the left axilla and the left hypochondrium.

Flatulence is a frequent symptom, and is not due to bacterial fermentation of the food, but to one or other of the following conditions: (1) In the middle-aged and old it may be due to accumulation of small quantities of gas, chiefly carbonic acid, which are developed from time to time in the stomach and small intestine, and are retained there. (2) It is sometimes due to swallowed air or to swallowed saliva, which is secreted in excess, and the carbonates of which are decomposed by the acids in the contents of the stomach. (3) It may be due to the regurgitation of gas from the small intestine, or of pancreatic juice, the carbonates of which are decomposed by the hydrochloric acid. This occurs in *myasthenia* of the stomach with a flaccid pylorus. In some cases it has been supposed that large quantities of gas may be discharged from the blood into the stomach and intestines, and then eructated.

The occurrence of vomiting varies in different cases of gastric irritation. When present, it is directly due to the irritating food in the stomach, to the excessive secretion of hydrochloric acid, espe-

cially in anæmic patients, or in those with excitable nervous systems. In chronic gastric irritation the attacks of vomiting are few and far between, and are due usually to some particular indiscretion of diet, such as the eating of heavy suppers. In the subacute attacks of gastric irritation, vomiting is a rule, although it may be absent. It may occur after every meal, either directly or in one or two hours. The vomiting consists of partially digested food and a little mucus. It is hyperacid, due to hydrochloric acid. This hyperacidity may not be present if the vomiting occurs directly after food, and, in the prolonged cases, the stomach-contents may be, from time to time, deficient in hydrochloric acid, although this deficiency is never so marked as in cases of carcinoma or of gastric catarrh. At first the appetite is normal; later on it is increased, and may even be voracious; it may become capricious, or may suffer marked diminution. The sinking feeling, or the sensation of want of food, which so many of these patients experience, is most commonly due to the presence of hyperacid gastric contents. It is relieved by food, the proteids of which, combining with the free hydrochloric acid, relieve the symptoms. The tongue is frequently coated, especially in the morning on waking, and there is a nasty taste in the mouth, which is clammy from mucus. Eructation of small quantities of acid fluid (pyrosis) frequently occurs, and is sometimes the cause of the coated tongue. Recurrent and severe attacks of hyperchlorhydria are frequently ushered in by salivation, or rather by gushes of saliva into the mouth, and the secretion of saliva may amount to pints during an attack; it is swallowed and then vomited. Salivation may occur before a meal, but is usually observed after meals, at the time of the greatest acidity of the stomach-contents. More rarely, and in cases of long duration, there is a greatly deficient secretion of saliva, so that the mouth is always dry (*xerostomia*). Constipation is the rule in gastric irritation, the bowels being opened once in one or two days, or a week, or only with medicine. Frequently, however, diarrhoea and constipation alternate, one or two days of looseness of the bowels being followed by constipation. Lienteric diarrhoea may also occur, coming on directly after a meal. This condition appears to be associated with irritability of the muscular coat, whereby the food is rapidly discharged into the small intestine. The urine shows a tendency to alkalinity, an excessive excretion of phosphates, and a diminution in quantity. Albuminuria is rarely present, but albumoses may be found.

Patients subject to this disorder do not waste, owing, no doubt, to the fact that the increased secretion of gastric juice does not lead to a diminution in the amount of food assimilated, but, in prolonged cases, mal-assimilation of the food does occur, owing to *myasthenia* of the stomach, so that such patients are pale, and have flabby muscles, which are irritable to tapping. Wasting is usually associated with some dilatation of the stomach and with prolonged diarrhoea, but the loss of flesh is not progressive, and there are periods during which the patient may regain even a stone of the weight lost. Cases of gastric irritation may continue for many years, with periods of remission and of exacerbation. By a proper treatment, complete recovery is the rule; through neglect permanent injury may be done. Catarrh of the stomach may result, with a profound diminution in the functions of the organ,

or permanent and great dilatation may occur, with sometimes bacterial fermentation.

Gastric Insufficiency.—This is a condition in which the functions of the stomach are diminished. It may result from prolonged gastric irritation, and occurs in catarrh and cancer of the organ, but the term is here applied more particularly to those cases in which disorder of the organ follows, or is associated with, certain diseases. The symptoms are frequently brought out by the presence of food in the organ, but irritation is not the direct cause of the primary condition of the stomach.

ÆTIOLOGY.—The general depression of function which occurs in those who lead a sedentary life, with much mental work, affects the stomach, leading to deficient activity, especially towards the middle period of life in both men and women. In old age a similar diminution occurs, leading to the taking of a smaller amount of food. In women at the menopause, and in prolonged lactation, insufficiency is frequently observed. In young adults, however, some recognisable morbid condition of the body is present. A state of fever diminishes the activity of the digestive organs, and the return of function is usually slow. Deficient motor activity, and a deficient secretion of gastric juice are both observed, for example, with typhoid fever, scarlet fever, rheumatic fever, measles, and influenza, and are frequently associated with pulmonary tuberculosis. In other cases gastric insufficiency is produced by continued hæmorrhage, whether rectal or uterine, by prolonged suppuration, syphilis, or anæmia.

PATHOLOGICAL CONDITIONS.—In response to the stimulation of food, there is deficient secretion of gastric juice, and a diminished motor activity, both functions failing before the meal is digested. This leads to great delay of food in the organ, and to subsequent dilatation. Bacterial fermentation is, however, not very common. The stomach-contents, when removed or vomited, show imperfect digestion of the food, and a deficiency of hydrochloric acid (*hypochlorhydria*), or even an absence of the acid two hours after a test-meal (*achlorhydria*, *achylia gastrica*).

SYMPTOMS.—The symptoms come on directly after a meal, and they may last the whole day, as well as during the night. There is epigastric fullness, and a sense of depression in the chest, which may be associated with dyspnoea. Flatulence is a constant symptom, and is usually associated with signs of dilatation of the organ; fluid eructations do not usually occur, and vomiting is not a symptom. Reflex symptoms are extremely common, and are due partly to the excitability of the nervous system, and partly to the condition of anæmia present. Pain and tenderness in the lower part of the left axilla are observed, associated with flatulence. Headache is common, as well as drowsiness after meals, sleeplessness, lassitude, disinclination to exertion, mental inaptitude and apathy, and a melancholy view of life. The face is often pale and anxious-looking, and the complexion muddy; the appetite is always diminished, and the tongue is broad, pale, flabby, and tooth-indented, but it is not usually coated. The foul taste in the mouth, so common in gastric irritation, is not so frequently observed in insufficiency. Constipation is the rule; the pulse is feeble, not very frequent, but regular; wasting is very common, and the muscles are flabby. Gastric insufficiency may be a permanent condition in old age, or in those who have inherited a weak digestion.

When it occurs in febrile disorders, it is highly amenable to treatment, but, if neglected, it leads to great dilatation of the organ.

Nervous Dyspepsia.—*Gastric Irritation, with Prominence of Nervous Symptoms.* See STOMACH, Neuroses of.

DIAGNOSIS.—The diagnosis of functional disease has to be made from ulcer, catarrh, and cancer of the stomach.

1. *Diagnosis of functional disease from ulcer.*—There are not a few cases of ulcer which present the features of gastric irritation, and only declare themselves by an attack of hæmatemesis. In the diagnosis the points to be looked to are the character of the pain and vomiting, and the course of the disease. Both may occur in young women. In ulcer the pain and tenderness are localised in the epigastrium, are dependent on the ingestion of food, and are relieved by vomiting. Vomiting is frequent, especially on the continued taking of an unsuitable diet. A history of hæmatemesis would make the diagnosis clear. Gastric irritation, on the other hand, presents quite different features. During its course, there may be times at which nausea and vomiting occur after food over a period of several weeks, but the vomiting is not a serious or frequent symptom, and is readily controlled by treatment. It frequently ceases, owing to the abstinence by the patient from food. The pain is not commonly epigastric, nor is it associated with localised tenderness. If epigastric pain is present, the tenderness is usually diffused, and is not so persistent as in ulcer.

2. *Diagnosis of functional disease from gastric catarrh.*—Chronic gastric irritation and chronic catarrh bear a superficial resemblance in the symptoms they produce. The epigastric pain, which is only a transient symptom in gastric irritation, is frequent and often severe in catarrh. It is diffuse and associated with one or more areas of tenderness. Vomiting is associated with epigastric pain, and, in chronic catarrh, an examination of the vomited matter is the chief aid in the diagnosis. It usually, but not always, contains an appreciable quantity of glairy mucus, but the chief sign it shows is the greatly diminished quantity of free hydrochloric acid, with but slight digestion of the food. A small amount of blood may be seen, which is never observed in the vomit of gastric irritation. There is great tendency to dilatation of the stomach in catarrh. Bacterial fermentation may occur. A test-meal may be of great service in the diagnosis of the condition. See p. 1589.

Gastric insufficiency is distinguished from catarrh by the absence of continuous gastric pain and vomiting, and by the history, which shows some coincident or precedent disease, accounting for the diminution of the functions of the stomach.

3. *Diagnosis of functional disease from cancer.*—The suspicion of cancer of an important organ arises when, in a patient of middle age or beyond, there is progressive wasting, weakness and anæmia, without fever, and when there is no sign of wasting disease elsewhere, such as tuberculosis, chronic renal disease, and diabetes. Such symptoms during a definite period are observed in cancer of the stomach, and are associated with symptoms and physical signs referable to the organ. The symptoms which more particularly separate cancer of the stomach from functional disease are, in the early stages, the progressive loss of appetite and of weight, the presence of pain in the epigastrium, and

the occurrence of vomiting, with flatulence. The pain may at first be referable to food and may be relieved by diet; later it has no particular relation to the food. An examination of the vomited matter shows a diminution of the amount of free hydrochloric acid, an excess of organic acids, especially lactic acid, and the presence of bacteria and sarcinæ. When first seen the patient may present physical signs of dilatation of the stomach only (q.v.), or dilatation with an epigastric tumour. If dilatation alone be found, the diagnosis from functional disease is to be made mainly from the history, as in cancer there is a definite period during which the symptoms have lasted—a period, say of six or eight months—while in functional disease with great dilatation the history is that of years, and the wasting is not a feature as in cancer, although it may occur in cases of long standing. Treatment may also aid the diagnosis, as a great gain of weight, sometimes over fourteen pounds, may follow successful treatment of functional dilatation.

TREATMENT.—The treatment is both medicinal and dietetic, aided by massage and washing out the stomach. The conditions to be treated in functional disorders are hyperchlorhydria and hypochlorhydria, a diminished motor activity of the organ or occasionally spasm, and a varying degree of hyper-excitability of the nerves, associated with congestion. Restoration of the functions of the organ is a matter of time and treatment, but it does occur, except in cases of pronounced nervous dyspepsia. Powerful remedies and treatment do more harm than good. In the dietetic treatment, the objects are to give the patient, during the day, only such food as the stomach can digest with the least discomfort and to remove irritant articles from the diet. Food is to be reduced in quantity, and only freshly cooked digestible food is allowed. Articles of diet containing a large quantity of organic acids or salts, such as beef, beef-tea, many vegetable foods and fruits, are to be disallowed, as well as those containing an excessive amount of cellulose and of fat. Most important in the treatment is the removal, in the case of irritation of the stomach, of food-accessories, such as alcoholic drinks, strong tea, and coffee. Meals are to be regularly taken and not later than four hours before going to bed, and attention to the teeth is of the highest importance.

1. *Gastric irritation.*—In one class of cases there is great discomfort after food, with referred pains in the chest, irregular vomiting of very acid fluid, and flatulence. There is hypersecretion of hydrochloric acid and hyperæsthesia of the organ. The administration of acids, and in most cases of bitters, increases the discomfort. Alkalis are given as antacids, but are not given in sufficient doses to completely neutralise the acid contents of the stomach. They are best given with some sedative, such as bromide of potassium (5 to 10 grains), iodide of potassium (2 grains), cocaine hydrochloride ($\frac{1}{10}$ to $\frac{1}{5}$ of a grain), dilute hydrocyanic acid (3 minims), liquor morphinæ hydrochloridi (5 to 10 minims), or glycerine of carbolic acid (5 to 10 minims). It is usually best to begin with an alkaline mixture, containing 15 grains of bicarbonate of sodium, 3 minims of dilute hydrocyanic acid, and 5 minims of spirit of chloroform, to which may be added, in some cases, 10 grains of carbonate of bismuth. This mixture is to be taken half an hour after breakfast and after the midday meal, and on going to bed. It may also be taken once in the night,

if there is discomfort and insomnia. The administration of pepsin and other digestive ferments is of no avail. As regards diet, all alcoholic drinks are to be disallowed, as well as green vegetables and fruit. The patient is to live chiefly on a diet of milk, white bread, milk puddings, fresh fish, mutton and chicken. If the symptoms are severe, lying down is of great importance, and a further reduction in the solid articles of diet, which is then to be restricted to milk, prepared foods, eggs and bread.

If the condition has lasted a long time, especially in those cases in which there is wasting and flabbiness of the muscles, a period of four to six weeks' rest, with abstention from work, is necessary, and this is to be combined with careful dietetic and medicinal treatment, and with massage.

During recovery from gastric irritation, the first symptom to disappear is the discomfort after food, and the last is the constipation, which may last for some months after the gastric symptoms have abated.

2. *Gastric insufficiency.*—Although, in this condition, the treatment of the digestion has to be carried out carefully by means of the diet, yet a tonic treatment is essential, in order to improve the general condition. Such tonic treatment may be, in mild cases, limited to the prescription of fresh air, with a mixture containing a small dose of sulphate of iron and sulphate of quinine, or of dilute nitro-hydrochloric acid with nux vomica. Small quantities of alcohol may have to be allowed, and the diet is to consist solely of digestible articles. In pronounced cases, occurring after infective disease, general massage is of great service, especially if there is well-marked muscular weakness of the organ.

3. *Nervous dyspepsia.*—The treatment is one of extreme difficulty, and cases present an infinite variety of aspect; the effect of treatment is but slightly noticeable at first. Great idiosyncrasy regarding diet is observed, and, as a rule, it may be said that an exclusive milk-diet is not very serviceable. Thus it is found that in some cases with persistent vomiting the condition is not relieved by a diet of peptonised milk, nor even by rectal feeding; but is benefited by the prescription of readily digestible solid food, such as pounded fish, minced chicken, or mutton in small quantities at frequent intervals. Some patients, with severe epigastric pain or repeated vomiting, have to be treated, in the early stages, by rectal feeding; in others, daily washing out of the organ appears to be of service, but this is a practice which is frequently adopted by such patients, and continued for years, leading to a persistence of the symptoms. No special rules can be laid down for the medicinal treatment of such patients. They show intolerance of some drugs, as they do for articles of diet. A stomachic sedative is, however, usually required: such as cocaine hydrochloride in pill ($\frac{1}{10}$ to $\frac{1}{5}$ of a grain) or solution of hydrochloride of morphine (5 to 10 minims), with bicarbonate of sodium (10 grains). There may be intolerance either of acids or alkalis, and sometimes a tonic mixture of quinine and iron does most good. When the symptoms are pronounced and have lasted for a long time, and when there is well-marked insomnia and wasting, the only treatment available is complete rest in bed for four to six weeks, with massage and careful dieting. Even if improvement occurs, relapses are extremely frequent.

SIDNEY MARTIN.

STOMACH, Inflammation of the.—SYNON.: Gastritis; Gastric Catarrh.—The various forms of gastritis may be arranged as in the following scheme:—

A. Acute—

1. { Simple.
Toxic.

2. Phlegmonous { General.
Localised.

B. Subacute.

C. Chronic—

1. Simple.

2. Toxæmic.

3. Cirrhotic { General.
Localised.

D. Tubercular.

E. Syphilitic—

1. Gummatous.

2. Ulcerative.

A. Acute Inflammation.—1. *Acute Gastritis* (simple and toxic). SYNON.: *Gastritis glandularis acuta*; Acute Gastric Catarrh; Fr. *Gastrite aiguë*; Ger. *Gastritis akute*.

DEFINITION.—An acute inflammation of the coats of the stomach, especially of the mucous membrane, resulting in disturbances of function and alterations in form.

ÆTIOLOGY.—Acute gastritis may arise from direct local irritation of the tissues involved, or may be secondary to lesions of other parts of the body, general or localised.

Primary causes may be classified as: (1) Dietetic, (2) Toxic, (a) Organised, (b) Chemical.

Secondary causes are: (1) Acute Infectious Diseases, and (2) Constitutional Conditions (Gout, Rheumatism, Diabetes).

In addition to these causes as given above, it should be remembered that various chronic diseases, particularly those of the heart, liver, and kidneys, tend to render attacks of acute gastritis of readier occurrence.

Acute gastric catarrh, caused by *errors in diet*, is common at all ages and in all ranks of life. Among children it is frequently accompanied by a similar inflammation of the intestinal mucous membrane, and known as *gastro-enteritis*; hence it is often described as being most common among middle-aged and elderly persons, the cases in the young falling under another category. Women are said to be more subject to it than men, but this is doubtful. Too hot, too rich, or too much food ingested at one time; iced drinks; food swallowed in imperfectly chewed lumps, or in large quantity too quickly, are sufficient in themselves to set up irritation and lead to inflammation of the gastric mucous membrane.

But apart from such errors in diet *toxic and irritant substances* introduced into the stomach along with the food are frequently the cause of acute attacks. The commonest of these is undoubtedly alcohol, while the products of decomposition of articles of diet not infrequently are at fault. Several poisonous chemical substances act in the same way—notably arsenic, phosphorus, and mercuric chloride. It is still a moot point whether a true infective gastritis occurs or not. Oser and Lebert have suggested such a possibility, but no evidence has been brought forward as to the presence of any bacteria in the stomach to which it can be due. On the other hand the acute forms of gastritis which so often accompany such infectious diseases

as scarlet fever, measles, and other exanthems, certainly represent local irritation of the gastric mucous membrane caused by the presence of the *materies morbi*. This form is often known by the name of *Erythematous Gastritis*.

Constitutional disorders may either induce attacks of acute gastritis (for example, an attack of acute gout may select the walls of the stomach as its locus in place of a joint), or render the individual suffering from them far more liable to be attacked. Local errors, also, of function or motility, leading to the presence of hyperacid contents, whether from hydrochloric acid or the organic acids of fermentation and prolonged stay of food in the stomach are occasionally provocative agencies.

MORBID ANATOMY.—The naked-eye appearances shown by the mucous surface of the stomach in a state of acute catarrh rarely come before the pathologist; the disease is seldom fatal in itself, while the signs presented after death are very unlike those during life. Our chief source of information is still contained in Beaumont's observations upon Alexis St. Martin. The stomach is usually empty, all food introduced having been expelled; small in size, and contracted, but with a soft mucous membrane, more or less studded with superficial hæmorrhages, which are perhaps most numerous in the neighbourhood of the pylorus; irregularly congested and red in patches, and covered by a tough layer of thick and tenacious mucus, here and there, it may be, showing a pink tinge. Beaumont described small vesicles, surrounded by zones of deep congestion, especially in the pyloric region.

Microscopically, the epithelial cells are distended and granular, the granules picking up colouring agents badly, if a section be examined after the inflammatory process has proceeded beyond the superficial stage. The cells in the pyloric region are those which suffer most.

SYMPTOMS.—Sudden in onset, ushered in by feelings of intense nausea and gastric discomfort, acute gastric catarrh is early marked by severe vomiting and retching. The nerve-endings in the gastric wall and the neurons of the local gastric mechanism are so powerfully irritated that abnormal vaso-motor changes are reflexly induced throughout the body; the skin is pale, cold, frequently in goose-skin, and beaded with drops of sweat; patches of *herpes labialis* may rapidly form; the brain is also affected, functionally and mentally; the body-temperature may temporarily rise, one or more of the senses and sensibility in general may become deranged, vertigo occur, and exertion be impossible. The pain in the gastric region is severe, often burning, and frequently associated with a feeling of great weight in the stomach. Tenderness may be present on pressure.

Gastric contents vomited during an attack of acute catarrh vary less with the nature of the food taken beforehand than in almost any other condition where emesis occurs. They are almost always thick, porridgy, of evil odour, rich in mucus, fermented and sour. The sourness is due to organic acids, not to hydrochloric acid, which indeed is very seldom present in the free state, and scantily in proteid combination. The porridgy consistence of the vomited material apparently bears no relation to the fluidity of the ingesta recently swallowed; the condition may arise by a rapid passage of the supernatant fluid portion of the contents through the pylorus or from admixture with mucus.

When the acts of emesis are very powerful, and especially if they persist after the stomach is empty, blood may be brought up mingled with the food or with mucus only.

Beginning suddenly, running an acute course, the catarrh almost as quickly loses all its characteristic features. In favourable instances return to healthy conditions follows; in others the symptoms acquire a subacute character; and in others again pass into those of chronic gastritis.

DIAGNOSIS.—The diagnosis of acute gastric catarrh itself offers, as a rule, no difficulty; a correct appreciation, however, of how it has been caused and what it betokens is a much more important and occasionally obscure question. When a sequel to a debauch—in solids, fluids, or both—no trouble arises; if due to irritant poisoning, the rules for detection of such are laid down in text-books of Forensic Medicine. It is when intercurrent attacks complicate other forms of digestive disease, chronic constitutional maladies or acute infectious disorders, that accurate ascription to the true cause may be of so much value. The rapidity of onset, the nature of the vomited matter, the general vasomotor and sensory disturbance, the local gastric pain, serve to point out acute gastric catarrh. Careful investigation of the anamnesis, and intelligent appraisement of all the conditions which may possibly have induced an attack, should serve to indicate the basal lesion at fault.

PROGNOSIS.—As already mentioned, acute gastric catarrh is often completely recovered from after a short space of time, if reasonably treated. But it may take on a subacute character, and last in this form for a longer or shorter period, although cure is still possible. Should repeated acute attacks be experienced, the chronic forms commonly supervene.

TREATMENT.—The less drugs employed in the treatment of acute attacks of gastric inflammation, and the greater the sense shown by the physician, the greater the chance of speedy recovery. Acute gastritis usually arises from direct irritation of the gastric surface, and is best relieved by removal of the irritant, associated with as complete a condition of gastric quiescence as possible. As a general rule the exhibition of drugs proves but palliative, and may even exaggerate the condition, with the single exception perhaps of simple emetics. Nature strives to cure by expulsion of the irritant material by antiperistaltic action, or, if this is not possible (as not infrequently happens owing to personal idiosyncrasy and inability to vomit), by evacuation *per anum* in the form of diarrhoeal stools. In the first place, if nature has failed to induce her remedial measure of emesis, her well-meant endeavours should be aided; while, if these prove ineffectual, and the space of time which has elapsed since the primary inception of the morbid process would suggest that the stomach should have emptied the larger portion of its contents through the pylorus into the duodenum, the administration of intestinal lubricants, to hasten the passage of the deleterious stuff through the bowel, and its external riddance, is indicated.

One may be able to coax victims of acute gastritis, naturally incapable of unaided emesis, to vomit by giving them tepid or warm water in bulk to drink, or mustard in watery solution, preferably warm; or if the general reflex depression be so acute and urgent that instant evacuation of the

stomach-contents is demanded, by employment of zinc or copper sulphate by the mouth, or of apomorphine hypodermically. Such measures are to be succeeded by stomachic rest. Deprivation of all food for some time, if it be possible, acts well; if food must be given, it should only consist of milk, or milk and water, taken in small amounts at any one time; and in the course of some hours, according to the progress of the patient, added to by the inclusion of the blandest forms of proteid and farinaceous foods. If the source of the acute attack lie in the misuse of alcohol, the vomiting be severe, and the subsequent depression of mind or body intense, the need may become imperative for a temporary stimulation of the vital functions, lest they should stand still. The adoption of actively detergent methods in such cases requires always to be combined with the most careful and constant supervision, attention to the condition of the patient, and readiness to counteract any signs of collapse by the prompt exhibition of stimulants—‘a hair of the dog that bit him,’ preparations of ammonium, strong solutions of such readily absorbable proteid nourishment and extractive stimulants as are afforded by Bovril, Liebig’s extract and similar substances, or by various predigested proteid products exemplified by somatose, tropon and the like. If the symptoms of collapse are very urgent, the more diffusible stimulants are indicated; if less so, and the stomach is tolerant of them, the beneficial effects of liquid nutriment, although less rapidly produced, generally prove more lasting and curative in character. In all cases of collapse the external application of heat by means of hot-water bottles, blankets, &c., is always indicated; and every measure calculated to restore peripheral circulation, to diminish engorgement of the abdominal veins and remove the consequent over-accumulation of stagnating blood in them.

2. *Phlegmonous Inflammation of the Stomach (Gastritis Phlegmonosa Suppurativa vel Purulenta; Abscess of the Stomach).*

DEFINITION.—Circumscribed or diffuse suppurative inflammation situated in the submucous and muscular layers of the stomach.

ÆTIOLOGY.—Phlegmonous gastritis is a comparatively rare disease, either arising primarily, or developing secondarily during the course of pyæmia, fevers, or severe exanthemata. Males appear to be more liable to it than females, in the proportion of 5 to 1 according to Brinton, 4 to 1 according to Glaze. The active cause consists in the presence of pyogenic bacteria in the tissues of the stomach-wall.

MOREID ANATOMY.—Two forms can be distinguished. First, where the area of suppuration is circumscribed (*gastritis phlegmonosa circumscripta*), and only one focus, or at most two or three foci, are present; second, where there is a diffuse purulent infiltration of the submucosa and muscular layer. In both forms, the seat of inflammation is at first in the submucosa and muscularis; during the later stages the mucous membrane or the serous covering may become implicated, leading possibly to rupture into the gastric cavity or the peritoneal sac. The region most frequently involved is that in the neighbourhood of the pylorus. When circumscribed, the point of entrance of the bacterial agent is commonly to be found in a local solution of continuity in the mucous covering of the stomach; a broken-down cicatrix, the inheritance of an old gastric ulcer;

a gastric erosion ; or traumata of the mucosa. When diffuse, the condition is due to the presence in the general blood-stream of pyogenic organisms, as in pyæmia and puerperal septicæmia, rarely of the *Bacillus coli communis*, or of the bacterial agents actually proved or hypothetically supposed to be the source of the acute exanthemata, admixed as they usually are with some of the ordinary pyogenic forms, which induce the miliary points of suppuration. When the abdomen is opened after death in a fatal case of diffuse phlegmonous gastritis, the outer surface of the stomach is found to be dotted over with a large number of raised swellings of variable size, while on opening the viscus, similar and even more numerous elevations can be seen. The individual abscesses, which generally account for these projections, vary in size from a pea to a hazel-nut or walnut.

As the disease progresses, infiltration of the mucous membrane, by extension between the glandular tubules, and fatty degeneration of the muscular fibres themselves, often result.

The stomach-wall, enormously thickened and engorged with pus, may resemble a sponge, being penetrated by many communicating apertures, so that on compression pus wells out here and there over its surface. Localised sloughing of the superficial tissues may lead to the formation of ulcers at different points.

SYMPTOMS.—In the large majority of cases phlegmonous gastritis runs an acute course. The onset is sudden ; the symptoms rapidly become severe in character. From the beginning the patient is conscious of being seriously ill ; his temperature quickly runs up to, or above, 104° F. ; he is restless and alarmed and, it may be, delirious ; and death closes the scene after a few days, or at most after the lapse of a fortnight. Violent acts of vomiting usually, but not invariably, accompany it, and jaundice has been recorded in cases belonging to the idiopathic primary group (Brinton), due to an extension of the disease to the duodenum, or to the unrecognised presence of pyæmia giving rise to a pyæmic icterus. The material vomited during the earlier stages consists mainly of undigested food, mucus, and bile ; towards the close it may contain pus in varying quantity. Severe epigastric pain, an intense sensation of burning in the stomach, great thirst, parched tongue, and complete loss of appetite, are among the common symptoms met with.

DIAGNOSIS.—This is difficult during life. Even the appearance of pus in the vomit affords no absolute proof of the nature of the lesion, because the pus may have come from perigastric or extra-gastric suppuration, which has found its way into the stomach cavity. The symptoms simulate so closely those of acute localised peritonitis, of hepatic abscess (in the left lobe), and of splenic abscess, that no positive diagnosis can possibly be justified. A conjecture as to the actual location of the lesion may happen to be correct, but its correctness can only be a matter of chance.

TREATMENT.—Little can be done for this condition.

B. Subacute Gastritis. — **SYNON.** : Dyspepsia ; Gastric Catarrh.

DEFINITION. — Inflammation of the gastric mucous membrane, less severe than in acute gastritis, of moderate duration and variable course.

ÆTIOLOGY.—The customary division of gastritis into acute and chronic groups, with more or less sharply defined characteristics, seems to err in an insufficient regard for those common examples of gastric catarrh which assuredly are not acute, in the true sense of that qualification, nor yet can be correctly described as chronic. Many cases of simple dyspepsia of organic origin, entirely innocent of abnormal nervous influences, belong to this group ; the local inflammatory changes being of moderate intensity, having as yet induced but slight organic alterations of a lasting character. More frequent in females than in males, subacute gastritis principally occurs between the ages of fifteen and thirty in females, from twenty to sixty in males. Among women, domestic servants and factory-hands, the former class particularly, appear to be liable to attack ; outdoor labourers and miners among males. Anæmia and chlorosis are often associated with it in females ; out of 568 female cases collected from the Edinburgh Royal Infirmary records, 23·4 per cent. suffered from concomitant anæmia.

Subacute gastritis may proceed from any of the causes already detailed for acute gastritis, acting with less intensity and of more gradual occurrence ; or may follow for a time an acute attack. As a general rule the condition, if disregarded, if treated improperly or not at all, forms but an antecedent to the onset of chronic gastritis.

SYMPTOMS.—Yielding very similar symptoms to those met in acute catarrh, but diminished in intensity, the victim of subacute gastritis also suffers from epigastric pain and vomiting, flatulence and nausea, with distaste for food, chiefly because of the discomfort which follows its ingestion ; but he has little or none of the complete feeling of prostration caused by acute attacks ; no rise of temperature ; and retains greater command over the act, time, and place of vomiting. Mucus is not so conspicuous a constituent of the material expelled, but frequently is in larger quantities in the feces. The symptoms and signs afforded by the disturbance of gastric digestion, altered appetite and palate, vary directly with the underlying cause of the catarrh, and depend largely upon the extent of the gastric surface affected, as well as the depth ; upon the state of the nervous system, and how much it has had to do with its origin ; upon the condition of other associated digestive organs ; and lastly upon the habits and circumstances of the individual. The great majority of the commoner cases of dyspepsia are neither acute nor chronic, but suffer more or less distinctly from subacute gastric catarrh. Purely functional types of dyspepsia, it is true, have been described by many authorities as existing without any accompanying catarrh, and as capable of enduring for a length of time without inducing the same. It is probable, however, that very few cases of functional indigestion are to be met with in which organic lesions are completely absent.

C. Chronic Gastritis.—*Gastritis Catarrhalis Chronica* ; *Gastritis Glandularis Chronica*.

DEFINITION.—A chronic inflammatory affection of the various cellular elements in the gastric mucosa, leading to increase of connective tissue, and loss of function.

ÆTIOLOGY.—Chronic gastric catarrh almost always follows after precedent attacks of acute or subacute gastritis ; especially if the attacks have recurred more or less frequently, and have been neglected or maltreated. It is generally said to be

more common in males than in females, but the records of the Edinburgh Royal Infirmary for 1892-9 yield 79 cases of chronic gastric catarrh among males, 77 among females, out of 205 and 289 cases of gastric catarrh of all varieties respectively. It is met with chiefly in adults under 55; for women the decennium from 20 to 30 seems to be the most dangerous, for men from 30 to 50 years of age. Although distinct from chronic gastric irritation, where the primary sources of error lie in functional faults, chronic catarrh may be safely said never to be very far distant, in fact and in act, after gastric irritation in any form has been established. Prolonged disturbance of function or motility, and persistence in dietetic indiscretions, tend to initiate chronic inflammation of the gastric glands. Continued and excessive indulgence in protoplasmic stimulants and irritants, such as tea, too hot foods, alcohol, powerful condiments and spices; constant avoidance of any one of the necessary food-elements, or more or less rigorous confinement to articles of diet of a special and insufficient kind, form some of the commoner personal causes of chronic catarrh. Anæmic conditions; faulty metabolic processes; constitutional maladies—tubercular, syphilitic, gouty, rheumatic, glycosuric; attacks of acute disease, especially during the period of convalescence, constitute the general predisposing causes. Thus the ætiology of chronic gastric catarrh is seen to be akin to that of acute or subacute catarrh. The type of catarrh excited by any one or other of these pathological conditions varies directly with the variety and energy displayed by the agents severally, and with their duration. Repetition of irritation, however, soon leads, as in all else, to diminution in response, and progressively to more lasting organic changes in the tissues.

MORBID ANATOMY.—That chronic gastric catarrh may be separated into several more or less distinctly defined forms is suggested by the conditions presented by the mucosa and submucosa in different cases. Thus chronic catarrhal, chronic proliferating glandular and chronic atrophic glandular forms may be recognised, differing greatly from one another in their anatomical lesions during the earlier stages of disease; approximating more and more to a common type as time advances; and gradually passing through the earlier stages, in which the glandular elements are chiefly affected, into later stages marked by increase of connective-tissue cells at the expense of the cells of the glands. Fibrosis of the stomach, separately described, may be one of their sequels.

The appearances presented by the mucous membrane during the earlier stages of the lesions may be described as follows:

1. In chronic catarrhal gastritis the columnar epithelium of the glands proliferates and undergoes degeneration, goblet-cells being found in increased numbers, while the peptic cells are diminished: the acid-forming cells are unchanged. The connective-tissue is infiltrated with embryonic cells. The walls of the stomach are thickened and the mucosa is swollen, the surface being of an irregularly mottled, red colour, and covered with thick mucus. The gastric secretion contains more mucus than usual, along with less than the normal amount of acid and pepsin: digestive power is therefore weak. Motility remains normal.

2. In the chronic proliferating glandular form (*G. chronica glandularis hypersthenica*) the columnar

epithelium may disappear over large areas. Goblet-cells are lessened in number, peptic and acid-forming cells increased; there is slight increase of the connective tissue of the stomach-wall. The lining membrane is covered with mucus, and the mucosa is thick and swollen, denuded in places of its epithelium. The gastric juice contains excess of acid and pepsin, with varying amounts of mucus. Digestive power and motility vary in different cases, the former being often hindered by fermentative processes.

3. In the atrophic form (*G. glandularis atrophicans*) the columnar epithelium degenerates and goblet-cells are found in increased numbers; the peptic and acid-forming cells disappear. The connective tissue is increased, especially that lying between the glands. The stomach-wall is thin, and the inner surface smooth and lacking in folds. The gastric juice contains diminished amounts of acid and pepsin; mucus may occur in increased quantity. Digestive power is weak, but motility remains practically unaffected.

SYMPTOMS.—The symptoms of chronic gastric catarrh are so protean and so indefinite in character, and so often accompany other pathological conditions, that a full description of them would require too great a space. In its simplest form, and in the earlier stages, discomfort, feelings of gastric fullness or weight after food may be the only complaint of the patient. These symptoms may be combined with those resulting from gastric fermentation—flatulence, acidity, heartburn, variable appetite and capricious taste. As the ingestion of food, especially of solids, is followed by sensations of unrest, a distaste for it in any form gradually arises; less and less nourishment is taken; more and more does the consequent weakening of the organism aggravate the gastric condition.

Intestinal indigestion is a very common complication. The diminished acidity of the gastric contents permits bacterial forms to reach the bowel in large numbers, owing to inefficient antiseptic properties, and incomplete digestion of the food in the stomach causes increased intestinal fermentation and irritation. Loose motions, two or more each morning, of no great bulk, fetid, fluid or pulaceous, are frequently experienced, alternating with constipation of temporary duration and marked by excessive flatus passed *per anum*.

The intestinal processes, themselves due to the abnormal gastric condition, in turn exert a malign influence upon the cause of their being, aggravating the morbid state of the stomach, contributing to the upset of the body generally; and by so doing react upon themselves again, intensifying the causes of their misdoings, and establishing a true vicious chain, difficult to break.

Whether a chronic gastritis is catarrhal, hypersthenic or atrophic matters little clinically. The symptoms of each variety differ from one another, no doubt, to a certain extent, but the phenomena met with in the majority of cases of chronic gastric catarrh, whatever be their anatomical pathology, depend so much more upon individual idiosyncrasies, environment, habit of life, previous diet, and actual characters of the gastric contents, that such are of little value with regard to treatment and advisory rules. This one may exhibit pain after food, intense nausea before it; this pain before, nausea after. Another complains of a constant bitter taste in the mouth, of a sour taste, or

a sickly sweetish nauseating flavour; again, flatulence may be the *bête noire* of one, heartburn of another; inability to indulge in alcohol, however dilute, or the necessity for some quantity of the same before digestion can be carried on. One subject will eschew meat, a second vegetables, a third farinaceous foods. What one can tolerate another cannot.

Under these circumstances no hard and fast rule can be laid down as to the symptoms characteristic of chronic gastritis. Lesions apparently identical produce symptoms most diverse. All the abnormalities which can be associated with gastric disorders may be met with: heartburn; nausea; emesis; epigastric pain; sensation of fulness and weight; eructations of gas, tasteless and odourless, or evil-flavoured and nasty; retching; loss of appetite; capricious appetite; hunger appeased by a mouthful; sleeplessness, restlessness, hypochondriasis, and even melancholia; intestinal derangements; symptoms common to gastric ulcer and cancer; local tenderness and sensitiveness; dilatation and displacement—all are at times exhibited by patients suffering from chronic catarrh of the stomach of whatever type. Bulimia and excessive thirst, the latter especially when the gastric contents are regularly rejected or removed, are also met with.

When the condition is simply catarrhal the symptoms are chiefly subjective; no abnormal resistance, splashing, or sensitiveness may be evident. When hypersthenic, they only occur as a rule during the gastric digestion of food. Proteids are borne better than carbohydrates; heartburn and hyperacidity are common. Atrophic types are especially characterised by intestinal disorders, diarrhoea, or constipation; severe pain during digestion and marked inanition. Decrease in the normal proportion of the red corpuscles in the blood, more pronounced than in that of the hæmoglobin, is also a common accompaniment. The white corpuscles are fewer and more variable in type than usual.

DIAGNOSIS.—Chronic gastritis has to be differentiated from chronic functional disease of the stomach, from dilatation, displacements, chronic ulcer and cancer. It is frequently a matter of the greatest difficulty to come to a conclusion as to the nature of the disease. The points in favour of chronic gastritis are almost entirely negative; the absence of dilatation, or displacement, of hæmatemesis, past or present, of localised sensitive spots, of tumour, of dorsal painful areas, of neurotic antecedent and reflex causes aid in determining the nature of the disease. The chemical composition of the gastric contents aids still more. If hyperchlorhydria be present cancer is excluded, catarrhal and atrophic gastritis are negative; hypersthenic gastritis, ulcer and neurotic dyspepsia remaining. If hyperacidity from organic acids be found, ulcer is out of the question, catarrhal or atrophic gastritis or cancer probable; dilatation or displacement only if clinically supported.

Nervous dyspepsia is often chronic, and often simulates gastritis. Here, however, the subjective symptoms overshadow the objective, and usually some primary source can be discovered, mental, intestinal, or generative, while the corporeal effects are much less pronounced in dyspepsias which are primarily of purely nervous origin than in those arising from chronic gastritic lesions; less weight is lost, less outward appearance of illness presented;

more depression is shown, and greater tendency to magnify symptoms.

PROGNOSIS.—In all cases of chronic gastritis the prognosis should be guarded. Owing to the organic changes which originate it, little hope of any complete restoration of normal conditions can be entertained. But as the intestines lie behind the stomach as a powerful reserve force, if proper precautions be taken and persisted in, if the diet be regulated *secundum artem*, and the habits be irreproachable, the maimed remainder of the active agents in gastric digestion may suffice, aided by the bowel, to encompass all that is necessary for the maintenance of bodily health. But although the defect is thus compensated for, the subject represents a damaged life, and will need to avoid carefully all excesses and eccentricities of diet for the future.

TREATMENT.—Every case of gastritis presents individual points of difference. No hard and fast rule for treatment can therefore be laid down, though 'cut and dried' systems which take no heed of the sex, habits, general traits and special symptoms of individual patients may succeed in some instances, more by good luck than good guidance. For scientific treatment each case needs careful study and the exercise of sound judgment. Thus it is not only useless but actually harmful to order a milk-diet for one who is unable to digest it or dislikes it, unless it be prescribed in some special tentative form—for example, administered in small quantities at frequent intervals, or largely diluted with some bland watery fluid or water itself. Equally harmful is it to advise the ingestion of vegetables or bread in cases of hyperchlorhydria or of bacterial fermentation. All the facts require to be studied and the lines of treatment adjusted to them.

The most important rules of treatment may be thus formulated: (1) Never tax a chemically deranged stomach; (2) Never give such a case any rigid diet without first ascertaining the nature of the gastric secretion, and the kind of food best tolerated by the patient; (3) Give no large meals, but 'little and often'; (4) Alcohol is permissible, if helpful, but not if it acts as a disturbing agent; (5) Exercise, short, sharp and vigorous, with a rest afterwards, is beneficial, as opposed to official constitutional saunters; (6) Fresh air is most necessary; (7) The less medicine the better; (8) If the patient be anæmic, iron tonics should not be given until the general condition has been improved by the above measures; (9) If the gastric juice be deficient in hydrochloric acid, this may be given tentatively—best with strychnine, after meals, in a dilute form; (10) If, however, this acid be present in excess, it may be administered in small doses before meals; (11) Alkalis should not be given in hyperchlorhydria, except for temporary relief; (12) A careful search should be made for any possible complicating morbid condition, accessory or even primary; when found, this must be carefully treated; (13) All irritating articles of diet must be prohibited for a period—tea, coffee (unless it be 'milk and coffee,' not 'coffee and milk'), uncooked fruit, raw vegetables, excess of sugar—unless they are well tolerated in small amounts and much desired by the patient; (14) Any disorder of the intestine co-existing must be treated rather by antiseptics and antifermentatives than by purgative drugs. By careful attention to such rules as the

foregoing, cases which have not reached the most advanced stage, termed *Fibrosis ventriculi*, may be enabled to live in comparative comfort, although actual cure of the morbid condition is perhaps impossible. See p. 1593.

D. Gastritis Tuberculosa.—Tubercular disease of the gastric mucous membrane is not very common. Out of 1,420 cases of dyspepsia and gastritis treated in the Edinburgh Royal Infirmary from 1892 to 1899, tubercular concomitants were only recorded in 18; while among 760 patients admitted for gastric ulcer, only one was directly registered as tubercular; pulmonary phthisis was noted in only 6 instances. The small numbers shown by these returns do not imply that dyspeptic symptoms and gastric catarrh are not frequently met with as secondary adjuncts of tubercular disease; only that they rarely constitute so important a part of the symptom-complex as to merit registration. They are usually entirely subsidiary, and due rather to general than to local conditions. The indigestion common to pulmonary tuberculosis usually conforms to this rule. It generally arises from the constitutional lesion alone, or combined with actual tuberculosis of some portion of the alimentary tract above or below the stomach; seldom from local organic changes of a tubercular character, although simple catarrhal changes may often be present, resulting from the general dyscrasia. Van Valzah in his recent work is only able to refer to twenty-three authentic records of tubercular ulcer of the stomach. An important point in this connection is the frequent precedence of chronic gastritis and gastrectasis of tubercular disease of the lungs. The stomach-lesion, leading to inefficient metabolism, and thus to lessened vitality, facilitates tubercular invasion, not necessarily of the stomach itself—while this organ often suffers vicariously on development of tubercle elsewhere. The therapeutic measures often adopted in tubercular diseases are well fitted to aggravate any earlier gastric troubles, or even to originate such through the overtaxing of an organ already weakened by the tubercular toxins.

E. Gastritis Syphilitica.—Syphilis does not often invade the coats of the stomach, or, at least, syphilitic changes have seldom been met with in the tissues of the organ *post mortem*. Indeed the existence of such lesions is denied by many. Several cases, however, have been recorded in which multiple flat gummatous areas, a syphilitic ulcer, or a cicatrix of a previous ulcer (only occasionally more than one) were found in the stomach. The gummatous infiltration first begins in the submucous coat, spreads into the mucosa, now and then involving the whole mucous surface of the stomach by the coalescence of the separate growths. Einhorn, however, has lately insisted on three forms of syphilitic gastritis: an ulcerative, a gummatous, and a form productive of pyloric constriction. It has to be borne in mind that in the great majority of the recorded cases purporting to relate to gastric syphilis the accuracy of the diagnosis is open to grave doubt. On the other hand a very intractable chronic form of dyspepsia is met with during the third stage of syphilis, which yields more readily to iodides than to any routine method. The unfortunate heirs to hereditary syphilis are also said to develop similar lesions on occasion. Diagnosis of syphilitic gastritis during life is difficult. Loss of appetite,

gastric pains (especially after food), eructations, obstinate vomiting and diarrhoea, and tenderness over the bowel, are, as Herz says, scarcely definite enough to judge by. Even if a history of syphilis be clearly proved, little is gained, for similar symptoms accompany the dyspeptic disorders common in anæmia, and in several of the chronic systemic diseases. No opinion therefore can be safely offered as to the syphilitic causation of any case of dyspepsia, until the effects of anti-syphilitic treatment have been ascertained. It is an important rule, therefore, in the management of obstinate dyspeptic cases which refuse to yield to the usual methods, to make trial of anti-syphilitic remedies.

ALEXANDER LOCKHART GILLESPIE.

STOMACH, Malposition of.—Malposition of the stomach may be considered under the two headings: Malposition of the healthy viscus, and Malposition of the diseased viscus.

A. Malposition of the Healthy Stomach. The healthy stomach may take part in the displacement of all the abdominal viscera which occurs in general enteroptosis (p. 458). It may be dragged from its normal site by the great omentum contracting adhesions to the pelvic viscera or becoming involved in a hernial sac. It may itself form part of the contents of a hernia, more especially of the umbilical variety. As the result of congenital or acquired defects of the diaphragm, the stomach may be situated wholly or in part within the thoracic cavity. It may be pushed from its normal situation in any direction by abdominal, pelvic, or thoracic tumours. The displacement of the stomach forwards and downwards by collections of fluid occupying the position of the pancreas and the lesser sac of the omentum is one of the most characteristic signs of this interesting disease. See PANCREAS, p. 1154.

SYMPTOMS.—In many of the above conditions the symptoms of the primary disease overshadow any that may be due to the displacement of the stomach. In others, notwithstanding the malposition, the gastric functions are normally performed. There remains a small proportion of cases in which, the cause being unimportant, the displacement of the stomach gives rise to definite symptoms. These symptoms are either those of atonic dyspepsia or of pyloric obstruction; the former being induced by defective blood-supply or impaired mobility of the organ, and the latter by mechanical interference with the exit of the gastric contents.

TREATMENT.—The treatment of dyspepsia due to malposition of the stomach must be based on the same principles as guide us in dealing with dyspepsia generally. The diet must be carefully regulated as to quality and quantity. Muscular activity must be stimulated by nuxvomica, gentian, and other tonics; and the secretions regulated by acids or alkalis, presented before or after meals according to individual requirements. Should the existence of some adhesion fixing the stomach in an abnormal position be diagnosed with any degree of certainty, and the symptoms be unrelieved by simpler measures, an exploratory laparotomy may be indicated. Surgical interference may be more confidently undertaken if the symptoms are those of persistent pyloric obstruction. For in these circumstances, should the surgeon fail to find this suspected cause of the obstruction, he may be able to demonstrate its true nature and overcome it by some operative measure.

B. Malposition of the Diseased Stomach.

A stomach which is already the seat of disease is more likely to be displaced than the healthy organ. The increased weight of the viscus and its contents in a permanently dilated stomach may cause it to occupy a lower position than normal. In such cases the outline of the organ may sometimes be distinctly seen, the greater curvature reaching almost to the pubes and the lesser crossing the abdomen above the umbilicus. In cancer or chronic ulcer of the stomach when the peritoneum becomes involved adhesions are formed to neighbouring viscera, and thus the stomach may be gradually dragged from its normal position.

SYMPTOMS.—It is generally difficult to distinguish between the symptoms of the original disease and those which are the result of the malposition. When to the symptoms of simple dilatation are subsequently added those of obstructive dilatation, the latter may reasonably be attributed to kinking of the pyloric extremity from sagging down of the stomach. In ulcer or growth symptoms of obstruction are more likely to be due to organic stenosis of the pylorus.

TREATMENT.—The therapeutic measures are those indicated for the treatment of the original disease.

LAURISTON E. SHAW.

STOMACH, Morbid Growths of.—**PATHOLOGY.**—New-growths of the stomach may be either simple or malignant.

Simple Growths are rare, and when present seldom give rise to symptoms or exert any influence upon the duration of life. They vary in structure and appearance according to the coat of the organ in which they arise. Local over-growth of the mucous membrane results in filiform or cauliflower-like processes which are termed *papillomata* or *simple villous tumours*. When the submucous tissue is implicated, smooth sessile or pedunculated excrescences—*polypi*—are produced. Polypi may be single or multiple, and are sometimes met with in the neighbourhood of a gastric ulcer. If the muscular coat is the seat of a simple tumour, localised firm nodules are formed, producing slightly elevated flat projections beneath the mucous membranes. They are called *myomata* or *fibro-myomata* according to the proportions of unstriated muscle and fibrous tissue composing them. *Lipomata* have been described arising from the subperitoneal connective tissue. In association with Hodgkin's disease aggregations of uniform small round-cells may be found in the submucous tissue of the stomach, giving rise to tumours of various size projecting into the cavity of the organ and covered by normal mucous membrane. This condition, termed *lymphadenoma*, occupies, in a pathological sense, an intermediate position between simple and malignant growths. Clinically these masses resemble the simple growths in the rarity with which they give rise to symptoms of gastric disorder.

Malignant New-growths.—While primary growth of the stomach is common, deposits secondary to growths elsewhere are rare. A primary growth in one part of the organ may, however, be associated with secondary nodules in neighbouring portions of the mucous membrane. Of primary growths there is a great preponderance of carcinoma as compared with sarcoma.

Carcinoma.—Carcinomata of the stomach may be of the scirrhous and medullary types, and contain

spheroidal or cylindrical cells. The proportion of fibrous stroma to the cellular elements appears to be an accidental condition, for in certain examples of the disease different portions of the same growth may exhibit considerable variation in this respect. The character of the cells lining the alveoli appears to be an essential feature of the growth, as evidenced by the fact that the same histological features may be found not only in all parts of a very diffuse growth, but also in its secondary deposits in distant parts of the body. Colloid degeneration is of common occurrence in all forms of carcinoma of the stomach. Of forty-four unselected cases of carcinoma of the stomach, Dr. Perry and the present writer found that thirty-two belonged to the spheroidal-celled and twelve to the cylindrical-celled group. At the same time it was noted that, on the average, the stroma was more abundant in spheroidal than in cylindrical-celled growths, and that as a consequence large soft medullary tumours generally belonged to the latter, and hard contracting growths to the former category. Growths which caused universal infiltration of the organ were usually found to be of the spheroidal-celled type. Examples of each type of growth were found in all parts of the stomach, except at the cardiac orifice. The few examples of growth limited to this orifice were all found to have their alveoli filled with spheroidal cells. The age or sex of the patient seemed to have no influence in determining the variety of cancer affecting the stomach.

Carcinoma of the stomach has its origin in the deeper layers of the mucous membrane, and gradually extends thence into all the coats of the organ. The greatest development of new tissue takes place in the submucosa. Columns of cells dip down between the muscular fibres, and ultimately destroy them. The remaining fibres undergo a considerable hypertrophy, so that the muscular coat may often be recognised by the naked eye to be more than twice its usual thickness. The implication of the superficial layer of the mucous membrane leads to its destruction and to the production of an ulcer. Sooner or later the serous coat is affected, and nodules of growth are visible from the exterior of the organ, usually following the course of the lymph-vessels. According as the development of the new-growth takes place in a perpendicular or in a horizontal plane carcinoma presents itself as a prominent fungoid mass projecting into the cavity, or as a diffuse plaque-like infiltration of the wall of the organ. In many cases these two conditions are combined. As already stated, the mucous membrane generally becomes ulcerated, but in the early stages it may merely present an appearance of undue rugosity, or it may be smoothly stretched over sub-jacent masses. Very rarely it becomes villous. Small nodules of growth, called satellites, are sometimes seen around the main mass.

In slowly growing carcinomata, especially of the spheroidal-celled variety, the portion of the organ implicated may undergo considerable shrinking, and as a result the whole stomach may be contracted or its lumen narrowed at some particular point, especially the pylorus. Cancer of the stomach may be found limited to the pylorus, to the lesser curvature, to the cardiac orifice, or more rarely to the fundus of the organ. Before death takes place the disease is generally pretty widely diffused, and in certain cases the entire organ is involved. The most frequent site of carcinoma is the pylorus.

In a series of cases examined by the writer the pylorus was implicated in 70 per cent. Whether the disease starts at the pylorus or ultimately reaches this orifice from some other site, it is exceedingly rare for carcinoma to extend beyond the stomach into the duodenum. Such an extension through the pylorus is, however, common in sarcoma. On the other hand, gastric carcinoma involving the cardiac orifice usually implicates the lower end of the œsophagus. Some authors have suggested that such growths are primary in the œsophagus, and extend thence into the stomach. The fact, however, that they are usually spheroidal-celled growths, while cancer of the œsophagus is a squamous-celled epithelioma, makes this suggestion improbable. Whenever either orifice of the stomach is involved in the growth, obstruction is likely to occur, usually as the result of stenosis from contraction of the fibrous stroma of the neoplasm, rarely by prominent masses projecting into the lumen. Obstruction of the cardia produces a simple atrophy of the stomach such as is seen in stenosis of the œsophagus higher up; obstruction of the pylorus by malignant growth is one of the most important causes of hypertrophy and dilatation of the stomach. *See p. 1595.*

When the entire stomach is infiltrated by scirrhus carcinoma there may be produced a remarkable diminution in the size of the viscus associated with a moderate thickening of its coats. A specimen is preserved in the museum of Guy's Hospital which measures only 7 inches along its greater curvature and 2 inches transversely at its widest part, the wall being not more than $\frac{1}{8}$ of an inch in thickness. In its earlier stages this special form of carcinomatous affection probably exhibits a greater thickening of the wall and a more moderate shrinking of the organ. To this general contraction and thickening of the viscus the name, 'india-rubber-bottle stomach' has been given, and much obscurity has existed as to its origin. It was at one time thought to be due to a special form of chronic gastritis. The difficulty in establishing its essentially neoplastic origin is due to the almost complete disappearance of the epithelial contents of the alveoli from the fibrous stroma of the growth. When limited to the pylorus such a condition was called 'simple scirrhus' of the pylorus; and when affecting the whole organ, 'chronic indurative gastritis' or 'cirrhosis of the stomach.' The recognition of typical carcinomatous elements in the neighbouring lymphatic glands revealed the true nature of the condition.

Death sometimes ensues while the malignant growth is strictly limited to the viscus. In many cases, however, secondary affections follow. The malignant deposit may ulcerate through all the coats of the organ, and lay open the peritoneal cavity, or it may become adherent to and invade adjacent viscera. Sloughing ulcerous excavations may be produced in the liver; the duodenum or colon may be opened and their cavities become continuous with that of the stomach. The abdominal wall may be involved in the growth, and very rarely an external fistula result. The spleen, diaphragm, pleura or pericardium may also be directly invaded. A large artery in the neighbourhood of the stomach may be laid open, and fatal hæmatemesis produced. The growth may also be carried by lymphatics or blood-vessels into other parts: the glands, liver and peritoneum being the

organs most frequently affected by secondary deposits in this way. The abdominal glands are those usually invaded, but it is important to remember that carcinomatous enlargement of cervical or inguinal glands has sometimes been the first symptom to attract attention in cases of gastric growth. Secondary deposits are found in between 70 and 80 per cent. of the cases.

The association between cancer of the stomach and simple ulcer demands attention. Many cases are recorded in which patients who have for many years suffered from symptoms of simple ulcer have been found upon *post-mortem* examination to be affected with carcinoma of the stomach. In some such cases a healed or open ulcer, having the appearance of a simple ulcer, is seen in the midst of the cancerous infiltration. The assumption that the ulcer has proved a suitable soil for the development of malignant disease seems justified. On the other hand, in some examples of cancer of the stomach in which the symptoms have been of short duration, a punched-out smooth-based ulcer may be found on or in the neighbourhood of a malignant deposit, and it is perhaps not unreasonable to imagine that the solvent action of the gastric juice, which is mainly responsible for producing simple ulceration, may influence the course of ulceration in cancer. It must be remembered also that the edges of a chronic simple ulcer may be thickened by inflammatory exudation and surrounded by a warty condition of the mucous membrane—appearances which may be mistaken for cancer, unless a microscopical examination is made. No case should therefore be regarded as an example of carcinoma engrafted on simple ulcer, unless there is a conclusive history of the pre-existence of an ulcer and histological evidence of carcinomatous deposit.

Sarcoma.—As already stated, sarcoma is a much rarer disease than carcinoma. Its rarity is perhaps not so great as existing statistics would seem to indicate. In the absence of systematic histological examination, some cases have doubtless been included as examples of the commoner disease. The writer has submitted to microscopical examination six specimens of sarcoma of the stomach, and in all the growth was found to be of the small-round-celled type, sometimes called lympho-sarcoma.

From an investigation of these specimens and of other recorded cases the following appear to be the chief particulars in which the morbid anatomy of sarcoma of the stomach differs from that of carcinoma. There is less tendency to ulceration of the mucous membrane. When the mucous membrane is destroyed it is usually in connection with extensive sloughing of the sarcomatous tumour. Earlier and more complete destruction of the muscular tissue takes place, and as a consequence the hypertrophy of this coat, so common in carcinoma, is not observed. There appears to be little if any tendency to contraction of the growth, and the pylorus is therefore not so commonly obstructed as in carcinoma. The pylorus is, however, frequently involved in the sarcomatous infiltration, and when this is the case the deposit may extend into the duodenum, an event which is very rare in the other form of malignant disease. The sarcomatous deposit may form localised nodular masses, or may exist as a general infiltration of the whole organ. The amount of new tissue formed is usually greater in sarcoma than in carcinoma, and when the whole

organ is involved tumours of great size may be produced.

ÆTIOLOGY.—In describing the ætiology and symptoms of malignant disease of the stomach the term 'cancer' will be used to include both forms of growth, certain special points of distinction being indicated as occasion may arise. Cancer of the stomach is essentially a disease of the *latter half of life*. Welch found in analysing over 2,000 cases that 75 per cent. occurred between the ages of 40 and 70, the percentage for the three decades being as follows: from 40 to 50, 25 per cent.; from 50 to 60, 30 per cent.; from 60 to 70, 20 per cent. Dr. Perry and the present writer, in investigating the histology of a small group of cases, found the average age at death in cases of true carcinoma to be 52, the oldest being 81 and the youngest 32. As to the relative frequency in the two *sexes*, considerable variety has been noticed in different series. A preponderance of males over females is however constant, some series indicating the ratio as 5 to 1, and others as 5 to 4. The exciting cause of cancer is still unknown, and beyond the fact already mentioned of the possible relationship of carcinoma to simple ulcer of the stomach, there is no evidence of the existence of any constant predisposing causes of the invasion of the stomach by malignant disease. *Hereditary predisposition* is not more often present than in cases of cancer of other organs. Chronic dyspepsia, gastritis, and traumatism, when noted as preceding cancer of the stomach, are probably merely accidental associations.

SYMPTOMS.—The symptoms of a typical case are as follows: A man between fifty and sixty years of age, having previously enjoyed good health, begins to lose strength and weight and to become pale. His appetite is capricious; easily digested food causes pain or a feeling of discomfort, and it is now and then rejected a few hours after it has been swallowed. At first the vomit has merely the appearance of undigested food, but later it is dark in colour and mixed with a black sooty fluid resembling coffee-grounds. If the abdomen is now carefully examined some tenderness and resistance may be detected in the epigastrium or below the left costal arch, or a more or less definite mass may be felt varying somewhat in position from day to day. Careful diet will at this period almost certainly relieve the more urgent symptoms; but ultimately these return with increased severity, pain after food of any description becomes intense, and vomiting and hæmatemesis are almost of daily occurrence. Side by side with these symptoms of gastric disturbance the general health rapidly deteriorates; the emaciation and anæmia are extreme, and muscular power is altogether lost. The circulation fails, attacks of syncope are common, and the dependent parts of the body become œdematous. Towards the end the more distressing symptoms, such as pain and vomiting, may be in abeyance; but the progress of the disease is constant, and death takes place in from six months to a year from the onset of symptoms. Before referring more in detail to these symptoms it is perhaps well to draw attention to the fact that cancer of the stomach may certainly reach an advanced stage without any symptoms whatever being noticed. Extensive malignant growth of the stomach is not very uncommonly found in the bodies of patients who have been killed or died of some acute disease, and who have regarded themselves as in good health until the

moment of the accident or the onset of the sudden illness. This class of case must be distinguished from the so-called 'latent cancer of the stomach,' a term which has been applied to a still commoner group, in which the patient dies from the effect of cancer of the stomach, but presents such indefinite symptoms that the essential disease is overlooked.

The symptoms of cancer of the stomach may be considered in detail under four headings.

1. Symptoms due to involvement of the Stomach.—These are pain, vomiting, and hæmatemesis.

Pain is a frequent symptom (80 or 90 per cent.), and may have any of the features indicative of gastric disorder. It may be constant and uninfluenced in any way by the ingestion of food, in which case it is probably the result of the compression of nerves by the growth or by its secondary deposits. When related to the swallowing of food, the pain may occur immediately after a meal, or may be delayed till one or more hours after food is taken. On the other hand, pain which comes on some three or four hours after one meal may be distinctly alleviated by the next. The pain may be generally diffused over the gastric region, may be confined to the epigastrium, or felt only in the back. It is sometimes associated with localised areas of hyperæsthesia (*see* p. 1142). The pain most characteristic of cancer of the stomach is a constant gnawing sensation in the epigastrium and back, greatly aggravated shortly after food is swallowed, and considerably relieved if vomiting takes place. With our present knowledge it is not usually possible to attach any special pathological significance to different varieties of pain. It is reasonable to suppose that a hyperæsthetic condition of the mucous membrane, flatulent distension of the organ, vigorous peristaltic action, and the dragging upon external adhesions may all play a part in causing pain in individual cases.

Vomiting is not so common a symptom as pain. Only 10 or 20 per cent. of cases run their whole course without vomiting, but many patients who have persistent pain vomit only occasionally. The most constant cause of vomiting in cancer of the stomach is obstruction of the pylorus associated with gastric dilatation. In these cases the vomiting takes place at fairly long intervals (36 to 48 hours); the matter ejected is large in volume, may present evidence of having undergone fermentation, and sometimes contains undigested particles of food eaten many days before.

In cases where there is general contraction of the stomach vomiting is sometimes entirely absent. When present it usually occurs at short intervals, and the amount ejected is of course small. In many cases no mechanical explanation for the vomiting can be found. This symptom may result from the failure of the diseased organ to digest the food, or it may be a more or less voluntary act in order to relieve pain. It is rarely induced by an over-distension of the viscus by blood, a common cause in simple gastric ulcer. Of more importance than the frequency and character of the act of vomiting are the features of the material vomited, or of the contents of the stomach withdrawn by a soft tube after a test-meal has been given (p. 1589). Very occasionally the vomit has a horribly offensive odour. In such cases necrosis of large masses of growth or a fistulous communication between the stomach and lower bowel has been found at the autopsy. The absence

of free hydrochloric acid from the contents of the stomach has frequently been observed in cases of gastric cancer. A notable exception to this rule is said to exist in cases of cancer following upon simple ulcer. Further investigation on this point is desirable, but it may be stated generally that the existence of free hydrochloric acid in normal amount is strong evidence against the presence of malignant disease of the stomach. On the other hand, the presence of lactic acid in the gastric contents favours a diagnosis of cancer. Careful microscopical examination may sometimes reveal the presence of portions of malignant growth.

Hæmatemesis.—The number of cases in which bleeding takes place into the stomach from the ulcerated surface of the growth cannot be accurately determined. Hæmorrhage is rarely so profuse as to induce vomiting, and unless vomiting takes place concurrently from some other cause, the existence of bleeding may be overlooked. Altered blood is found in the motions, with or without hæmatemesis. Osler observed the vomiting of blood in 24 per cent. of his cases. The amount vomited may be large or small, but is usually small. The blood is generally dark in colour, as if it had been long retained in the stomach. When in large quantities it gives the characteristic 'coffee-ground' appearance to the vomit. Profuse hæmatemesis is but rarely the direct cause of death; repeated small losses accelerate the patient's end. It is unusual for the pathologist to be able to recognise an open artery as the source of the bleeding. See HÆMATEMESIS, p. 620.

2. Physical Signs of the Involvement of the Stomach.—Careful inspection and palpation of the abdomen will usually enable the physician to detect some departure from the normal condition. The abdomen should be entirely uncovered in a good light, and no pains spared to obtain complete relaxation of the abdominal muscles. An area of hyperæsthesia, a point of tenderness on deep palpation, or a sense of resistance may be the only indication of the existence of growth. In some cases clear evidence of hypertrophy and dilatation of the stomach may be found as indicated by distension of the upper part of the abdomen, succussion, and visible peristalsis (p. 1596). In others a tumour may be seen or felt, in or near the gastric region (p. 1588). The normal relations of the parts may be altered, and in the absence of symptoms of gastric disorder, it may be difficult to determine the viscus in which the tumour is situated. Many cases of gastric neoplasm have been mistaken for growth in the spleen, liver, colon, pancreas or lymphatic glands. Careful investigation as to the relation of the tumour to the gastric resonance may enable a diagnosis to be made, and with the object of determining this relation it may be desirable cautiously to distend the stomach with gas. A gastric tumour may vary its position in accordance with the amount of distension of the viscus. It commonly descends on inspiration, and may be moved by the physician's hand, or by the patient turning from side to side. It is obvious that the tumour will be most easily felt if it occupies the pylorus or the greater curvature. If the lesser curvature is alone involved, or if the whole organ is contracted, it is likely to escape detection. A small 'india-rubber-bottle stomach' has, however, sometimes been recognised as a hard mass projecting beyond the left costal arch. Whether the gastric growth forms a palpable tumour or not, it is some-

times possible to detect masses formed by secondary deposits in neighbouring organs.

3. General Symptoms.—These symptoms, usually included in the term 'cancerous cachexia,' are wasting, anæmia, pyrexia, and œdema.

Wasting and loss of strength are prominent symptoms in nearly all cases. They are partly due to the nature and partly to the situation of the disease. In most cases the wasting is easily recognised to be out of proportion to the loss of digestive power, and is often indeed observed before any symptoms of gastric disturbance are in evidence. Anæmia is equally common, and is an early symptom. Great attention has lately been paid to examination of the blood; but with our present knowledge little assistance in diagnosis is thereby given, except to differentiate between pernicious anæmia and gastric cancer. The anæmia of cancer is rarely so extreme as in the idiopathic variety, and is invariably associated with a deficiency of hæmoglobin relatively greater than the diminution in the number of red blood-corpuscles. Osler found more or less fever in half his cases, and failed to establish its relationship either to ulceration of the growth or to the existence of secondary deposits. It is probably a direct effect of the neoplasm. Œdema of the lower extremities is fairly common, and general anasarca rare. They are both attributable to the anæmic state and to the enfeebled circulation. The possibility of secondary deposits causing pressure upon veins must not be disregarded. The same conditions of the circulation which favour œdema are probably also responsible for producing thrombosis of the veins.

4. Secondary Symptoms.—These are the result of an extension of the growth to other parts, or of the development of secondary deposits. A moderate degree of ascites may be present, either as the result of cancerous deposits in the peritoneum or of obstruction to the portal vein. Jaundice, from growth in the liver, may be the earliest manifestation of disease, or it may come on a few days before the patient's death. General peritonitis from perforation of the stomach is very rare. If perforation takes place a localised peritoneal abscess is the usual result. Metastases in the supraclavicular or inguinal lymphatic glands, or in the region of the umbilicus, may sometimes be the first clue to the malignant nature of the gastric trouble from which a patient is suffering.

DIFFERENTIAL DIAGNOSIS.—The diagnosis of cancer of the stomach depends largely upon the recognition of symptoms belonging to two or more of the four groups enumerated above. It is not uncommon in the earlier stages, or even throughout the disease, for cases to present symptoms strictly confined to one of the above groups, or the symptoms in one group may so predominate as to cause others to be overlooked. The conditions for which cancer of the stomach may be mistaken will of course depend upon the group to which the predominant symptoms belong. When pain and vomiting are the main symptoms, dyspepsia and chronic gastritis must be considered; while if these symptoms are complicated by hæmatemesis, gastric ulcer or cirrhosis of the liver may be mistaken for cancer. Hypertrophy and dilatation of the stomach may be caused by cicatrisation of a simple ulcer, as well as by cancerous stenosis of the pylorus. A mass of growth in the stomach producing a definite tumour unaccompanied by symptoms of gastric

disturbance may be mistaken for simple or neoplastic enlargement of neighbouring viscera. The greatest difficulty in diagnosis occurs when the general symptoms of cancerous cachexia are present without symptoms or physical signs of local involvement of the stomach, or when the latter are in abeyance while the secondary effects of the growth are evident. Such cases have received the name of 'latent cancer' of the stomach. During life they may be regarded as examples of pernicious anæmia, general tuberculosis or Bright's disease, or if their cancerous nature is recognised the situation of the growth may be undetermined, or its secondary deposits in the liver or peritoneum alone detected.

TREATMENT.—There is no evidence that cancer of the stomach, when once established, can be 'cured' except as a result of its complete removal by the surgeon. Even when so removed, the tendency to recurrence is very great. The earlier the operation is performed the less the tendency to recurrence. Herein lies the great difficulty in surgical treatment. In the early stages the diagnosis is often impossible; in the later stages, when diagnosis becomes certain, successful removal is improbable. The want of success in the later stages is due to two causes. In the first place the patient's cachectic condition renders him an unsuitable subject for so serious an operation, and in the second place metastases in distant parts are likely to have already occurred. Some authors have confidently stated that no case in which the diagnosis can be made is suitable for surgical treatment. But constant progress in methods of early diagnosis and in surgical technique alters our point of view. If the physician bears constantly in mind that every case of gastric trouble in a patient of middle age may be one of cancer of the stomach, and carefully employs all the means of diagnosis at his disposal, he will be able to place many suitable cases in the hands of the surgeon.

Hitherto we have considered surgical treatment in early cases with the object of complete removal of the growth. The surgeon may also be called in later to alleviate symptoms in cases that are obviously too far advanced for radical cure. When there is obstruction at either orifice life may be prolonged by appropriate surgical measures. With growth involving the cardiac orifice gastrostomy, if performed before the patient has reached an extreme condition of starvation, may prove of great benefit. Nourishment can then be well maintained, and the removal of irritation to the growth by the passage of food may alleviate pain and arrest the progress of the neoplasm. On the other hand, pyloric obstruction should be met by making an anastomosis between the stomach and a loop of small intestine. Not only may life be considerably prolonged by such an operation, but a most striking improvement may ensue in the patient's condition. Pain and vomiting may be entirely relieved, and the patient's ability to take food greatly increased.

Apart from surgical measures considerable alleviation to suffering may be brought about by diet, by washing out the stomach, and by drugs. So great may be the effect of medical treatment that it is necessary to bear in mind that a rapid relief of symptoms must not cause a diagnosis of cancer to be lightly given up.

Diet.—The dietetic treatment of cancer of the stomach does not materially differ from that to be employed in cases of digestive failure from other

causes. As a general principle it is well to allow the patient to take the most substantial diet that experience shows him to be able to digest without serious pain. The time may come when nothing but predigested milk will be tolerated by the stomach, or when feeding must be entirely effected by nutrient enemata. This date will probably be only hastened if the diet is too much restricted in the earlier stages of the disease. Bearing in mind this principle, and having regard to the fact that we cannot hope to restore the patient's normal digestive powers, the diet must be chosen according to the directions laid down in pp. 1597, 1601, 1603, and 1606. It is often wise to consult the patient's palate, even though his choice of diet may appear to run counter to physiological laws.

Lavage.—The operation should at first be undertaken daily, and subsequently two or three times a week. The most suitable time is about half an hour before one of the principal meals, either in the morning or the evening. Washing is especially indicated in cases of pyloric obstruction with retention of food; but excellent results are often obtained in cases where no organic obstruction exists. Products of decomposition or portions of necrotic growth are likely to be present in all cases of cancer, and it is their complete removal which is responsible for the relief of pain and vomiting which so often follows this proceeding. Tepid boiled water is the best medium to use. Various antiseptic solutions have been recommended, but if such are employed it must be borne in mind that very occasionally the fluid injected cannot be easily removed. The antiseptic solution should therefore be dilute and innocuous. See pp. 1597 and 854.

Medicinal.—Various drugs may be given with the object of increasing the digestive power, arresting decomposition, or allaying pain. The absence of free hydrochloric acid from the gastric secretions in cancer of the stomach would seem to indicate that this drug might be given with advantage, and in the early stages an acid mixture containing nux vomica is often usefully prescribed after meals. As a general rule, however, alkaline mixtures prove more effectual in relieving pain. Opium or morphine should not be withheld if the pain is severe, and is unrelieved by washing out the stomach. Morphine may be conveniently combined with bismuth suspended in mucilage, while a pill containing opium, nux vomica, and creosote often proves beneficial where pain is associated with rapid fermentation of the gastric contents.

LAURISTON E. SHAW.

STOMACH, Neuroses of the.—Gastric neuroses may be classified as: I. Motor; II. Sensory; III. Secretory. Under each one of these we may distinguish (a) states of excitation, and (b) states of depression.

Irritative Motor Neuroses.—1. *Cardiospasm.*—Cardiospasm is a secondary disease in the great majority of cases, due either to hyperæsthesia, to very strong irritation of the mucous membrane of the cardia, or to abnormal expansion of the stomach by air and gases. It may occur in ulcer and carcinoma of the lower end of the œsophagus and of the cardia.

The prominent symptoms depend upon the inability to pass solids, liquids or gases, in either direction from the cardia: the strongest efforts at vomiting bring up nothing. There are two forms

of this neurosis, the acute and chronic. The acute cardiospasm appears suddenly, spasmodically, and is of short duration. It is recognised only when a tube is, for instance, introduced into the stomach, or when food or drink is taken by the patient. The chronic form is a very stubborn and grave disease, and may even become the cause of death through inanition. The patients have an unmistakable feeling that deglutition is impeded if they happen to swallow during an acute cramp. If in spite of this food is still swallowed, the lower part of the œsophagus immediately above the stomach becomes distended.

The recognition of cardiospasm is made by auscultating for the deglutition-sounds with a stethoscope while the patient is directed to swallow some water; absence of the second deglutition-sound means an obstruction at the lower end of the œsophagus or at the cardia. Passage of the stomach-tube gives information concerning the permeability of the œsophagus.

Treatment consists in the avoidance of causes increasing neurasthenia; correction of aerophagia; introduction of firm thick tubes, which are allowed to remain in position for twenty minutes; and application of cocaine hydrochloride and camphor-menthol to the lower end of the œsophagus and cardia. The galvanic current is of value in the treatment, the anode being placed in the cardia by an intragastric electrode, the cathode over the cervical spine. The bromides may give relief if continued two to three weeks.

2. *Pyloric spasm*.—This may be due to gastric hyperæsthesia, to chemical irritation by excess of hydrochloric acid or by abnormal formation of organic acids, to dilatation of the stomach by gases, and to toxic and irritative substances formed by intragastric fermentation. Secondary spasm may accompany ulcer, or ulcerating carcinoma of the pylorus.

It may be assumed to exist when atony of the stomach occurs without any assignable cause. Persistent pyloric spasm may lead to pronounced gastric dilatation. If associated with intense pain and hyperacidity, gastric ulcer should be suspected.

By way of treatment the pylorus may be intubated by the author's method of duodenal intubation (Hemmeter's *Diseases of the Stomach*, 2nd edition, p. 53). The bromides, 30 grs., combined with $\frac{1}{2}$ gr. ext. belladonnæ, or 5 grs. chloral hydrate, are very useful in this condition. The galvanic current, and spraying with cocaine and menthol, may also be employed.

3. *Gastrospasm*.—Gastrospasm signifies a spasmodic contraction of the entire gastric musculature. The whole stomach may be contracted, so as to resemble a cannon-ball. It is fortunately a very rare condition. It closely resembles gastric hyperperistalsis.

4. *Gastric hyperperistalsis*.—‘Peristaltic unrest’ is the name Kussmaul gives to a state of the stomach characterised by the appearance of extraordinarily rapid contractions, appearing especially after meals, but continuing also during the day and sometimes through the night with an entirely empty stomach. The patients complain of disagreeable sensations of heaving to and fro, of unrest, and contractions in the region of the stomach. When there is ectasis or dislocation of the stomach present simultaneously these abnormally strong contractions may be seen and felt externally. Sometimes, also, peristaltic

unrest of the small intestine co-exists with that of the stomach.

Increased activity of the stomach may be brought about—(1) As a reflex process, through hyperæsthesia of the sensory nerves; (2) by a strong stimulation of the mucous membrane of the stomach by excess of hydrochloric acid, by organic acids, and by distension from abnormal fermentation; (3) as the result of an advanced stenosis of the pylorus or duodenum; and (4) owing to an increased irritability of the motor nerves.

Sexual excesses, repeated intense emotions, an unsuitable mode of living, general nervousness, as well as anæmia, increase the disposition to this disease.

The patients frequently complain of a lack of appetite, belching, nausea, and vomiting. Loss of flesh may occur, so that a suspicion of malignant disease may arise. If the small intestine is also the seat of active peristaltic unrest, intestinal gases and liquids sometimes regurgitate into the stomach; the eructations are then very foul-smelling, and even fæulent.

Treatment consists in avoidance of sexual excesses, mental shocks, and over-exertion. If the peristaltic unrest is a partial or resultant effect of a decided neurasthenia or anæmia, change of air and hydropathic procedures are useful. Anæmia must also be corrected. Sedatives, like the bromides, opium, and belladonna, are said to exert a more controlling effect on the intestinal than on gastric hyperperistalsis.

In severe cases in which the peristaltic unrest continues through the night, rest in bed and a milk diet are recommended, and cold bandages or packings of the stomach should be tried, and if these do not relieve, then warm cataplasms. Any immoderate distension of the stomach is to be strictly avoided. The present writer has had satisfactory results with exclusive rectal feeding in two cases of peristaltic unrest.

Of medicines, sodium, ammonium, or strontium bromide, in doses of 45 to 75 grs. three times in twelve hours, or extract of belladonna ($\frac{1}{4}$ to $\frac{1}{2}$ of a grain), are to be recommended. In a persistent case of peristaltic unrest in a gouty patient salicylate of sodium (20 grs.) along with bismuth subnitrate (16 grs.) three times daily appeared useful.

5. *Nervous eructation*.—The belching up of tasteless or offensive gases is a frequent symptom in most gastric diseases, and occurs at times in every normal person. The pathological eructation which occurs in neurasthenia consists of the explosive evacuation of tasteless gas in large quantities. The attacks are usually paroxysmal, and the gas that is expelled is air which has been swallowed. Nervous individuals, particularly hysterical patients, may belch up air during the entire day, and often during the night.

An exaggerated form of this disease is known as *pneumatosis*. Considerable dyspnoea may occur in these cases resembling the ‘asthma dyspepticum’ of Hensch. In many cases persistent constipation will be found to be an ætiological factor.

In order to cure this disorder the patient and his attendant must be instructed that the eructation is largely a habit, and that by close observation the patient can be interrupted in the act of swallowing air. Penzoldt cured a patient of this kind by making him keep his mouth open for a half-hour,

as it is impossible to swallow air when the mouth is open. The explosive eructations of hysterical patients are best treated by methods directed towards the psychical condition of the case. Quincke has seen cures by introducing a thick, soft stomach-tube, which is permitted to rest for a while in the œsophagus. Cases that depend upon aspiration by alternate expansion and contraction of the stomach are benefited by the intragastric application of the galvanic current. The neurasthenic foundation of the disease should receive careful attention, e.g. by a course of surf-bathing. Cold sponging and massage are very useful aids in treatment. Among the drugs that have been recommended are small and frequently repeated doses of arsenic, belladonna, or atropine. Hypodermic injections of morphine may be required in severe cases.

6. *Nervous, habitual, or reflex vomiting.*—There are three forms of nervous vomiting: (1) The cerebral or spinal vomiting, which is caused by direct or indirect stimulation of the vomiting centre in the medulla oblongata from foci of irritation in the brain and spinal marrow. (2) Nervous vomiting, occurring as a symptom of hysteria or neurasthenia. (3) The reflex vomiting, in a more restricted sense, brought about by reflex irritations from various other organs in the body.

(1) *Cerebral vomiting.*—See VOMITING.

Spinal vomiting (gastric crises).—See TABES DORSALIS.

Periodical vomiting (Leyden).—This is a combination of symptoms in which the prominent feature is vomiting that returns at regular intervals. The attacks begin without any marked prodromal symptoms, in the midst of apparently good health. Gastralgia may introduce the attack or follow it. The appetite is lost, pulse small and frequent, tongue coated and dry. The patients may have intense headache or even slight delirium. It appears occasionally as a primary, idiopathic neurosis of the vagi; it has also been known to occur with hydronephrosis, floating kidney, diseases of the uterus and ovaries, intestinal entozoa, and nicotine-poisoning.

(2) *Nervous vomiting in the course of neurasthenia and hysteria* (M. Rosenthal).—These patients frequently complain of severe pain in the gastric region, pointing to a hyperæsthesia of the sensory nerves. The following points are characteristic of vomiting of nervous origin (Stiller): (1) the facility of the emesis; (2) the independence of the quality and quantity of the ingesta; (3) the capriciousness with which very bizarre articles of diet are frequently retained to the exclusion of others; (4) sometimes the elective vomiting of certain substances which seemingly are separated from the mixed chyme; (5) the carelessness with which the patient endures the habitual sickness; (6) the tolerance of the body to the effect of inanition caused by the habitual vomiting; (7) the extraordinary influence of the slightest causes that act on mood or temperament; (8) the frequent occurrence of emesis when no food has been taken and the stomach is apparently empty; (9) the presence of other nervous symptoms alternating or contemporaneous with the vomiting; to these Boas adds (10) the absence of important secretory or motor disturbances. Nausea and retching are absent in the vomiting of hysterical patients.

Juvenile vomiting is an expression of a dyspepsia developed in school children as the result of

mental over-exertion. The symptoms are dyspeptic complaints, gastralgia, vomiting, great pallor, dilatation of pupils, slowing of the pulse, and constipation.

(3) *Reflex vomiting in a more restricted sense.*—This may occur as a result of abdominal disease, not only grave disorders such as peritonitis and the various forms of colic, but also of slight derangements of the female sexual organs. Normal menstruation and pregnancy are occasionally accompanied by emesis (see PREGNANCY, Disorders of).

Whenever possible the treatment must be directed to the underlying causal diseases. Gastralgic pains and hyperæsthesia can be relieved by a hot cataplasm on the stomach, but the application of the galvanic current—the anode on or in the stomach, the cathode alternately on the sternum and spinal column—will be more efficacious. Internal gastric douching with warm water, and spraying the inside of the stomach with menthol and cocaine, are also generally followed by cessation of the pain. With regard to diet, the idiosyncrasy of the patient should be carefully studied. ‘No diet can be suggested that shall be universally applicable to all cases.’ The ingestion of liquids must, as a rule, be very much limited, and thirst relieved by enemata. If every meal is vomited, it is best to give nourishment in very small quantities—iced-milk, champagne, cold tea or coffee, or egg-albumen with brandy, or clam-bouillon in teaspoonful doses. Superacidity must receive appropriate treatment. When there is abnormal hyperæsthesia of the stomach, it is well to feed the patient by rectal enemata for about a week or ten days. The most effective sedative is morphine, particularly the hypodermic injection of $\frac{1}{4}$ of a grain, together with $\frac{1}{150}$ of a grain of atropine sulphate; or suppositories containing extr. belladonnæ, gr. $\frac{1}{4}$, with codeine phosphate, gr. j, may be tried. When the vomiting persists, even during the night, the bromides, together with chloral hydrate, are of approved efficacy. Hysterical vomiting is best controlled by withholding all food by mouth, and giving nutrient enemata.

Depressive Motor Neuroses.—(1) *Insufficiency or incontinence of the cardia.*—Incontinence of the cardia, due to paresis or paralysis of the motor nerves of the ring-muscle, is a comparatively rare malady, though somewhat more frequent than that of the pylorus. It appears either as an independent disease or as a resultant of other neuroses. Energetic peristalsis of the stomach, with the additional influence of the abdominal pressure, will in this condition raise portions of the gastric contents into the œsophagus, and even into the mouth. From this result regurgitation and rumination.

Regurgitation.—At a longer or shorter period after meals large quantities of the liquid and solid contents of the stomach are, at first involuntarily, brought up again into the mouth, and are then ejected. The patient generally learns how to facilitate the ascension of the ingesta by means of rather severe contractions of the musculature of the abdomen. Long-continued regurgitation may develop into rumination.

Since regurgitation is promoted by hasty eating and quick swallowing of insufficiently chewed foods, especially when the latter are difficult of digestion, a diet should be prescribed that is easily digestible, and the patients should be directed to eat slowly

and chew thoroughly. They should combat regurgitation to the utmost of their power. In stubborn cases the swallowing of small pieces of ice is recommended (Alt), which may reflexly induce the musculature of the cardia to contract. In addition massage of the epigastrium, internal and external galvanism and faradism, as well as internal administration of strychnine nitrate ($\frac{1}{30}$ gr.) are indicated. The galvanic current should be applied in the same manner as in cardiospasm.

Rumination or Merycism.—Patients afflicted with this neurosis return the ingesta from the stomach through the oesophagus back into the mouth, to reswallow them, as a rule, after they have been chewed again. This is not only done without exertion or nausea, but apparently with a certain enjoyment. The regurgitation of ingesta from the stomach into the mouth is usually at first voluntary, but later on involuntary. The ascent of the food causes a pleasurable sensation, and the patients assist the act by means of the pressure of their abdominal muscles. The condition of the secretory function is variable. A neuropathic constitution is a frequent factor in the development of rumination. Heredity seems to have some effect in the matter, but the element of imitation and suggestion cannot well be eliminated here.

Medicinal treatment in this disease is of little value. The state of the secretions should be carefully determined, and subacidity or superacidity corrected by appropriate means. The physician should, however, in all cases insist on slow eating and careful chewing; the food should be easily digestible and largely composed of gruels and diet of a soft consistency. The patient should always take his meals in the presence of persons for whom he has respect and who understand how to combat the morbid habit. The success of the treatment will depend upon the will-power of the patient himself, who must resist the temptation to ruminate with all the self-control at his command. He should be guarded against using the contraction of the abdominal muscles to assist the act. A trial might be made with the intragastric use of the faradic and galvanic currents. Hydropathic methods are sometimes useful. In one case observed by the present writer, in which every meal was persistently ruminated, rectal alimentation for twelve days entirely cured the patient. In another case the patient was cured by the administration of ten grains of quinine after each meal; probably the quinine rendered the food so disgustingly bitter that the patient suppressed the regurgitation.

(2) *Insufficiency or incontinence of the pylorus.*—This may be caused by organic diseases of the stomach and intestines, by carcinoma and ulcer, or by a stenosis of the duodenum leading to advanced dilatation of the initial part of the same. Ebstein has described rare cases of insufficiency, which appear, in the absence of anatomical changes, genuine neuroses, due to paralysis of the motor nerves of the pyloric sphincter; also instances in which it was a concomitant of myelitis due to compression, of hysteria and of gout. It may, perhaps, occur also as an idiopathic malady. If the muscular insufficiency is confined to the pylorus, then the foods and liquids either remain a very much shorter time than usual in the stomach, or enter the intestines immediately after their ingestion; thus the whole, or almost the whole, burden of digestion falls upon the intestine. Since, however, the in-

testine, in normal conditions, may entirely make up for lack of digestion in the stomach, disturbances of nutrition generally fail to appear, especially when an easily digestible diet is prescribed.

The symptoms of pyloric insufficiency are, in brief, the following: If frequent vomiting and belching existed, these suddenly cease after the setting in of the insufficiency. If rather large particles of food get into the intestine, the increased peristalsis may cause diarrhoea. This may also be brought about by very cold or very hot drinks or foods. If a quantity of air was swallowed with the foods, or if drinks rich in carbonic acid have been imbibed, a very acute tympanites of the intestine may develop from the escape of air or carbonic-acid gas.

Insufficiency of the pylorus should be suspected if one cannot succeed in distending the stomach by the artificial production of carbon dioxide in the organ by tartaric acid and sod. bicarb. Ewald, Boas, and other authors contend that this evidence is not conclusive; but any possible source of error may be removed by letting the patient eat a test-breakfast before the distension of the stomach, since then the closure of the normal pylorus becomes so firm that the carbonic-acid gas set free cannot at once escape into the intestine. If the air passes quickly into the intestine, tympanites of jejunum and ileum soon becomes evident. For a proof of the purely nervous origin of insufficiency it is necessary to exclude the above-mentioned diseases of the stomach and intestine, and such organic diseases of the stomach as chronic gastritis, which probably bring about a serous infiltration of the annular muscle, and may lead to a temporary insufficiency (Eichhorst, Boas).

Insufficiency of the pylorus may be recognised by the author's method of intubating the duodenum (*Archiv f. Verdauungskrankheiten*, Bd. II. S. 85), and by the spiral revolving sound of Kuhn and of Türk.

Only dietetic treatment is necessary, if there are no symptoms of intestinal irritation. In order to relieve the intestine of its additional task, easily digestible, well-prepared foods, which are to be carefully masticated, and are not to be taken too hot or too cold, should be prescribed. If, on the other hand, complaints such as diarrhoea appear, we must attempt, in addition to the treatment of the causal disease, to get rid of the insufficiency by means of massage, internal and external galvanism, and faradism applied directly to the pylorus, douches, and eventually also by giving strychnine sulphate, gr. $\frac{1}{30}$, three times a day. Flatulence and constipation call for massage and electricity, to be applied also to the intestine, and dilute hydrochloric acid should be administered in doses of 30 drops largely diluted if test-meal analysis shows absence of this acid.

(3) *Atony of the stomach* (Myasthenia Gastrica; Insufficiency of the Stomach). See STOMACH, Dilatation of.

Irritative Sensory Neuroses.—(1) *Hyperæsthesia.*—Hyperæsthesia of the stomach is probably a neurosis of the vagus, and a mild form of gastralgia. Clinically, the two forms of gastric sensibility—viz. gastralgia and hyperæsthesia—are differentiated by the following facts: The unpleasant sensations of pressure, fulness, and pain in the epigastrium, with eructations, nausea, and vomiting, occur in hyperæsthesia only after the

ingestion of food ; that is, there must be a digestive stimulation of the mucosa. The distress occurs only after meals, very rarely with an empty stomach. In gastralgia the pains and other distress occur with equal intensity in the full as well as in the empty stomach ; digestive irritation is not necessary to cause gastralgia. Hyperæsthesia lasts several days, weeks, or even months, with uniform or gradually increasing intensity, and during this time dyspeptic symptoms occur daily after each meal ; in gastralgia, however, the pains last only during the attacks, generally for a few hours.

The primary idiopathic form occurs very frequently as an accompaniment to chlorosis and anæmia, particularly with women and young girls. Also after repeated overloading of the stomach with indigestible food ; long-continued use of very salt or acid or spiced foods ; and the ingestion of very hot or very cold drinks after long fasting, and in debilitated states following sexual and alcoholic excesses, and chloroform-narcosis.

Patients with this neurosis frequently feel the pulsations of the abdominal aorta, and complain of beating and pulsating in the stomach. Then, again, they have a feeling of heat or cold, or a gnawing, burning sensation, and an impression of restlessness through the entire stomach. The ingestion of food, no matter of what consistency, causes a sensation of discomfort, fullness, nausea, and even vomiting. These sensations may increase to a typical gastralgia.

The treatment will be directed in the first place to the correction of the underlying fundamental disease. Wherever this is not possible, or wherever an idiopathic form of hyperæsthesia is present, all irritants which can exert detrimental influence upon the stomach must be excluded. All bodily and mental exertion must be avoided. In severe cases the Weir-Mitchell rest-cure, together with Leube's ulcer-cure, has, in our experience, been very efficacious. Hot, moist applications to the stomach are very soothing. Galvanism is a capital method of treating this affection.

Gastric idiosyncrasies are those peculiar forms of hyperæsthesia in which neuropathic and sometimes perfectly healthy persons have morbid sensations only after ingesting certain foods. These sensations consist of headache, light fever, cutaneous erythema, and urticaria. The author has observed persons who developed urticaria after eating crabs, potatoes, cheese or strawberries. One patient regularly develops an acute acne whenever she eats cheese, another develops fever whenever he partakes of crabs. Pick strongly recommends the use of creosote in these idiosyncrasies. Ichthyol internally is also efficacious.

(2) *Gastralgia* (Cardialgia ; Gastrodynia).—Gastralgia, or neuralgia of the stomach, occurs in periodical and spasmodic attacks of severe gastric pain, alternating with intervals of freedom from pain.

Gastralgia is frequently a result of motor or secretory neuroses—of gastrosplasm, pylorospasm, and cardiosplasm, superacidity, and supersecretion. The root of the vagus nerve may be irritated by functional and anatomical diseases of the medulla and adjacent portions of the central nervous system. We have observed a number of cases of malarial gastralgia in which the attacks occurred at regular intervals, and could be distinctly associated with the evolution of the characteristic malarial parasite in the blood.

A very careful examination is necessary before we decide that there is no real organic trouble at the foundation of the gastralgia. Occasionally we may find that gastralgias occur with small median herniæ of the linea alba. Leyden has described gastralgia with subacute myelitis, and Oser with myelitis due to compression.

In case of doubt it is advisable to treat the disease as if it were an ulcer. In true gastralgia the fundamental cause must, if possible, be discovered and removed. When we can find no organic cause, the most effective agent in our experience has been the galvanic current, using very strong currents—not less than twenty-five milliamperes. Oser claims to have observed cessation of the pains after application of the faradic current. When the pains are not too intense the internal administration of phosphate of codeine (half of a grain every three hours), chloral hydrate (fifteen grains every four hours), Dover's powder, tincture or extract of hyoscyamus, extract of belladonna, and camphorated tincture of opium are available remedies.

Gastralgokenosis.—Under this name Boas describes a painful emptiness of the stomach which occurs one to two hours after meals, and may be so severe as to embarrass the respiration of the patient. The paroxysms last only from one quarter to one half an hour and are not connected with bulimia. These attacks are said to be relieved by the ingestion of bread.

(3) *Anomalies of the sensations of hunger and appetite. Bulimia or Hyperorexia*.—Morbid increase of the sensation of hunger may occur as an independent neurosis, as a result of abnormal irritability of the centre controlling the sensation of hunger, or as a symptom of organic diseases (diabetes, Graves's disease, gastric ulcer, tapeworm). The affection expresses itself by violent sensations of hunger coming on suddenly, even shortly after the completion of a full meal, and if the desire for food is not immediately gratified, the patients exhibit signs of weakness, headache, pallor of the face, palpitation of the heart, roaring noises in the ears, and gastric diseases. In the intervals between the attacks hunger and appetite are normal, but there are cases in which bulimia may alternate with anorexia.

Depressive Sensory Neuroses.—(1) *Acoria* (ἀ, priv. ; κόρος, satiety).—Absence of the normal feeling of satiation, even after very abundant meals, without increase of hunger or appetite. The disease is generally secondary to neurasthenia, hysteria, or certain psychoses, and occurs in sexual neurasthenics. In these patients no impression whatever from the stomach informs them that they have eaten enough.

The treatment of bulimia when it is a secondary disease must have regard to removal of the primary cause, such as intestinal parasites, genito-urinary diseases, hyperacidity or ulcer, and any existing neurasthenia, hysteria or psychosis. The bromides are very valuable remedies to reduce the irritability of the hunger-centre. Arsenic, in the form of Fowler's solution, is highly recommended by Boas. Rosenthal recommends subcutaneous injections of extract of opium, and has seen good results in bulimia from cocaine hydrochloride. Morphine is a remedy that has been followed by good results in this affection. Electricity is sometimes useful. These patients should be watched during their eating and the meal interrupted when a normal

quantity has been ingested; thorough mastication and insalivation should be insisted upon. Strychnine and massage of the stomach suggest themselves as rational means of treatment.

(2) *Nervous anorexia*.—By anorexia is meant the entire absence of appetite and loss of the sensation of hunger. The superlative degree of this sensation is disgust and repugnance toward all food. There are probably no pathological conditions, either of the stomach or of any other organ of the body, in which anorexia is not occasionally met with. Very frequently chronic gastritis, incipient tuberculosis and carcinoma, begin with this symptom before any other signs or symptoms are manifest.

The primary object of treatment must be to improve the general nervous condition, to correct any existing fundamental disease, to act upon the psychological sphere by persuasion, suggestion, and firm but kind argument; and finally, to combat the anorexia itself directly. In anæmia mild preparations of iron are almost indispensable. The Weir-Mitchell rest-cure, together with the use of baths, massage and electricity, has, in many cases in our experience, produced happy results. When there is an absolute repugnance for food, or when the patient is insane, artificial compulsory alimentation should not be postponed too long.

Irritative Neuroses of Secretion.—(1) *Hyperchylia* (Hyper- or Superacidity, Hyperchlorhydria). See STOMACH, Functional Disorders of.

(2) *Periodical atypical flow of gastric juice* (Gastroxynsis (Rossbach), Gastroxie (Lépine), Gastro-succorrhœa Periodica (Reichmann)).—Gastroxynsis, or periodical flow of gastric juice, is an atypical secretion of the peptic glands, since it does not occur after a normal digestive stimulation, but rather when the stomach is empty. The attacks are associated with intense gastric distress, severe spasmodic pain, and vomiting of considerable quantities of very acid gastric juice. This peculiar neurosis is found almost exclusively among the educated classes, and particularly among those individuals who are subjected to unremitting mental exertion. It may also follow nicotine-poisoning and dietetic errors. The attacks occur, as a rule, in the middle of the night, or in the early hours of the morning. The patient has a very pale appearance, and the extremities are frequently cold. A few hours after the first vomiting of gastric juice the attack may be repeated, and again an equally large quantity of gastric secretion, containing no food-particles whatever, may be vomited. The patients are usually in good health, and severe thirst, loss of appetite, cephalalgia and great prostration, are characteristic symptoms. Periodical vomiting, when associated with hyperacidity, must be carefully distinguished from gastroxynsis.

Treatment includes, in the first place, the avoidance of stimulants and narcotics, alcohol and tobacco, as well as strong coffee. It is most essential that the patients should avoid mental overwork. Physical exercise should be indulged in moderately but systematically. The bicycle is an excellent remedy for periodical flow of gastric juice; and also horse-exercise, swimming, rowing, fencing, gymnastic exercises, and outdoor games. During the attack itself, the effects of the excess of acid should be counterbalanced by copious draughts of suspensions of calcined magnesina, ammonio-magnesium phosphate, or bicarbonate of sodium. When the vomiting has

occurred at short intervals, one should not hesitate to pass the stomach-tube and wash out the stomach.

Chronic continuous flow of gastric juice (Chronic Hyper- or Supersecretion (Riegel), Gastro-succorrhœa Chronica (Reichmann)).—The diagnosis of this hypothetical disease depends upon the presence of gastric juice containing hydrochloric acid and ferments in the fasting stomach.

The present writer inclines to the opinion that chronic hypersecretion is in the majority of cases not a spontaneous idiopathic neurosis, but a secondary symptomatic phenomenon. The most frequent causes are ulcer, pylorospasm and mechanical insufficiency.

Depressive Neuroses of Secretion.—

(1) *Subacidity* (Hypochlorhydria or Hypochylia). See STOMACH, Functional Disorders of.

(2) *Achylia gastrica* (absence of the secretion of gastric juice; nervous inactivity, atrophy of the stomach; anadenia ventriculi; phthisis ventriculi; achlorhydria).—The term *achylia gastrica* was first proposed by Einhorn to designate a class of diseases in which no gastric juice is secreted.

The affection is found to exist in two varieties—first, the primary idiopathic, possibly inherited, achylia; secondly, the acquired or secondary achylia. The primary idiopathic variety of achylia is characterised by the fact that absence of secretion is evident before any marked anatomical changes have occurred in the mucosa which could explain the loss of function. It is, therefore, as a rule, not regarded as a result of an actual disease, but as an individual peculiarity, possibly an inherited functional debility. There are undoubtedly persons in whom gastric secretion may be absent for years, or permanently wanting, yet who, apparently, may enjoy robust health. The majority of these individuals, however, have suffered from frequent dyspeptic complaints, which are partly of a purely nervous character.

The results of the examination of the gastric contents, in simple, uncomplicated achylia, are quite characteristic. The fasting stomach, examined in the morning before any food is taken, is empty. One hour after the Ewald test-breakfast the contents of the stomach have the same appearance as they have in the mouth before they are swallowed. Contents drawn in this manner are generally slightly acid, equal to the acidity found in the test-meal before it is eaten. The gastric contents, when filtered and mixed with hydrochloric acid sufficient to produce the reaction with Congo-red paper, cannot digest discs of egg-albumen. Milk taken by achylic patients may be drawn out twenty to thirty minutes afterwards uncoagulated. Persons with achylia may for many years have no subjective or objective disturbance of any kind; but sooner or later dyspeptic complaints arise, accompanied by eructation, fulness, and pressure after eating, gradually leading to attacks of severe gastralgia.

Achylia gastrica is due to two conditions (Martius): (1) a primary secretory debility of the stomach, constituting simple achylia gastrica; it has been supposed that bacterial infection is an ætiological factor in bringing about this state of the mucosa; (2) atrophy of the gastric mucosa (anadenia), with secondary achylia gastrica. The primary achylia gastrica is either congenital or developed on the basis of a very early predisposition. It is associated with inherited debility of

the nervous system, and prevails among so-called neuropathic patients.

It is logical to prescribe dilute hydrochloric acid for all these cases whenever it agrees well. When the appetite is absolutely lost, it may be restored by washing out the stomach with bitter tonics, such as gentian and quassia. It is expedient not to be too exacting with diet-orders. All foods should be well chewed, or preferably finely divided during the process of cooking. The more food that is ingested and well tolerated, the better for the patient in these cases.

A remedy little known, but a very valuable adjuvant in treatment for lack of digestive ferment, is the juice of fresh pineapple. This has decided proteolytic power, and, besides, is a pleasant, easily procured remedy. The ferment is active only in the fresh fruit, and is destroyed in the preserved pineapple.

Nervous dyspepsia (Leube).—(*Neurasthenia gastrica*, Ewald).—There are two main forms of gastric indigestion that may be classified as nervous dyspepsia: (a) that in which the nervous channels are sympathetically involved owing to anatomical changes in the stomach; and (b) that co-existing with an apparently normal anatomical state of the organ. Whatever the underlying basis or etiology of the disease, the ultimate symptoms can be ascribed to a functional sensory neurosis and over-excitability of the gastric nerves, which may become so acute that they react in a pathological manner upon the influence of normal digestive stimulation. *Neurasthenia gastrica* has been observed after intense emotional excitement, exhausting mental work, alcoholic and sexual excesses, and abuse of tobacco; also associated with pulmonary phthisis, nephritis, and malaria.

Jürgens has discovered total degeneration of the plexus of Meissner and Auerbach in forty-one cases of nervous dyspepsia. In one of the cases in which the sensory disturbances were predominant, and the intestinal functions involved also, this author found a distinct degeneration of the muscularis of the stomach and intestine.

The clinical picture is extremely variable. It is characteristic of nervous dyspepsia that the gastric distress is directly dependent upon the ingestion of food—that it occurs, as a rule, only after meals, and not on an empty stomach. Furthermore, the quality and quantity of the food and dietetic errors exert little influence upon the dyspepsia, but the sensations of the patient are very much under the influence of the emotional state. The suffering is most severe when the *neurasthenia gastrica* is accompanied by hyperacidity. In this case it increases during the second period of digestion, as the acidity becomes greater. Such types are relieved by the administration of alkalis, which, however, are useless with achylia. The epigastric region is not very sensitive, nor are there any characteristic pain-points discoverable.

There may be normal gastric secretion, hyperacidity, or inactivity. When inactivity exists, the ferments can still be demonstrated in the gastric contents. This important fact will serve to distinguish this type of nervous dyspepsia from typical achylia gastrica. The peristalsis of the stomach is in most cases undisturbed, but there are cases in which temporary motor insufficiency occurs.

There are pain and pressure in the head, giddiness, tinnitus aurium, flashes before the eyes, rapid pulse, exhaustion, cool extremities, attacks of faint-

ing, palpitations of the heart, dyspnoea; obstinate constipation is often met with; also borborygmi and flatulence.

The course of the disease is chronic, and it may, in severe cases, by continued and progressive loss of strength and emaciation, prove fatal. When the cause, such as sexual excesses, abuse of alcohol and tobacco, bodily and mental over-exertion, can be removed, the resulting nervous dyspepsia may be permanently cured.

Heterochylia (*érepes*, other; and *χυλός*, secretion).—This term is suggested by the writer to denote a rapidly alternating state of secretion, occurring chiefly in nervous dyspepsia.

Nervous dyspepsia with inactivity may be confounded with chronic gastritis or carcinoma, and nervous dyspepsia with hyperacidity may be confounded with ulcer, while other forms again may bear a striking resemblance to atony or myasthenia. For the separation of chronic gastritis from nervous dyspepsia, the following facts are of importance: Chronic gastritis is accompanied more frequently by vomiting; the stomach contains large quantities of mucus and a few streaks of blood; we may also have stagnation of the contents. The course of chronic gastritis is more uniform and typical, and the dyspeptic symptoms are directly influenced by the quality and quantity of the ingesta. In carcinoma the distress is present at all times, even on an empty stomach, vomiting is frequent, and the ferments are absent when the HCl-secretion is lost. In nervous dyspepsia the ferments are still present, though hydrochloric acid may be absent. The differentiation of nervous dyspepsia from ulcer becomes difficult only in those cases in which there has been no hæmatemesis. The constant dependence of gastric pain upon the food, and the sharply circumscribed painful points in the epigastric region and in the back, are unmistakable criteria.

In treating these cases the fundamental causes of disease should be sought out, and, if possible, removed. In those forms of nervous dyspepsia which depend upon an undue excitation of the nervous system, due to sexual excesses, abuse of alcohol and nicotine, or excessive mental or bodily exertion, improvement cannot be hoped for unless these states are remedied.

The physician must gain the absolute confidence of his patient. For this purpose he should show a sincere interest in the suffering of his patient, even if, after a repeated and thorough examination, he should become convinced that his complaints are exaggerated.

A course of mild gymnastic training—riding, rowing, fencing, or the bicycle, moderately used—is a better means of promoting appetite and regular evacuations than drugs. A sojourn in the mountains or at the sea-side is a great help. Massage improves the nutrition of the muscles and nerves, and favours a vigorous circulation, metabolism, and regular evacuations. Cold sponge-baths, also, taken in the morning immediately after rising, have a bracing effect. The favourable effects of hydrotherapeutic methods do not become manifest until they have been applied for two or three weeks. They are then followed by improvement in the appetite and sleep. When the insomnia is persistent a warm salt bath, at the temperature of the body, often acts similarly to an hypnotic.

Irrigations and douches of the gastric mucosa are used to reduce the hyperæsthesia of the gastric

nerves, and for this purpose carbonated waters are preferable to still waters. Galvanism of the abdomen and the spinal region and general faradisation are also applicable in these cases.

The physician must see that the articles of food possess considerable variety and are well cooked and appetising. Experience is the best guide.

Large enemata of pure olive-oil (300 c.c. at a time), combined with abdominal massage, are sometimes curative in the nervous constipation, particularly the membranous colitis present in these patients. Perhaps the most effective treatment, on the whole, is that designated as the Weir-Mitchell rest-cure, a combination of hydrotherapeutic, electrical, and dietetic treatment, with gymnastics, rest, massage, and as much sleep as possible.

The drugs that have been employed in neurasthenia gastrica are the tonics, sedatives, and hypnotics. In complete acidity the basic orexine (5 grains three times a day) has been much lauded by Penzoldt, but the writer has not been able to convince himself that this drug can restore the secretion of HCl. The fluid extract of condurango (one teaspoonful three times a day) and the bitter tonics, calumba, gentian, quassia, in doses of one drachm three times a day, are sometimes of value. The remedy we have most faith in is the sulphate of strychnine ($\frac{1}{10}$ of a grain three times a day continued for one month at least). When malaria is associated with the nervous dyspepsia quinine is the best remedy.

JOHN C. HEMMETER.

STOMACH, Perforation of, and its Results.—Perforation of the stomach is but rarely the result of mechanical injury by swallowed bodies; it is usually the result of disease—sometimes of the action of corrosive poison, but more commonly of ulcer or carcinoma of the organ. It occurs in from 13 to 18 per cent. of all cases of ulcer, and is a comparatively rare event in cancer. Perforation in ulcer of the stomach is most frequent in young females, and is more likely to occur if the ulcer is situated towards the anterior surface, where it is not in contact with any solid organ. Eighty per cent. of ulcers on the anterior surface are said to perforate. The results of perforation in ulcer depend on adhesions of the base of the ulcer to a solid organ, such as the pancreas, spleen, or liver, or to the abdominal wall. If the base is completely adherent to the solid organ, and perforation occurs, abscess may be formed in the liver, pancreas, or spleen. In other cases there is abscess-formation in the tough adhesions uniting the ulcer to the transverse colon or to the anterior abdominal wall. In yet other cases perforation may have one of two results: the contents of the stomach may be extruded into the general peritoneal cavity, or they may be shut into the upper peritoneal cavity, sometimes by adhesions, though not in all cases. General peritonitis may be the result of the first, and a localised abscess (subphrenic) the result of the second event.

The clinical aspects of perforation are best considered under three headings: (1) Perforation into an adhesion; (2) Perforation into the general peritoneal cavity, succeeded by general peritonitis; (3) Perforation into the upper peritoneal cavity, succeeded by formation of a subphrenic abscess.

Rupture of an ulcer usually occurs without warning; taking place after a meal, not uncom-

monly of indigestible food, or after some sudden exertion, perhaps on a full stomach. It may occur in a fit of sneezing or coughing, or in vomiting, and has been known to follow the administration of strong purgatives. It sometimes occurs in the early morning, on getting out of bed, but it more frequently happens when the patient is walking about in the day. The earliest symptom is that of acute pain, referred to the upper part of the abdomen, with the sensation of faintness; sometimes there is nausea and vomiting. Acute pain is sometimes absent, and the onset of perforation is shown only by an exacerbation of the pain previously experienced after food. There may be slight hæmatemesis. The pulse is extremely rapid, and there may be dyspnoea, and the features soon become pinched, drawn, and haggard.

1. **Perforation into an adhesion** may be accompanied by the symptoms which have just been described, and by no others, except, perhaps, a slight rise of temperature in the next few days. There are no physical signs of the extrusion of the stomach-contents into the peritoneal cavity, and, after a period of treatment, the patient gets well without surgical interference.

2. **Perforation into the general peritoneal cavity.**—The escaped stomach-contents may either be retained in the upper part of the peritoneal cavity—that is, between the diaphragm and the upper abdominal organs (liver, stomach, spleen), or they may pass to the lower part of the cavity. The contents consist of gas and liquid, usually acid. In perforations of ulcers on the anterior surface, when there are no adhesions, the stomach-contents enter the lower part of the peritoneal cavity; but, when there are adhesions, or when the perforation is on the posterior surface, the stomach-contents may be retained in the upper part of the abdomen. The clinical features of cases when there is extrusion of a large quantity of stomach-contents into the peritoneal cavity are very characteristic. The patient lies in bed, on the back, sometimes with the knees drawn up; the features are pinched or haggard, and expressive of pain; the pulse, some hours after the perforation, is small, very rapid, and compressible. An examination of the abdomen shows uniform and sometimes great distension, with the absence of abdominal respiration and a great increase of tension in all parts. Percussion gives a tympanitic note over the whole of the front of the abdomen, including the hepatic area, and, not infrequently, in the flanks, a dull note, indicative of fluid. A rectal examination may show a tense swelling in Douglas's pouch.

3. **Perforation into the upper peritoneal cavity.**—In this event, the physical signs are discovered chiefly in that region, and on one or other side. There is an absence of abdominal respiration, and the tenseness of the abdomen is chiefly marked in the upper part, in the epigastric and hypochondriac regions. Tenderness may be acute over this region. Percussion reveals the disappearance of the liver-dullness above the costal margin. Here there may be a tympanitic note, which may extend upwards over the sternum, as high as the fourth rib. The heart's apex-beat may be displaced, directly outwards or upwards. In the later stage of the illness general peritonitis supervenes, if the perforation is into the general peritoneal cavity, or a subphrenic abscess if the perforation is into the upper peritoneal cavity. In the former

case the fever which ensues is not, as a rule, high—ranging from 100° to 102° . The severe general symptoms continue, and vomiting and retching may be frequent, as well as a distressing hiccup. Great tenderness may develop, especially over the lower two-thirds of the abdomen.

Subphrenic Abscess.—The subphrenic abscess is below the diaphragm, and is shut in by adhesions between the stomach and the surrounding organs. It may occur from perforation of an ulcer in any part of the duodenum and stomach, except the lower part of the anterior wall. If the ulcer is near the pylorus the abscess is formed on the right side; if it is on the posterior wall, or on the anterior wall, near the cardiac end, the abscess is formed on the left side. The falciform ligament of the liver forms the boundary of the abscess. In twenty-nine cases of subphrenic abscess, a perforating ulcer had formed in the small curve, near the cardiac end in twelve cases, on the posterior wall in ten cases, and on the anterior surface in seven cases.

Subphrenic abscess is not always due to perforating ulcer of the stomach or duodenum. About 40 per cent. are due to this cause; about 4 per cent. to perforation in cancer of the stomach or oesophagus, while the other cases are due to appendicitis, gall-stones, perinephritic abscess, splenic abscess, injury, and hydatid of the liver. Some of these conditions produce an abscess in the subperitoneal cellular tissue, as in the extension upwards of abscesses from the appendix or kidney. An intraperitoneal abscess, however, results from rupture of a gastric or duodenal ulcer, or of an hepatic or splenic abscess, or an abscess of the gall-bladder. It is the intraperitoneal abscess which will be discussed here.

MORBID ANATOMY.—In right subphrenic abscess the left wall is formed by the falciform ligament of the liver. On the right it is bounded by the thorax, below by the liver, and above by the diaphragm. In left subphrenic abscess the boundaries are as follows: above the diaphragm, below the left lobe of the liver and the anterior surface of the stomach; in front the abdominal wall, united by adhesions to the anterior surface of the stomach; on the right side the falciform ligament, and on the left adhesions between the cardiac end of the stomach, the spleen, and the diaphragm. Although originally right- or left-sided, a subphrenic abscess may infect the opposite side, and thus occupy all the space beneath the diaphragm. In this case, the falciform ligament is sometimes perforated, and sometimes intact.

The formation of a large abscess in this neighbourhood compresses the lung above it, displaces the heart either away from it or directly upwards, and if on the right side pushes down the liver, even as far as the umbilicus. The contents of the abscess vary somewhat. In all cases pus and gas are present; in some cases they are sweet, in other cases foul-smelling, owing to putrefactive decomposition. The gas in the abscess is derived partly from the gas present in the stomach at the time of perforation, and partly from putrefactive decomposition occurring subsequently in the extruded stomach-contents. Remains of food may be found in a recent abscess.

The perforation in the stomach shows various appearances. It is usually patent, but it is sometimes closed, a pucker being left in the ulcer showing where it had perforated.

EFFECTS.—An abscess in this situation, foul as it often is, will excite inflammation in the neighbourhood, and therefore the usual accompaniment of subphrenic abscess is an affection of the pleura and lung above it. Thus pleurisy, with or without effusion, or empyema with sweet or fetid pus, may be present on the same side as the abscess; the lung may be pneumonic, or an abscess may be developed in it, and extensive destruction of the lung may occur in consequence, or gangrene may result. Affections of the pleura and lung may occur without a direct connection between the abscess and pleura; in some cases, however, the pleura and abscess communicate through an opening in the diaphragm. Of 45 cases collected by Maydl, the pleura was normal in 11, adherent in 10, and contained a serous fluid in 9, and pus in 15 cases.

SYMPTOMS.—The development of a subphrenic abscess is preceded by the symptoms which have been described as occurring in perforation of the stomach or duodenum and in the peritonitis resulting; that is, there is sudden pain followed by fever, tenderness of the abdomen, and the other signs of peritonitis. But there are soon signs of localisation of the inflammation to the upper part of the abdomen; and in the fully developed subphrenic abscess the symptoms resemble those of pneumothorax; there being fever of varying intensity, usually from about 100° to 102° F., with dyspnoea, but, as a rule, no cough or expectoration. The general appearance of the patient indicates in many cases the presence of a severe illness, and there is bodily weakness, with an expression of pain and a drawn countenance. The chief signs of the disease are elicited by physical examination.

PHYSICAL EXAMINATION.—*Inspection.*—The heart's apex is slightly displaced horizontally away from the disease; in right subphrenic abscess towards the left, and in left subphrenic abscess either upwards or towards the right. There is but slight bulging of the side, the intercostal spaces being practically normal. The respiratory movements vary somewhat; in some cases there is cessation of the abdominal movements, in others these are normal; but there is deficient movement as regards expansion and elevation on the same side of the thorax as the abscess.

Palpation.—Palpation confirms inspection in the above points, and in some cases a thrill may be elicited over the abscess by a sudden jerking movement given to the abdominal wall. Tenderness may be completely absent. Examination of the abdomen by palpation also reveals the displacement of the liver, the lower edge of which in right subphrenic abscess may be discovered nearly on a level with the umbilicus. In left-sided abscess the spleen is not usually felt, being pushed against the thoracic wall.

Percussion.—Percussion gives very varying signs. Over the lower part of the thorax on the side of the abscess, there is a tympanitic note over an area varying in extent according to the amount of gas contained in the cavity. The upper limit of this area is rounded and sharply marked off from the resonance obtained over the lung. Below, on the right side, the liver-dulness over the lower thoracic wall may be completely absent, a tympanitic note only being elicited; and when present this obliteration of the thoracic liver-dulness is an important sign of subphrenic abscess. Posteriorly in the thorax there may be dulness when the patient is in the recum-

bent position; and this dulness shifts its position with alteration of the posture of the patient. On the left side, similar variations in resonance may be discovered, and in front there is not infrequently tympanitic resonance in the upper epigastric region, and this may be continuous with an area of similar resonance over the cardiac area.

Auscultation.—Commencing from above, vesicular breathing is heard from below the clavicle down to the upper margin of the tympanitic resonance, diminishing in intensity below owing to the collapse of the lung. Over the area of the tympanitic resonance normal breath-sounds are quite absent and may be replaced by amphoric breathing. Posteriorly the breath-sound is absent over the area of dulness. Adventitious sounds may be elicited, viz. metallic tinkle by tapping the abdomen near the abscess, or the bell-sound by the usual means.

Variations in these physical signs are observed when, in addition to the subphrenic abscess, the pleura or lung above is affected. There may be above the abscess signs of fluid in the pleura, viz. dulness, with absence of breath-sounds; or there may be tubular breathing and increased vocal resonance with crepitations, showing consolidation of the lung. In some cases the signs of pneumonia may obscure those due to subphrenic abscess.

On aspirating the abscess both gas and fluid are obtained, the latter having the character previously described. If a mercurial manometer be connected with the abscess-cavity it will be found that there is an increase of pressure during inspiration, and a decrease during expiration (Pfuhl). This is directly opposite to what occurs when a manometer is introduced into the pleural cavity, and is a distinguishing point between an abscess above and one below the diaphragm. The test, however, does not always succeed.

DIAGNOSIS.—1. *As to the Presence of Subphrenic Abscess.*—The chief point in the diagnosis to be settled is whether the cavity is above or below the diaphragm—whether it is a pyo-pneumothorax or a subphrenic abscess. The physical signs are practically the same in pyo-pneumothorax and in subphrenic abscess; that is, they are the signs of a cavity containing fluid and gas. But the subphrenic abscess differs from pneumothorax in producing less displacement of the heart and less bulging of the side affected. These two physical signs, however, vary so much in pneumothorax that no great stress can be laid on them as a distinction between the two diseases. Of more importance are the physical signs of tuberculosis which are present in pneumothorax, when this occurs in either the early or the late stages of the disease, viz. consolidation or excavation of one or other apex. The history of the case is of great importance. The absence of cough and expectoration and the mode of onset of the disease demonstrate its occurrence in the upper part of the abdomen and not in the chest. From other chest-conditions subphrenic abscess is readily distinguished by the physical signs which have been dealt with. It must be borne in mind, however, that diseases of the lung and pleura may complicate subphrenic abscess; and physical signs may be obtained posteriorly, and above the upper line of tympanitic resonance, indicating an affection of the lung or pleura—pleurisy with effusion, empyema, pneumonia, or pneumonic abscess.

2. *Diagnosis as to the Cause of the Subphrenic Abscess.*—The diagnosis as to whether perforating

ulcer of the stomach or of the duodenum is the cause of the abscess is not usually possible; it rests on the previous history of ulcer as regards pain directly after food, vomiting, hæmatemesis, melæna, &c., and on the occurrence of the symptoms of perforation as previously described. The history of ulcer may be absent, but the symptoms of perforation always precede the development of a subphrenic abscess due to ulcer.

The cases due to carcinoma may be diagnosed from the presence of symptoms peculiar to cancer of the œsophagus or stomach. It is in the later stages of carcinoma that perforation occurs, and it is not a common event.

Abscesses occurring on the right side of the upper part of the abdomen may be in the liver or may be subphrenic and due to typhlitis and perinephritis (when it is extra-peritoneal), or to rupture of a gastric ulcer (when it is intra-peritoneal). On the left side, the abscess may be due to a gastric ulcer or to disease of the colon or kidney. Great difficulty is sometimes experienced in the diagnosis between a collection of pus in the liver and one between the liver and the diaphragm. In the latter case the abscess may contain gas; in the former there is either the history of dysentery preceding the illness, or there may be the negative history of a benign tumour (hydatid). The exact nature of some of these cases is, however, unrecognised before an operation. With typhlitic abscess the diagnosis rests on the previous history of disease localised in the right iliac fossa and the presence of actual signs of disease in that situation, viz. induration or abscess. With renal abscess, the diagnosis may be made clear by a history of the symptoms of calculus, and by the presence of pus in the urine.

COURSE.—Subphrenic abscess is a serious condition, which ends fatally either by septic poisoning or more commonly by producing putrid empyema and pneumonic abscess. In some cases the abscess discharges itself through the lung, and although this must be considered the most favourable natural mode of cure of the disease, yet it is one which entails a prolonged illness to the patient, and which sets up destructive changes in the lung. In other cases the abscess bursts into the general peritoneal cavity, causing death by general peritonitis. The rapidity with which subphrenic abscess kills varies greatly; it is to some extent dependent on the affections of the lung which complicate it. Of 178 cases collected by Maydl, 98 died without an operation, 6 healed without operation, and of the 74 operated upon 35 died and 39 recovered. It may, therefore, be looked upon as practically a fatal disease unless relieved by operation.

SIDNEY MARTIN.

STOMACH, Ulceration of.—INTRODUCTION.

The term 'ulcer of the stomach' is sometimes reserved for that particular kind of ulceration known under the names of 'perforating,' 'simple,' 'round,' or 'peptic' ulcer. Ulcers are also met with in the course of various disorders of the stomach as well as of certain of the general infective diseases. Acute ulcers prone to rapid healing occur in some forms of acute gastric catarrh, and chronic ulcers varying in size, depth, and duration are seen in certain forms of chronic gastric catarrh. Superficial erosions and ulcers are not uncommon in atrophied conditions of the mucosa. Ulcers may also follow injury, the ingestion of corrosive poisons,

and venous congestion due to the portal obstruction of certain hepatic and cardiac diseases. They are even rarer in general infective diseases, such as yellow fever, typhoid fever, diphtheria, pyæmia, anthrax, small-pox, and tuberculosis, and when present are generally multiple. Their mode of origin is probably similar in all these cases, viz. by a hæmorrhagic infiltration of a part of the mucosa, to which the stomach is very liable, impeding and arresting the circulation therein, and thus allowing of its digestion and erosion through the action of the gastric juice. Their first stage is probably identical with superficial erosions (hæmorrhagic erosions) which involve only a slight thickness of mucosa and generally heal rapidly. In some cases, however, where the nutrition becomes more extensively impaired, the ulceration spreads and may even lead to perforation. Ulceration also occurs in cancer of the stomach (see p. 1600). The signs and symptoms to which these different forms of ulcers give rise may closely simulate those of the simple or perforating form, while in other cases they are subsidiary to or even masked by those appertaining to the disease of which they are but a part.

Simple Gastric Ulcer.—**DEFINITION.**—A disease of the stomach characterised by the presence of an ulcer of varying depth, beginning in the mucous coat and attended by pain, vomiting, and hæmatemesis.

ÆTIOLOGY.—The exact causation of gastric ulcer is still an unsolved problem, notwithstanding the many ingenious theories which have been advanced. There is a strong weight of evidence in favour of its being produced by many very different conditions. Thus any agent, whether nutritional, toxic, chemical, mechanical, or bacterial, of sufficient power to interfere seriously with the vitality of a part of the stomach-wall, may cause its ulceration. Indeed, more than one such agent may sometimes be at work. The chief facts and theories supposed to influence the causation of the ulcer may be arranged as follows:

1. *Frequency.*—*Post-mortem* records, counting together both open ulcers and scars, give a considerably higher proportion of cases than do clinical records, viz. 4 to 5 per cent., as against .75 to 1 per cent.; and inasmuch as the former, though open to fallacies, are less liable to error than the latter, it may be tentatively suggested that about 4 per cent. of all individuals are the subjects of gastric ulcer at some time of their life. For many reasons it is only possible to reach the actual frequency approximately. The 5 per cent. generally accepted by authorities is probably rather high.

2. *Sex.*—It is more frequent in women than men. There is some discrepancy between the *post-mortem* and clinical results. So far as *post-mortem* records go, the proportion of three females to two males would seem to be fairly correct. On the other hand, clinical records give a much higher proportion of women, two or three or even more females to one male. The discrepancy is probably due to the fact that the disease is more frequently fatal in men than in women. The acute form which is so prone to heal occurs almost exclusively in young women.

3. *Age.*—In determining the frequency of ulcer at any age, attention must be paid to the time at which the disease apparently began, hence clinical records are in this respect likely to be more correct than *post-mortem* results. There is now a general

consensus of opinion that it is most frequent, in the case of women, from the age of twenty to thirty, and in men from that of thirty to fifty. It is rare before puberty.

4. *Occupation.*—This cannot be held to have much influence in the production of the ulcer, though cooks, housemaids, metal-turners, tailors, and all workmen whose work entails mechanical pressure upon the epigastrium, are held by some authorities to be more prone to the disease. It is also more common among the poor, probably because of their lower state of general nutrition.

5. *Associated diseases.*—The simple ulcer of the stomach has been met with in a number of diseases, such as chlorosis, amenorrhœa, syphilis, tuberculosis, malaria, chronic cardiac and renal disease, and a causal relationship between them has been suggested. The evidence in its favour is slight, except in the case of chlorosis, in which ulcer of the stomach is of very frequent occurrence. This is particularly true of the acute variety seen in young women. Chlorosis is, however, only rarely accompanied by gastric ulcer, and, moreover, when the two occur together it is generally in the later and not in the earlier stages of the disease, so that the ulcer may be merely related to the long-standing poverty of the blood which is common to all anæmias. A causal relationship between them can neither be denied nor proved at the present time.

PATHOGENESIS.—It is when we seek for the actual exciting causes that we find the greatest diversity of opinion. Practically every local condition which might possibly cause ulceration has been brought forward in explanation, e.g. injury, inflammation, impeded nutrition through one or other change in the arteries, a congestion of the veins, an affection of the nerves, and an alteration in the composition and conditions of the gastric secretions. Since the simple ulcer is met with only in the stomach and adjacent parts of the œsophagus and duodenum it is reasonable to suppose that the corroding action of the gastric juice has much to do with its production. So long as the stomach-wall preserves a certain standard of vitality, it resists this action, but if it falls below this standard in any area, destruction of that area is likely to follow from the digestive and corroding action of the gastric juice upon it. The histological appearances of the edges and floor of the ulcer support this view, as they exhibit in all cases where the process is still advancing, purely necrotic phenomena with an entire absence of all signs of inflammation. The conditions which may bring about such a lowered state of vitality in a limited area of the gastric wall naturally then require attention. They are as follows:—

(a) *Embolism.*—The arteries of the stomach show a free collateral circulation, but it has been thought that if a branch be occluded by an embolus, the part of the stomach-wall supplied by that branch will necrose and, becoming eroded, form an ulcer. The appearances presented by the ulcer are in such complete harmony with the theory of its production in this manner, that it passed unchallenged for a long time. It was only when it was realised that such an embolism had never been demonstrated, that in the majority of cases of gastric ulcer the ordinary sources of emboli did not exist, and that emboli artificially introduced into the blood-stream rarely entered the coronary arteries, that doubt was thrown upon the explanation.

(b) *Thrombosis*.—An acute thrombosis of a branch of the coronary artery is theoretically an equally satisfactory explanation, but practical experience shows that it rarely, if ever, occurs. The gastric arteries are usually healthy in stomachs which are the seat of gastric ulcer, and thrombosis does not occur in healthy arteries. It is true that in certain cases the gastric arteries are diseased, and various forms of endarteritis, amyloid disease, and other degenerations have been found; but while these may help to account for the formation of individual ulcers, they cannot be held to throw light upon its production generally.

(c) *Spasm of the arteries*.—A local spasm might lower nutrition in a definite area of the stomach-wall, and thus produce ulceration, but the existence of such a spasm is purely hypothetical and its production difficult of explanation.

(d) *Venous engorgement*.—This is not a common condition in gastric ulcer, whereas it is common in other morbid states, e.g. hepatic cirrhosis and cardiac disease, in which gastric ulceration is uncommon. It may, however, at times assist in its production by causing a hemorrhagic infiltration of a local area. It has also been suggested that spasm of the muscular coat may lead to a similar condition by compression of the veins.

(e) *Nervous influences*.—The nerves of the stomach influence its blood-vessels, its muscular contractions, the secretion of its juices, and its general state of nutrition. The result of stimulation of the gastric mucosa in health is a relaxation of vascular tone, and therefore dilatation; but it is conceivable that morbid stimuli might produce the opposite result, viz. an increase of tone, amounting to spasm and so to ulceration. It is also conceivable that they might bring about irregular contractions of the muscular coats of the stomach-wall, and hence ulceration through compression of the veins. The loss of the normal trophic influence by a part of the stomach-wall has also been suggested, but all these theories entirely lack evidence in their support. The alterations in the gastric secretions brought about by nervous or other influences still remain to be considered. The pepsin is unaltered, but the hydrochloric acid is usually increased in amount. This increased secretion of hydrochloric acid is held by many to be the chief causal factor in the production of gastric ulcer, but if so, it is difficult to explain why it should act over such a strictly limited area. Some explain this by suggesting that the abnormal nervous impulses act only on a circular group of glands. More serious objections still consist in the facts that hyperacidity is not a constant feature in the disease, being generally absent in the acute variety and in about one-third of the chronic cases, and that hyperacidity occurs as a functional disease of the stomach in which ulceration is rare.

(f) *Inflammation*.—Ordinary inflammations of the stomach are only accompanied by slight ulcers which quickly heal. Severe inflammations may cause necrosis or hemorrhagic infiltrations and subsequent ulceration of the mucosa, but ulcers produced in this way show inflammatory conditions in their edges and floor, and affect the fundus and greater curvature rather than the pyloric region and lesser curvature. Inflammation of the solitary glands has been advocated by Fenwick as the origin of some forms of gastric ulcer, and this view is probably correct, as such ulcers by extension may easily assume the form of acute perforating ulcers.

(g) *Bacterial necrosis*.—Bacteria have occasionally been found in the margins of an ulcer and in partially detached sloughs, and it is further known that the ingestion of large quantities of fluid may for a time inhibit the bactericidal properties of the gastric juice, so that active bacteria may come to settle in the stomach-wall. It is no argument against a bacterial causation that no specific micro-organism has so far been described, for any of the ordinary inflammatory bacteria of sufficient virulence to cause necrosis elsewhere might act in the same way in the stomach. Indeed we know that certain bacteria, e.g. those of typhoid fever and tuberculosis, can cause the same necrosis in the stomach-wall which they produce in other parts of the body. In these cases, however, the general disease is of great importance, whereas in gastric ulcer the patients are generally otherwise healthy. Moreover, bacteria have been found only in the necrotic tissue of the edges and floor of the ulcer, never in the healthy tissue around, or in the margins of a fully formed ulcer, and hence it is at least as probable that they are subsequent to, as that they are prior to the necrosis. Numerous bacteria enter the stomach with the food, and will naturally settle in a necrosed area.

(h) *Mechanical, Chemical, and Thermal injuries*.—Mechanical injuries of the stomach usually heal rapidly without ulceration, but they may result in hemorrhagic infiltration and ulceration. Such ulcers are of acute formation, and usually heal rapidly. Chemical injuries such as follow upon the ingestion of corrosive fluids may result in necrosis or intense inflammation followed by ulceration. Such ulcers may come to be indistinguishable from the ordinary gastric ulcer. Thermal injuries from the ingestion of hot food or liquid have been shown experimentally in dogs to produce hemorrhagic infiltration and ulceration, but there is no clinical evidence to show that they do so in man.

MORBID ANATOMY.—The number, situation, size, shape, and general appearances of the ulcer have to be carefully described, and a distinction drawn between ulcers of acute and chronic formation.

1. *Number*.—In the chronic variety a single ulcer is met with about nine times more frequently than a greater number; but in the acute variety multiple ulcers are at least as common as a single ulcer. When multiple, two are more frequent than three, three than four, and so on. In exceptional cases large numbers are present.

2. *Situation*.—The posterior surface near the lesser curvature in the pyloric region is the site in about three-fourths of all cases. The chronic form occurs here fully three times oftener than elsewhere, but the acute form is as frequent in the middle or cardiac regions as it is in the pyloric. Occasionally the ulcer involves the pyloric, or much more rarely the cardiac orifice, either in the primary ulceration or the subsequent cicatrisation, causing obstruction to the entrance or exit of food. When the ulcers are multiple, they mostly affect the posterior surface, though when acute one or more are usually seen also on the anterior surface. Puckerings and cicatrices representing former ulcers are seen much more frequently than the open ulcer, especially in the middle and cardiac regions; three to one is the generally accepted proportion, but it should not be looked upon as more than an approximate estimate. When present along with open ulcers, they are generally situated near them. They are rarely seen on the anterior surface, as such ulcers are prone to perforate

and not to heal. When the preceding ulcer has been small, they are very difficult to detect; when large, there is a smooth central depression devoid of mucosa, much smaller than was the original ulcer, for healing has caused considerable contraction and drawing together of the mucous margins.

3. *Size*.—The acute are usually smaller than the chronic. The former are often likened in size to a threepenny-piece, and the latter to a sixpenny- or shilling-piece. This rough and ready method has tended to exaggerate their size. A threepenny-piece is over half an inch in diameter, whereas the acute ulcer often does not exceed a quarter of an inch, and the chronic form generally measures half to one inch, sometimes less and often more. Exceptional cases with diameters of several inches have been seen.

4. *Shape*.—The smaller ones, particularly the acute, are usually circular or oval, while the larger ones, almost always chronic, are often oval, triangular, quadrilateral, scalloped or irregular in shape. These last usually arise from the confluence of several adjacent ulcers. Horseshoe or girdle-shaped ulcers generally occur in the middle or lower third of the stomach, and by their large size and extensive contraction cause hour-glass and other deformities of the organ.

5. *Edges*.—The edges of the acute ulcer are soft, smooth, and clean-cut as if punched out, while those of the chronic variety are firm, thickened and fibrous in appearance, or firm, smooth, and depressed. The depth generally reaches some part of the muscular coats, but often penetrates further to the serous coat. In the acute variety the diameter usually gets markedly less as each successive coat is penetrated, so that the ulcer presents a typical terraced appearance, as if a smaller punch had been used for each coat. In the chronic variety, the terraced appearance is not seen, but a generally smooth, firm, and sloping surface from the mucous margin to the floor. Thus both varieties have a typical funnel shape. Occasionally the chronic form shows great thickening in the walls and floor.

6. *Floor*.—In the acute variety the floor and edges may show a little hæmorrhage or some necrotic tissue, but usually they are formed by one of the but little altered coats of the stomach—submucous, muscular, or serous. The serous coat may show on its outer surface some congestion and fibrous exudation; more pronounced if it be actually penetrated. If the perforation be small a clear watery mucous fluid, which fills and distends the stomach, usually wells out of the aperture; if large, the swollen and congested mucous coat may also pour through it. In the chronic variety the floor is usually smooth and firm, if formed by any of the coats of the stomach, the serous coat often showing considerable fibrous thickening. Perforation may produce a general peritonitis, adhesion of the affected part of the stomach to some neighbouring organ, or a local abscess (see pp. 1619 to 1621).

7. *The condition of the stomach-wall in the neighbourhood of the ulcer*.—The state of the surrounding mucous membrane is of the greatest interest. Judging from *post-mortem* appearances it is generally quite unaltered right up to the very margins of the ulcer, but certain observations made during life assert that this is really not a true picture, inasmuch as it has lost all traces of the inflammatory changes of greater or less severity which, always present during life, rapidly disappear after death. If there be such a gastritis of any severity and extent,

whether concomitant with or subsequent to the ulcer, and the congestion and swelling have been described as great, it would help to explain the symptoms, and, moreover, be of much practical importance in treatment. The general experience of surgeons, however, who are rapidly becoming better informed of the appearances of the stomach in various morbid states, does not appear to support the existence of much, if any, gastritis in most cases, and hence we are at present inclined to believe that the *post-mortem* picture is a fairly faithful one.

8. *Microscopical appearances of the ulcer*.—These can only be very shortly referred to here. Suffice it to say that in the acute and advancing chronic forms there are signs only of necrosis, none of inflammation. When healing has begun the inflammatory reaction in the floor and edges becomes well marked, but this is a result not a part of the ulcerative process. The edges become adherent to the floor, and the new tissue is always fibrous, little regeneration of glandular or muscular tissue occurring in most cases. There is no doubt that some regeneration of the glandular part of the gastric mucosa does occur in certain circumstances; and it is probable that it does so at any rate in the small and superficial gastric ulcers which may thus heal without a recognisable scar.

SYMPTOMS.—1. There may be practically no symptoms, as shown by the fact that an unsuspected gastric ulcer or cicatrix is sometimes discovered at a *post-mortem*, or by rapidly occurring death from its perforation in persons previously in the best of health. This is spoken of clinically as the 'latent type.' 2. There may be only various symptoms of dyspepsia, e.g. discomfort and fullness after food, distension and flatulence, acidity, &c. The appetite is generally good, but thirst is often great. Constipation is the rule. These indications may last for months or years without the appearance of any of the characteristic symptoms. This is the clinical 'chronic dyspeptic type,' which includes also cases attended by pain and occasional vomiting. 3. The characteristic symptoms are pain, vomiting, and hæmatemesis; these require detailed consideration.

Pain.—This is the most constant of the symptoms, although it may be entirely absent. In its typical and severe forms it is more characteristic of the chronic than of the acute variety. The situation, intensity, time of onset, and duration of the pain are of importance. (1) *Situation*.—The pain is usually distinctly localised to the epigastric region below the ensiform cartilage, though in the more chronic cases it may be lower and more diffused. It is also, especially in the latter cases, often experienced at the back, in the middle line between the sixth and eighth dorsal vertebrae, or lower and to the left. It is sometimes described as passing through from the front to the back. It also sometimes radiates to the sides of the body (see p. 1142), and up to the shoulders, and even down the arms. Even when it is strictly localised or influenced by the position of the patient it is not a safe guide to the exact site of the ulcer. The passage of a weak electric current from the epigastrium or left hypochondrium (negative pole) to the lower dorsal region (positive pole) soon after a meal is more trustworthy but often fails. The negative electrode is moved about on the skin of the epigastric and left hypochondriac regions and gives rise to a slight tingling sensation only, until it comes to be placed over the site of the ulcer, when severe pain

is felt. (2) *Intensity*.—In the acute and in the early stages of the chronic variety, the pain is usually not very intense, but as the chronic form progresses the pain usually becomes more severe, and is described as heavy, boring, burning, or stabbing; sometimes it is spasmodic or colicky. It is often so severe that no drug except morphine gives relief. It is frequently influenced favourably by the position of the patient, being less when lying down, and sometimes, though rarely, also relieved by firm pressure, which is, however, not a safe procedure. It is usually increased by palpation, slight pressure, muscular effort, mental exertion, and by the menstrual periods. (3) *Time of onset*.—The pain usually commences shortly after meals—ten to twenty minutes—but it is sometimes delayed much longer, even hours. It is occasionally only experienced at night as a gnawing or burning sensation, which is relieved by taking a small quantity of food. Palpation or slight pressure, even that of the wearing apparel, may bring it on. (4) *Duration*.—The pain is rarely continuous, particularly in the acute variety. It usually lasts until the food leaves the stomach by the pylorus or is vomited, when it generally disappears more or less quickly. It thus often lasts several hours. It may occur at intervals for days, weeks, or months, or be entirely absent for like periods. It gradually disappears with the cicatrization of the ulcer. When the pain is the most marked and prominent symptom it constitutes clinically the 'chronic gastralgic type.' There is often, in addition to the pain, a hyperæsthesia of the skin in the epigastrium, and also sometimes under the left breast (p. 1142).

Vomiting.—This symptom is rarer in the acute than in the chronic variety. It is frequently preceded by nausea, discomfort, or waterbrash in both varieties, and it usually relieves the pain in the latter much more completely than in the former. It may occur early or late in the course of the disease. It may follow the ingestion of food immediately, or be delayed for an hour or longer. In the former case it consists of partly digested food, in the latter it is more copious, liquid, and frothy like barm. The filtrate shows the presence of free hydrochloric acid (p. 1591). It is increased in amount in about two-thirds of the chronic cases, while in the remainder it is normal in amount except for a few cases, particularly those of marked anæmia, in which it is diminished. In the acute variety there is usually no hyperacidity. The filtrate may also show the presence of lactic acid (p. 1592). The amount of pepsin is generally unaltered, though occasionally increased, and in a few old cases diminished. When vomiting is the prominent feature it constitutes clinically the 'vomiting' or 'catarrhal type.'

Hæmatemesis.—This occurs in roughly one-third to one-half of all cases. It may take place early or late in the course of the disease, and with or without previous pain or vomiting, or any other symptom. (1) *Source*.—When small in amount the blood may come from capillaries and small vascular twigs in the edges and floor of the ulcer. When considerable in amount it always comes from erosion of one of the coronary arteries or other medium-sized or larger vessel. (2) *Amount*.—In the acute variety it is usually sudden and profuse—8 to 10 oz. or more in a few minutes—and tends to cease rapidly. In chronic cases the amount is liable to greater variation and the attacks have a greater tendency to recur.

Usually there are several recurrences at intervals of a few days, and then complete cessation for some time. The attacks are apt to come on during digestion or exercise, and may be preceded by a feeling of nausea or faintness. (3) *Appearances*.—It is generally bright red, clotted, and alkaline, especially in the acute variety. When allowed to remain longer in the stomach it is variously altered by the gastric juice, and appears dark red, or coloured like prune-juice or coffee-grounds. (4) *Melæna*.—The motions are black like tar. This occurs with or without hæmatemesis, particularly when the ulcer is near the pylorus, and is present only in those cases in which a considerable quantity of blood passes on into the intestine. It has always to be carefully inquired for, as much blood may be unsuspectingly lost in this way. The usual indications of considerable losses of blood, e.g. giddiness, faintness, weakness, clammy skin, low temperature, and soft, quick, small pulse, are observed. Two clinical types, the 'acute hæmorrhagic' and the 'chronic hæmorrhagic,' are often spoken of, in which the hæmatemesis is the prominent feature.

The other symptoms refer to the alimentary and urinary systems, and are chiefly covered by the dyspeptic symptoms already mentioned. The appetite is good, but if there be pain the patient is afraid to eat. Thirst and constipation are common. The urine may contain albumoses, acetone, or diacetic acid. The chlorides are often diminished, and the phosphates increased. The general nutrition may be good or much impaired (the cachectic type). There may be marked anæmia, amenorrhœa, headache, and sleeplessness.

Perforation and its results are considered elsewhere (p. 1619).

DIAGNOSIS.—In many cases a diagnosis is easy, in some it is difficult, in a few it is impossible. Even after a careful analysis of all the symptoms, the case may have to be kept under observation for some time, before a diagnosis of ulcer can be ventured upon. None of the characteristic symptoms of ulcer can be absolutely relied upon, for epigastric pain is met with in several other diseases, e.g. gastric cancer, chronic gastric catarrh, nervous dyspepsia, and gall-stones; vomiting in the same diseases and in the gastric crises of locomotor ataxia; while hæmatemesis occurs in a large number of both gastric and other diseases, e.g. gastric cancer, gastritis, varicose veins of stomach or œsophagus, passive congestion of the portal system from hepatic cirrhosis, pressure of a tumour, chronic cardiac or pulmonary disease, or enlarged spleen; toxic diseases such as yellow fever, acute yellow atrophy, purpura, &c.; constitutional states such as hæmophilia, &c.; injuries to the stomach-wall; or the blood may come from some position higher up than the stomach, e.g. nose, pharynx, lung, œsophagus, &c., and flow into the stomach and be afterwards vomited. Further, the diagnosis between ulcer and some forms of anæmia, e.g. chlorosis and pernicious anæmia, is often difficult, and it is to be remembered that they may co-exist.

PROGNOSIS.—The prognosis is very favourable, for probably over 90 per cent. of all cases recover, while in the acute variety alone the percentage is still higher. It may be taken as a fact that hospital cases make a more uniform recovery than those treated outside, and on the average the hospital cases are the more serious examples of the disease. A certain proportion of the cases which leave the

hospital cured or greatly improved suffer relapses afterwards, which may readily yield to appropriate treatment on re-admission to hospital. It is not unreasonable to think that, if the proper treatment were always rigorously carried out, very few if any would relapse. It is very rare indeed for a hospital case not to improve steadily under proper treatment, provided the patient survives the first few days after admission, and it does not seem too much to say that all cases, with very few exceptions, may recover if proper treatment be applied early enough. If all symptoms have disappeared for months and subsequently break out again, the case is practically a new one and not a true relapse, even though the ulcer occurs at its previous site. If the ulcer be large, the cicatrization will be correspondingly extensive, and in the pyloric region especially this may cause trouble from pyloric obstruction long afterwards. This is due, however, to the anatomical peculiarities of the parts, and so far as the ulcer is concerned ought not to be considered as an imperfect cure. Recent advances in abdominal surgery have made it possible to cope with this condition with most gratifying success. There remain then only those cases in which the ulcer passes on rapidly to perforation or gives rise to severe and uncontrollable hæmorrhage, and those cases which die from exhaustion or some rare complication. It is extremely difficult to arrive at an accurate estimate of the mortality. Of course, if over 90 per cent. recover, then less than 10 per cent. die, and it appears for many reasons probable that this is not far from the truth. Most of the statistics on this point are too old to be reliable, for it is obvious that the advances in recognition and treatment, which have been made within recent years and will we hope continue to be made in the future, must tend to decrease the mortality from all these sources. It is the general experience that death from perforation is much more common than from hæmorrhage, so that if 10 per cent. be the true total mortality, at least 6 per cent. must be put to the credit of perforation, and not more than 3 per cent. to hæmorrhage. Even 3 per cent. is probably too large, for it is the universal experience that hæmorrhage is very rarely suddenly fatal, and under the present improved methods of treatment it is likely to be almost always successfully controlled in the further progress of the case.

TREATMENT.—Medical.—Medical treatment is all that is necessary in the great majority of cases. It aims at giving the stomach as much rest as possible, and may be considered under the heads of rest, diet, and drugs. It is impossible to lay down general rules to suit all cases, and modifications must be made to suit individual peculiarities. Patience is the keynote of success. The slightest return of untoward symptoms requires immediate attention, and a rigorous continuance of appropriate treatment. The treatment should last on the average at least three months—in the very chronic cases much longer, a year or more—and should in all cases be continued for many weeks after all symptoms have disappeared.

Rest is best obtained in bed, and at least the first fortnight should be spent entirely there. It is advisable for most cases to keep their beds still longer, three weeks or more, and sometimes during the greater part of the treatment. The recurrence of active symptoms should always be followed by a period of rest in bed. This procedure ought to be

rigorously enforced whenever it is possible, and relaxed only in exceptional cases.

Diet.—Milk is the ideal diet, and it should be carefully tried in all cases. It is a favourite plan with many to give 5 oz. every hour for the first three days, then 10 oz. every two hours for the next week or so, and then gradually increase it. To find out what suits each case is far better than to follow any rule. Proceed cautiously at first, and aim at reaching doses of 10 to 15 oz. four times daily at four-hourly intervals as soon as possible, remembering carefully that any distension or irritation of the stomach has to be avoided. Afterwards increase the quantity to between one and two quarts in the twenty-four hours. Each dose should be moderately warmed and sipped slowly, especially at first. Occasionally it suits better when iced. These milk-meals should be continued for a month, and as patients get tired of them they may be varied, after the first day or two, by alternating them once or twice a day with weak beef-tea, Leube's, Liebig's or Valentine's meat-juice, Carnigen, a good beef-powder, or somatose, either by themselves or added to the milk. It is advisable also to add a little lime-water or a pinch of bicarbonate of sodium to the milk to prevent the formation of large masses of casein and favour digestion. Barley-water, rice-water, oatmeal or oat-flour water added to the milk varies the flavour and increases its digestibility. An egg beaten up in milk may be tried at the end of the first week, and given once or twice daily thereafter, or a little Benger's food or ground rice or arrowroot may be used as an alternative to thicken the milk. Skimmed milk or butter-milk is often well borne when ordinary milk is not. This is also true of sterilised milk. When none of these is tolerated, peptonised milk should be given, and when all of them fail nutrient enemata must be resorted to. Avoid tea, coffee, and alcohol in all its forms.

Nutrient Enemata.—Before giving a nutrient enema the bowel should be washed out with a quart of warm water, to which a teaspoonful of common salt has been added. This should be done twice in the twenty-four hours, and the nutrient enema given one hour after the injected water has been voided. The temperature of the nutrient enemata should be 100° F., and they should be administered every four to six hours. They should be about 8 to 10 oz. in bulk, but if such quantities are not well borne, 2 to 3 oz. may be tried. They should consist chiefly of peptonised milk or beef-tea, to which the yolk of one or two eggs and 5 grains of bicarbonate of sodium or two teaspoonfuls of wine, whisky, or rum, if there is much weakness, or a few drops of laudanum, if much irritation, may be added. Many prefer to give an enema (2 to 3 oz.) of beef-tea and raw egg with a little brandy. It is rarely necessary to continue exclusive rectal feeding longer than two to three days, except in persistent vomiting and after hæmorrhage, when it may be necessary to do so for a week or even a fortnight. It is to be remembered, however, that it is a very imperfect method of nutrition, and a little peptonised milk (1 or 2 oz. frequently) ought to be given by the mouth as soon as possible, and then cautiously increased while the nutrient enemata are gradually dropped.

Solid Food.—After about a month, if pain and vomiting have long disappeared, begin to give solid food cautiously—a little bread and milk, arrowroot,

tapioca or sago, or ground rice may be given with the milk; and after three or four days more a scrambled or softly steamed egg may be tried. After a week, a little grated boiled fish or chicken, or raw-meat pulp or scraped raw beef (the latter are often well borne much earlier in the treatment, even when a milk-diet disagrees). After another week, raw eggs or soft-boiled or poached eggs, sweetbreads, tripe, brains, stale bread, thin bread and butter, may be given. Then lamb-chops, mutton-chops, underdone steaks with thin thoroughly toasted or stale bread may be tried. Then fish, chicken, and white meat with milk and rice-puddings may be allowed. The patient may now return to his work and gradually resume ordinary diet, but all indigestible foods, such as curries, shell-fish, vegetables (except rice), pastry, &c., must be avoided. Any form of food, however simple, which the patient finds to be followed by discomfort, must be rigorously excluded from his dietary. He must avoid all muscular fatigue and mental worry, and scrupulously continue his treatment for months after he is apparently cured.

Drugs.—No drugs exercise any influence upon the ulcer other than to protect it somewhat from the irritative action of the gastric juice. Drugs are chiefly given to relieve pain, vomiting, hæmatemesis, and constipation, and to correct the anæmia if present. (1) *Pain*.—This usually subsides after a few days' rest in bed and milk-diet, but certain drugs may be of much use, e.g. a dilute warm solution of bicarbonate of sodium frequently sipped; a little prepared chalk, spirit of peppermint, and carbonate of magnesium added to it increase its flavour and efficacy; or 30 to 60 grs. of the sub-nitrate or carbonate of bismuth, with 15 grs. of bicarbonate of sodium thrice daily, half an hour before each meal, to which may be added a little dilute hydrocyanic acid (3–5 m), or to m of tincture of nux vomica, or $\frac{1}{10}$ gr. of morphine or $\frac{1}{4}$ gr. of hydrochloride of cocaine, or a combination of them. Small doses of morphine frequently repeated and given by the mouth often do much good. Very severe cases require morphine-injections. Linseed-meal poultices and hot fomentations or even blisters over the epigastrium are often of great value in relieving pain, and should be used as a routine procedure for the first three weeks whenever pain is present. When the patient cannot lie up, nitrate of silver is of value in relieving pain. It should be given in $\frac{1}{4}$ gr. doses in pill or preferably in solution thrice daily, and gradually increased to $\frac{1}{2}$ to 1 gr. Discontinue it for a week during every month to avoid argyria. (2) *Vomiting*.—Rest in bed, rectal feeding, and bismuth and cocaine, &c., as above. (3) *Hæmatemesis*.—The patient should lie on his back with his head low, and should not move, even slightly. He should be covered with a tight blanket and have ice applied to the epigastrium. No drug is to be given by the mouth, but hypodermic injections of morphine and ergotina may be useful. Some have found oil of turpentine (30 m to 60 m) given in capsules or as an emulsion, with white of egg, very valuable in severe bleeding. When collapsed a pint or so of saline solution (6 parts NaCl to 1,000 parts water) should be slowly injected subcutaneously. Rectal feeding should be exclusively employed for a time. The patient should be confined to bed for a month after the bleeding has ceased. (4) *Constipation*.—This is often very troublesome, and requires to be relieved by purga-

tives for the first month at least. Enemata of soap and water, of castor oil or glycerine, are to be used. Laxatives may be given afterwards by the mouth, and castor oil is by far the best. Carlsbad salts (NaCl 1 oz., NaHCO₃ 2 oz., Na₂SO₄ 4 oz.) in 1- to 2-teaspoonful doses in a large tumblerful of warm water every morning before breakfast, or some natural aperient water, such as Friedrichshall, &c., may be substituted, or aloin or a little cascara sagrada given at night. (5) *Anæmia*.—Iron, in its scale-preparations, or reduced iron, or the saccharated carbonate, or some of its more modern preparations must be given, but not too soon, not until healing is complete, as it is liable to retard recovery.

Surgical.—This is required in perforation, hæmatemesis, obstruction, and complications such as subphrenic abscess. In perforation, laparotomy is performed and the perforation closed by suture. If this be not done a fatal result is almost inevitable (95 per cent.). The outlook is better the shorter the interval which occurs between the perforation and the laparotomy. In profuse and recurring hæmorrhage the ulcer may be cauterised and a gastro-enterostomy performed. Several successful cases have been recorded. For obstruction and gastric dilatation, divulsion of the pylorus, pyloroplasty, or gastro-enterostomy may be resorted to.

R. F. C. LEITH.

STOMACHICS (στόμαχος, the stomach).—

SYNON.: Fr. *Stomachiques*; Ger. *Magenmittel*.

DEFINITION.—Substances which increase the functional activity of the stomach.

ENUMERATION.—The most important stomachics are alcohol, acids, alkalis, aromatics, arsenic, bitters, pepsin, and strychnine or nux vomica.

ACTION.—Some stomachics, such as alcohol and dilute alkalis, increase the secretion of gastric juice; possibly also bitters, and small doses of arsenic. Dilute acids, given after meals, and pepsin supply the essentials of gastric juice when secretion is deficient. It is not improbable that the peristaltic movements of the stomach are increased by strychnine and nux vomica. We want experiments on the action of drugs which increase absorption. It is also probable that some of the good results of bitters are due to their preventing abnormal processes of fermentation in the stomach.

T. LAUDER BRUNTON.

STOMATITIS (στόμα, the mouth).—Inflammation of the mouth. See MOUTH, Diseases of.

STONE.—A popular name for calculus. See CALCULI; and CONCRETIONS.

STONE - GRINDER'S PHTHISIS. — See PNEUMOCONIOSES.

STOOLS.—SYNON.: Fæces; Motions; Fr. *Excréments*; *les Celles*; Ger. *Stuhlgänge*; *Stühle*.

INTRODUCTION.—An examination of the fæces frequently affords valuable evidence of the condition of the organs engaged in the process of digestion, and furnishes important data on which to found a diagnosis and suggest a rational treatment. Not only may structural changes in the alimentary tract be discovered, but also the completeness of action of the various digestive juices be recognised. As with the examination of the renal secretion, a previous knowledge of the healthy characters of the fæces is an essential: this being granted, the

investigation may be pursued on the same lines in both cases, as regards the general, microscopical, and chemical characters. Since, however, the characters of the *fecës* are much more directly dependent on the ingesta, their examination cannot be so valuable an index of tissue-change as is that of the urine.

I. Physical Examination.—**1. QUANTITY.**—This is extremely variable. Taking the normal average for an adult to be about 5 ounces daily, it may vary from $2\frac{1}{2}$ to $10\frac{1}{2}$ ounces. The quantity would seem to bear no relation to the size or weight of the individual, but is rather influenced by the quantity and kind of food taken, and by the activity of the secretions of the alimentary canal. With an average diet, it is estimated that the *fecës* form one-seventh to one-eighth of the weight of the ingesta. As a rule, the amount is increased by a vegetable diet. In children it would seem the total daily amount is relatively slightly greater, while in old age there is an absolute diminution. When in disease the quantity is increased, it is chiefly that of the fluid portion, while a diminution affects both the solid and fluid parts. The writer has noticed a class of cases of intestinal derangement characterised, among other symptoms, by the daily passage—especially in the earlier hours of the day—of several very large pultaceous stools, amounting to a total quantity several times in excess of the normal, and this without a large ingestion of food; the lower part of the ileum, the cæcum, and the ascending colon appear to be in a condition of chronic catarrh in these cases. Tea is said to diminish the quantity of the *fecës* (Chambers). See CONSTIPATION; and DIARRHOEA.

2. CONSISTENCE AND APPEARANCE.—Departures from the normal cylindrical shape are frequent, and depend very much on the existence of constipation or diarrhoea. In infants the evacuations should be unformed and of a pappy consistency. The contents of the bowels pass from a semi-fluid condition in the ileum to the firmer state in the colon, mainly from an absorption of fluid constituents; should there be any delay in the passage the motions are liable to become hard and nodular (*scybalæ*), and this condition may occasionally be extreme, the *fecës* having all the appearance of sheep's dung, and being passed with considerable pain. Certain drugs, such as vegetable astringents, and many preparations of iron, bismuth, or lead, tend to make the *fecës* hard and firm. On the other hand, an increased peristalsis is associated with motions of all degrees of fluidity. This is very marked in the various forms of irritation to which the intestinal mucous membrane is liable, from the simple effects of a saline purge to the extreme conditions of ulceration, as in typhoid fever or dysentery. The rate of passage of the intestinal contents, together with the amount of intestinal secretion, are the conditions determining the various degrees of consistency of the stools designated by the terms '*scybalous*,' '*formed*,' '*semi-formed*,' '*pultaceous*,' '*loose*,' and '*fluid*.'

- The existence of hæmorrhoids, rectal growths, or an enlarged prostate, may be recognised by groovings and marks on the excrement. It is very common in cases of stricture of the colon to find the motions flattened and ribbon-like, or as cylinders much contracted in diameter. Such appearances, however, are by no means constant, for it has been clearly shown that a considerable stricture, even as

low down as the junction of the sigmoid flexure and rectum, may co-exist with motions of normal appearance, the *fecæ*l matter becoming remoulded below the seat of constriction. But the invariable occurrence of such contracted motions is strongly in favour of stricture. Occasionally, as in *psilosis intestini*, the motions are passed in a fermenting condition, presenting a frothy brown or yeast-like appearance, and containing *sarcinæ*, similar to certain vomits. See *PSILOSIS*.

3. COLOUR.—This is dependent on stercobilin, which is regarded as identical with hydrobilirubin (*urobilin*), a derivative of bilirubin ($C_{16}H_{18}N_2O_3$), the chief bile-pigment, and is subject to considerable variation even within the limits of health. The usual brown colour becomes much darker if the *fecës* be long retained, or with an exclusive meat-diet; pale yellow with milk-food, as seen in infants; while it tends towards a greenish tint when vegetables form the bulk of the food.

Unaltered bile-pigment is never found in healthy stools. The conversion of bilirubin into stercobilin, regarded by MacMunn as a process of intermediate oxidation, normally commences in the first part of the colon; but if from any other cause—such as the use of aperients or ulceration or other affection of the bowels—the intestinal contents be hurried along and a diarrhoea established, then bile-pigments, as such, may be found in the motions, causing the bright yellow colour of the well-known '*bilious stool*,' and often leading to much smarting of the anus when voided. In dysentery, the presence of bile in the motions is frequent, especially staining the mucus which is so abundant in the motions of that disease; globules of mucus from the small intestine, similarly coloured, may be seen in the stools of typhoid fever. Other constituents of the *fecës*, such as the shed intestinal epithelium, may also be stained with unaltered bile under the same circumstances.

It is noteworthy that the meconium contains a considerable amount of the normal bile-pigments, bilirubin and biliverdin, but no stercobilin.

The principal alterations in the colour of the stools are—

(a) *Pale and colourless stools.*—All degrees of deficiency of colour may be met with, producing the so-called '*clayey*' or '*putty-like*' stools. This condition is seen in its most marked degree when the bile is absolutely excluded from the intestine, as by an impacted gall-stone; the motions being unformed, lumpy, '*porridge-like*,' or *scybalous*, and almost or quite colourless, frequently, however, accompanied by a small quantity of distinctly bile-coloured fluid, which is secreted by the mucous membrane of the bowel from the bile-laden blood. The causes of pale stools when there is no such obstruction to the bile-flow are varied and not always apparent. In children the explanation is sometimes to be found in the presence in the motions of a large proportion of undigested fat (derived from the milk-food); in various anæmic states the fundamental deficiency of blood-pigment appears to be the cause, and this may account for the frequent occurrence of this condition in rickets. But there remain many cases in which such explanations do not apply, and for which the cause can only be definitely ascertained when we know more certainly than we do at present what becomes of the bile as regards its reabsorption and decomposition in the intestine. The occurrence of colourless

or clay-coloured stools in cases where there is no perversion of the biliary secretion or of its discharge into the duodenum, but where disease of the pancreas has been proved to exist, has suggested 'that the formation of the colouring-matter of the fæces depends on the mutual reaction of the bile and pancreatic fluid, under the influences met with in the intestinal tract;' though what the nature of this interaction is remains unexplained (*see PANCREAS, Diseases of*). A remarkable case which was under the writer's care would tend to show that the production of clay-coloured stools, in cases where the bile reaches the intestine and there is no jaundice, is due to some interference with those changes in the bile which normally take place in the first part of the colon. The patient died from the remote effects of an accident in which he had been severely squeezed between the buffers of a train; for several months previous to death he suffered from constant diarrhoea, the motions being invariably copious and quite colourless. *Post mortem*, the cæcum was found to be represented by a quantity of inflammatory fibrous tissue involving the adjacent parietes, excavated in which were a series of irregular spaces and channels outside the peritoneal cavity, by which continuity was maintained between the ileum and ascending colon; down to the end of the uninjured ileum the bowel-contents were of normal condition and colour (the patient taking almost an ordinary diet) and contained bile, but in the colon they were colourless, as voided, while in the segment of mesentery corresponding to the cæcum and commencement of the colon, the lymphatic vessels were outlined by black pigment, presumably due to absorption of the biliary colouring-matter from the damaged portion of the intestinal canal. Further support for this view is to be found in the character of the motions met with in psilosis of the intestine, they being large, formed, white, and acid in reaction. *See PSILOSIS*.

(β) *Black stools*.—This condition is well marked when blood has escaped into the stomach and passes through the bowels. The hæmoglobin is decomposed by the gastric juice, and its constituent iron is converted into the black sulphide by the sulphuretted hydrogen present in the intestines. Such stools may look like tar; or if they have been long retained they become hard and almost coke-like in appearance (*see MELÆNA*). Iron, bismuth, or charcoal taken internally will similarly colour the fæces; but if they are taken in only small quantities the motions are slaty rather than black.

(γ) *Green stools*.—These are of frequent occurrence in children, and seem to be due to the presence of biliverdin ($C_{16}H_{18}N_2O_6$), an oxidation product of the biliary colouring-matter, bilirubin, which under normal circumstances is reduced; and it not infrequently results from a dose of calomel, which prevents the reduction taking place.

(δ) Certain articles of diet and drugs are liable to colour the fæces more or less distinctly. Thus spinach, coffee, claret, and logwood impart to the excrement their characteristic tints; rhubarb, senna, and santalin cause a bright-yellow colour; and much cocoa may make the stools grey.

4. *ODOUR*.—The characteristic odour of the fæces is chiefly due to certain substances, especially skatol, and to a less degree indol, developed during the pancreatic digestion of proteids, and partly to special secretions from the glands of the colon. Impaired intestinal digestion, particularly, it would

appear, if there be any abnormal bacillary action, is apt to cause fœtid stools, but this effect is very variable. Absence of bile from the alimentary canal, by interfering with the pancreatic digestion, and also by the want of its own special antiseptic power, is often, but not always, accompanied by very ill-smelling motions. In certain diseases of the colon, as dysentery, the evacuations are of a most foul and acrid character, owing to putrid changes in the sloughs thrown off from the ulcerated bowel. In children, the alvine discharges are frequently offensive from errors in diet, and emit a peculiar sour odour.

5. *REACTION*.—The reaction of the fæces in health may be slightly acid, or slightly alkaline. This variability is due to the nature of the food, and still more to the extent and character of the changes in the colon. The stools in some diseases, as typhoid fever, are distinctly alkaline, and in others, as infantile diarrhoea, markedly acid; the colourless stools in obstruction of the bile-duct are also very acid from a large excess of free fatty acids.

6. *FOREIGN BODIES*.—By inspection of the evacuations we may discover—

(a) Substances *accidentally* swallowed, such as coins, pins, &c.

(b) *Indigestible food-residua*, such as fish-bones, the stones, skins, and peel of fruits, fig-seeds, the ligneous grit in pears, &c. Small seeds and particles of vegetable tissue, if long retained in the canal, may become encrusted with lime-salts, and, if abundant, form what has been called intestinal sand (*sable intestinal*). *See CONCRETIONS*.

(c) *Undigested food*, that is, portions of food that have escaped digestion. In certain severe disturbances of the digestive functions some of the food may be passed scarcely, if at all, altered, and may be easily recognised. This condition, known as 'lenty,' is especially prone to occur in the intestinal catarrh of young children during dentition. Curdy lumps derived from milk, and consisting of undigested masses of coagulated casein entangling fat, are often met with in infantile diarrhoea. 'On a moderate diet unaltered proteid is never found' (Halliburton).

(d) *Fat*.—This special element of the food may occur in the motions in such quantity and in such forms as to require separate mention. Anything more than a trace in the fæces is to be regarded as abnormal, and as the expression of a failure in its digestion or absorption. This may be due to an excessive ingestion, as may occur in a milk-diet, or where undue quantities of olive or cod-liver oil are given for medicinal purposes; or to a deficiency of the digestive fluids, especially the pancreatic juice. The presence of fat in the stools has long been known as a diagnostic sign of pancreatic disease (*see PANCREAS, Diseases of*), and is of not infrequent occurrence in diabetes. In those morbid states characterised by extensive destruction of the epithelium of the small intestine, fat may appear in the motions from not being absorbed, although the quantity taken may be but moderate, and the conditions for its digestion unimpaired.

The form in which fatty matter appears in the stools is very variable, and much depends upon the kind of fat taken. Masses of almost pure fat may be found; or lumps of greasy-looking substances, consisting mainly of crystals of the fatty acids, or compounds of these with earthy bases, forming soaps, may be met with. Occasionally these

substances may be voided in cylindrical form, which has been compared to macaroni.

(e) *Mucus*.—The amount of this substance in normal fæces is quite inappreciable, but in catarrhal and other inflammatory states of the lower end of the ileum and colon it is formed in considerable quantity. Its disposition in respect to the fecal matter is, to a great extent, diagnostic of its site of production. Thus in catarrh of the ileum, with the very bulky stools above-mentioned, it is intimately diffused through the fæces in microscopic particles; in the motions of typhoid fever, bile-stained globules of mucus may be seen with the naked eye. It may be taken as a general rule that the more distinctly separate the mucus is from the excrement, the lower down in the bowel does it come from. When it occurs in masses adherent to or apart from the fecal matter, it comes from the sigmoid flexure or rectum; while from the upper part of the colon the mucus appears as fair-sized globules mixed with the stool. In dysenteric inflammation and ulceration of the colon the mucus frequently forms discrete particles, which have been compared to grains of boiled sago or to frog-spawn, and may be mixed with pus and blood.

(f) *Blood*.—Blood voided *per anum* presents very different appearances according to its source. When coming from the stomach or upper part of the intestine it is much altered, being black and tarry (see MELÆNA). Even when recognisable as blood, there is a considerable range of variety in colour, as well as degree of admixture with the fecal matter. On the one hand, it may be passed in a perfectly pure state, quite free from foreign matter, as would be the case when the bleeding took place from an eroded vessel low down in the bowel, or even as high up as the ileum, provided the quantity were considerable, and it were discharged immediately after its escape. Practically, the purer and brighter the blood, the lower down is its source. Or it may occur as a brownish-red material thoroughly mixed with the fæces, and then comes from the commencement of the colon or small intestine; or streaks or smears of blood scarcely altered in appearance, with or without mucus, and attached to the surface of the motion, suggest a lesion in the lower part of the colon and rectum. The blood, from internal piles or extreme congestion of the venules of the rectum, has a characteristic purplish tint, and is frequently passed quite free from feculent matter. See also p. 789.

(g) *Pus*.—This is not a very frequent constituent of the stools, the amount in ordinary catarrhal states of the bowel being too small, as a rule, to be recognised without the microscope. In dysentery, however, the quantity is greater, and pus then becomes a prominent feature in the motions. When large quantities are passed, the source is usually an abscess which has burst into the canal.

(h) *Entozoa*, such as segments of tænia, the various round-worms, or the contents of hydatid cysts that may have burst into the canal, may be present in the fæces.

(i) *Miscellaneous*.—Under this head may be included gall-stones, intestinal concretions, mucous or membranous casts of the intestines (pp. 254, 795), portions of bowel sloughed off from intussusception (p. 783), or of new-growths &c.

II. Microscopical Examination.—See pp. 800, 121.

III. Chemical Examination.—It is seldom if ever that such examination furnishes evidence of primary importance, as does analysis of the urine.

The food is of course the main source of the constituents of the fæces, a few only of these components being derived from the bile and other digestive secretions. The shed epithelium and detritus from the intestinal mucous membrane form, however, no inconsiderable share of the bulk of the fæces.

For the chemical processes—often elaborate—required for their detection, reference must be made to standard works on physiological and pathological chemistry.

1. *Phenol* (C_6H_5OH), *indol* (C_8H_7N), and *skatol* (C_9H_9N) are normally formed in the intestines during the pancreatic digestion of proteids. A considerable proportion of these substances is absorbed, and, undergoing various chemical changes, is eliminated in the urine; but a considerable amount of each also leaves the body in the fæces, where they may be separated and detected by appropriate reagents. To skatol the odour of the fæces is mainly due, and it is said by Brieger to be absent from the evacuations of typhoid fever.

Leucine and *tyrosine*, which are also derived from the proteid elements of food by tryptic digestion, are not found in the fæces in health, though of frequent occurrence in the stools of various conditions of diarrhœa, especially cholera. See LEUCINE; and TYROSINE.

2. Two bodies—*excretin* and *stercorin*—have been described as characteristic of the fæces, but their existence is doubtful. They are non-nitrogenous, crystallisable, non-saponifiable bodies, differing in their crystalline form, and their solubility in alcohol and ether. They appear to be closely related to cholesterol, with which in many points they agree. It is said that when the bile which normally contains cholesterol is prevented reaching the intestines, neither of these bodies occurs in the fæces; and that they are also absent, being replaced by cholesterol, in the meconium, and in starving and hibernating animals, when there is no obstruction to the bile-flow. Flint considers about ten grains *per diem* to be the average amount of stercorin, and the excretin of Marcet to be about a fifth of that. *Cholesterol* itself, except in very small quantities, cannot be regarded as a normal constituent of the fæces; but the precise significance of its occurrence is uncertain. Its chief source is the bile, and only a small quantity comes from the food. See CHOLESTERIN.

3. *FATTY ACIDS, FATS, AND SOAPS*.—Various members of the fatty-acid series, such as acetic, butyric, caproic, valerianic acids, and the higher terms, oleic, palmitic, and stearic, only occur free in minute proportions, in ordinary circumstances, but the latter are readily increased to considerable amounts when the alkaline secretions of the liver and the pancreas are prevented from entering the intestines. The presence of neutral fats in the excrement may be taken to indicate that there has been excessive ingestion or a diminished digestion, since under ordinary circumstances they would be absorbed. When occurring in considerable amount in the stools they produce the so-called 'fat-diarrhœa,' described in various dyspeptic states. The soluble sodium- and potassium-soaps ordinarily formed by the ingested fats with the bile and pancreatic juices should be in great part taken up by the lacteals; but fats, meeting with any calcium- or

magnesium-salts that may be present in the alimentary canal, form with them insoluble hard soaps, which are passed in the fæces.

4. **SALTS.**—These are but in small amount, and are chiefly the earthy and triple phosphates, with small quantities of iron and silica; there is in health a marked absence of chlorides. When the stools are very alkaline the triple phosphates may be very abundant, as in typhoid fever; and in cholera discharges the whole amount of salts is largely increased, there being nearly an ounce in every hundred fluid ounces of evacuation, a large proportion of which consists of chlorides. A similar excess of these salts occurs in the stools of other diarrhoeal states, with a corresponding decrease in the urine.

5. **PIGMENT.**—The characters of the fæcal pigments have been already referred to.

6. **MUCIN, ALBUMEN, &c.**—A very appreciable amount of *muçin* may be extracted from the fæces by well mixing with lime-water, and adding acetic acid to the filtrate.

Albumen, as such, can scarcely be looked upon as a normal ingredient of the evacuations; but the fluid part of cholera-stools, which resembles dilute blood-serum in composition, contains a very appreciable quantity. In typhoid and other diarrhoeal stools albumen can be detected.

Peptones are not found in healthy fæces, but occur in considerable quantities in various diseases, of which the most frequent are typhoid fever, dysentery, tubercular ulceration of the intestines, and cirrhosis and carcinoma of the liver.

Ferments similar in action to ptyalin and pepsin are described as existing in the fæces, but how they may be modified in disease is quite unknown.

Certain of the groups of putrefactive bodies termed *ptomaines*, such as cadaverine and putrescine, have been recognised in the fæces. See p. 1333.

In uræmia and also in intestinal catarrh *urea* has been detected in the stools.

In certain diseases, especially cholera, dysentery, typhoid fever, intestinal catarrh, both acute and chronic, and to a less degree hepatic and pancreatic affections, the stools are more or less characteristic, though the diagnosis rarely depends on their appearances alone. They are described under their respective headings.

W. H. ALLCHIN.

STRABISMUS.—SYNON.: Squint; Fr. *Strabisme*; Ger. *Strabismus*; *Schielen*.

DEFINITION.—A condition in which the two eyes are not directed to the same point in space.

DESCRIPTION.—Squint is commonly either (1) *convergent*, or (2) *divergent*; but (3) it may be complex, where there is a deviation either *upwards* or *downwards*. When one eye appears to be normally directed, and the other to deviate, it is convenient to distinguish the former as the *working*, and the latter as the *squinting* eye.

The extent or degree of strabismus, or, as it is more usually called, the *magnitude* of a squint, is expressed in terms of millimetres. In convergent or divergent squint it is customary to measure the distance between an imaginary vertical line bisecting the palpebral fissure, and another imaginary vertical line bisecting the pupil of the deviating eye. In an upward or downward squint, the distance between the horizontal diameter of the pupil, and an imaginary horizontal line bisecting the palpebral fissure, would give the measurement required.

1. **Convergent Squint.**—This is seen under two principal forms: (a) that which depends upon *paralysis* or *paresis* of one of the external recti muscles, permitting the antagonist, the internal rectus, to exert a preponderating influence upon the position of the eye; and that which depends upon *excessive development* of both interni, in consequence of an error of refraction, whether (b) *hypermetropia*, or (c) *myopia*.

(a) *Paralytic Convergent Strabismus.*—This form of strabismus is met with in all degrees, from the slightest weakening of the affected external rectus to complete paralysis.

ÆTIOLOGY.—Paralytic convergent strabismus is primarily a nerve-affection, in which, however, the muscle concerned will after a time be liable to undergo degenerative changes. The strabismus usually commences somewhat suddenly, in persons of adult age, and often rapidly increases in degree; the paralysis, which at first was only partial, becoming complete. In the great majority of cases it is associated with syphilis; but it is also met with as a result of impaired nutrition or degenerative change in the nervous centres, consequent upon anxiety or over-work. In some of the syphilitic cases, it appears to be due to central mischief, such as gumma or arterial occlusion; in others to pressure upon the trunk of the sixth nerve by periosteal thickening or other morbid growth.

DIAGNOSIS.—In pronounced cases, the diagnosis is easy; and depends upon the fact that, even when the working eye is closed or covered, the squinting eye cannot be directed outwards by voluntary effort. If the paralysis, although considerable in degree, be not complete, the eye cannot be directed outwards as far as usual; if the paralysis be complete, the pupil cannot be carried external to the middle line of the palpebral fissure. When the affected muscle is only slightly weakened, the nature of the condition may not be at once apparent from the limitation of movement; and the degree of deviation may be so slight that it is not easy immediately to pronounce which eye is affected. This doubt may be removed, and the existence of paresis made manifest, by the following tests. The surgeon should stand in front of the seated patient, and should hold up before him, in the middle line and at a convenient reading distance, some small object, telling him to look at it steadily. By his own hand, or by a piece of ground-glass, the surgeon then cuts off the view of the object first from one of the patient's eyes and then from the other, watching their movements as he does so. When the object is concealed from the squinting eye, the other one, being already rightly directed, will remain stationary to continue the act of seeing, and the squinting eye will also remain stationary; but when the object is concealed from the working eye, the other, or squinting eye, being wrongly directed, and not receiving the image of the object upon its yellow spot, will make a slight outward movement in order to take up correct fixation. At the same moment, the working eye, behind the obstruction, will execute an inward movement of somewhat greater amplitude than the outward movement of its fellow. Let it be supposed that there is slight weakening of the right externus, producing slight inversion of the right eye. When the object is screened from the right eye, the left still sees it clearly and sharply, and both eyes remain at rest. When the object is screened from the left eye, the right receives the image upon a

point of its retina internal to its yellow spot, and sees it only indistinctly. The right eye, therefore, makes an excursion outwards, sufficient in amount to bring the image of the object upon its yellow spot, and to enable it to see better; but the motor impulse by which the necessary movement of the external rectus is called forth is conveyed at the same time to the internal rectus of the left eye, as a result of the habitual association of the two eyes and of their muscles in the act of looking towards the right; and the sound muscle, under a given motor impulse, contracts more vigorously than the weakened one. The result is that the excursion inwards of the working eye is larger than the excursion outwards of the squinting one; and in this way the fact of paresis of the right externus is rendered manifest.

This form of strabismus is at first attended by distressing double vision, which often produces giddiness, but which diminishes in time, as the patient learns to neglect or mentally to suppress the image of the squinting eye. The smaller the deviation, the more distressing will be the double vision; because, the nearer to the yellow spot the image of the squinting eye is, the more definite will it be, and the less readily will it be distinguished from that of the other. In cases of very slight deviation, the equality of the two images renders it difficult to tell the true from the false, and leads the patient into frequent error with regard to the position of the object looked at.

TREATMENT.—The treatment of paralytic strabismus is primarily that of the syphilis or of the nerve-exhaustion upon which the paralysis depends; but it is also necessary to endeavour to minimise the inconveniences of the double vision while it continues, and to provide against permanent degeneration of the paralysed muscle from disuse. The former indication may be fulfilled by covering the squinting eye with a patch, or with an opaque glass in a spectacle-frame; and, as the double vision is only troublesome when the eyes are directed to the side of the affected muscle, it is often sufficient to render opaque, by grinding or otherwise, the outer half of the glass which covers the affected eye. The nutrition of the muscle may be preserved, when the paralysis is incomplete, by systematic voluntary endeavours to call it into action; these endeavours being made three or four times a day for a few minutes at a time. For this purpose, the working eye should be closed or covered, and the squinting eye should be directed as much as possible towards the outer side. When the paralysis is complete, so that the eye cannot be carried beyond the middle line of the palpebral fissure, it may be necessary to exercise the affected muscle by localised electric currents, after the manner of Duchenne. In cases where there is no response to induced currents, those of a cell-battery will sometimes be found effectual. The exercise by electricity should be repeated at short intervals, such as every two or three days, until the nerve-function is beginning to be restored, so that the muscle can again be exercised by the will.

In cases of paralytic strabismus of old standing, it is sometimes necessary to have recourse to tenotomy of the contracted internus, before the eye can be restored to its correct position. It may be laid down as a general principle that nearly every case can be cured, by combined tenotomy and volitional or electrical exercises, as long as the paralysed muscle

will respond, in however small a degree, either to the will or to one form or other of electric current; but that where the eye does not move outwards in obedience to the will, and where neither induced nor battery-currents produce contraction of the paralysed muscle, no good is to be expected from either operative or medicinal treatment.

(b) *Convergent Strabismus due to Excessive Development of both Interni.*

ÆTIOLOGY.—As a result of errors of refraction, about 90 per cent. of this class of cases are due to flat-eye or *hypermetropia*. The flat formation of the eye requires, for acute vision of near objects, a strenuous accommodation-effort; and this, by the intimate association which exists between the nerve-centres governing the accommodation-muscles and those governing the interni, produces a corresponding effort of convergence. As soon as a child who is born with flat eyes begins to take careful notice of near things, his accommodation-muscles and his internal recti are both called into frequent and energetic exercise; and the consequence is that the interni become excessively developed in relation to their antagonists, the externi, so that the normal or resting position of the eyes, instead of being one of parallelism, becomes one of convergence. The result of this is that the child would receive double images, of equal intensity, of all objects situated either nearer to him, or farther from him, than the point at which the convergent optic axes would meet if prolonged. Let us suppose that this point is one foot distant from the eyes; and that the child wishes to look at an object which is eighteen inches distant. He cannot do this with both eyes, because the externi are unable to overcome their more powerful antagonists. If, however, he combines the right externus with the left internus, as in the act of looking to the right with both eyes, he becomes able to fix the object correctly with his right eye; and if he combines the left externus with the right internus, as in the action of looking to the left with both eyes, he becomes able to fix the object correctly with his left eye. But as, in either case, both eyes start from a position not of parallelism, but of convergence, the effort which carries the right eye from its convergent state to the middle of its palpebral fissure will carry the left from its convergent state to one of much greater convergence, and *vice versa* with the left eye; so that, while one eye is directed to the object of vision, the other is rolled far inwards. In this way, the image is received upon the yellow spot of the working eye, and upon so peripheral a portion of the retina of the squinting eye that it is easily neglected by the consciousness, and ceases to be a source of confusion or embarrassment.

DIAGNOSIS.—The state of things in an ordinary case of squint beginning in childhood is the following. In a state of rest, as when the attention is not directed to any object, or during sleep, or under an anæsthetic, the eyes are equally convergent; but as soon as any object is looked at, one eye fixes this object and the other rolls inwards. If the degree of flatness is alike in both eyes, and if the muscles in both are of equal power, sometimes one will be the squinting eye and sometimes the other; and in most cases this condition obtains for a time. The squint is then said to be 'alternating.' Generally speaking, however, it is for some reason easier to work with one eye than with the other; either because it is flat in a less degree, or because its

accommodation-muscle or its external rectus is stronger than the corresponding muscle of its fellow ; and then this eye is used in preference to, and gradually supersedes, its fellow ; becoming always the working, while that is always the squinting eye. The squint is then said to be 'permanent.'

TREATMENT.—It would appear at first sight, from the *rationale* of the affection, that the squint which depends upon flat-eye could always be prevented, or even cured, by the habitual use of convex spectacles ; but, as a matter of fact, the balance of power between the externi and the interni becomes deranged at so early a period of life that spectacles could not be applied until too late. In every pronounced case of strabismus it is necessary to perform an operation ; and the only question to be considered is that of the nature of this operation, and of the time most favourable for its performance.

In determining this question, the points chiefly to be taken into account are the state of vision, the balance of muscular power, and the age of the patient. When a squint becomes permanent, the vision of the habitually squinting eye frequently becomes impaired, apparently as a result of the continued mental suppression of the image which it receives, and in a person who is suffered to grow up to adult age squinting, this impairment of vision often falls little short of blindness, and admits of no remedy. No change is discoverable, generally speaking, by the ophthalmoscope ; but the power of responding to impressions upon the retina seems to be lost. On the other hand, as long as the squint is alternating, and each eye is used by turns, the sight does not usually suffer.

The immediate effect of tenotomy of one or both interni is to release the eyes from their position of enforced convergence, and to diminish the power of the interni to rotate them inwards. The divided muscles soon acquire new attachments farther back upon the eyeball than their former ones, so that their power is permanently diminished, and this diminution may even be in excess, so as to leave an undesirable preponderance of the externi, and a corresponding tendency to eversion. The surgeon, even by the best planned operation, cannot absolutely determine the future position of the eyes. That determination has to be effected by the muscles themselves under the guidance of vision ; and a perfect result after a squint-operation, by which is meant the restoration of parallelism when at rest, without impairment of the power of volitional convergence, can only be obtained by an instinctive rearrangement of the muscular forces concerned, a rearrangement mainly brought about by efforts to avoid double vision, which is often the immediate result of an operation. While, therefore, it is always possible to remove by tenotomy a coarse and manifest malposition, it is only possible to command a perfect result when the recti muscles are well-developed, when the acuteness of vision is equal or nearly so in the two eyes, and when the power of attention to visual impressions is sufficiently active to render double images distressing. The muscular development and the power of attention are both deficient in early childhood ; and hence, so long as vision does not suffer, it is better to defer operating for squint until about eight years of age. As long as the squint is alternating, there is no fear that the vision will suffer, and it is then safe and desirable

to wait ; but as soon as the squint becomes permanent, it is necessary to test the vision of the squinting eye from time to time, and to provide for this eye being exercised every day, by keeping the other closed or covered for short periods. If, in spite of such exercise, the vision of the squinting eye is found to be undergoing progressive deterioration, an operation should be performed without delay, at however early an age ; and the parents should be warned that it may perhaps be necessary, for the attainment of perfect harmony of movement between the two eyes, to operate again at some future time. Of late years many surgeons have preferred increasing the power of the externi by bringing their attachments nearer to the cornea, to the older operation of tenotomy ; but so much of the effect will depend upon the skill with which either operation is performed that it is impossible to lay down any general statement of their relative advantages.

It will sometimes happen that a child is first brought for advice at an earlier age than eight, in whom the squint has already become permanent in one eye, and in whom the vision of that eye has already begun to suffer. In such cases it is best to devote a few weeks to endeavours to improve the vision of the squinting eye by compulsory exercise ; and, if these endeavours should be in any degree successful, to continue them as long as improvement under their employment is perceptible. If no improvement should be produced, an operation should be performed without further loss of time.

(c) *The Convergent Squint of Short-sighted People.*—This is not a very common affection, and depends upon the fact that, spectacles to afford distant vision not having been worn, the externi, which produce the approximate parallelism of the optic axes required for distant vision, have not been exercised ; while the interni have been constantly exercised in producing convergence for the vision of near objects. The former muscles, therefore, have been suffered to fall into a condition of feebleness from disuse, while the latter have undergone abnormal development. In such cases the eyes are usually equally convergent, such a position giving single vision of near objects ; while double vision of distant ones is not irksome, on account of the indistinctness with which they are seen.

TREATMENT.—When the convergent squint of a short-sighted person is of small magnitude, it may sometimes be cured by wearing glasses which correct the short-sight for distance, and call upon the external recti to take up their proper function. More frequently, however, they fail to respond ; double vision is produced ; and tenotomy or advancement, followed by the use of spectacles, is required. Such cases usually turn out perfectly well.

2. **Divergent Squint.**—This is nearly always a consequence of defective vision of the squinting eye, which wanders outwards for want of guidance from visual impressions. It may also follow from unskilfully performed or excessive operations for the cure of convergent squint.

TREATMENT.—The operation for divergent squint is not a mere tenotomy, but requires the shortening of the internal rectus of the squinting eye, or its advancement to a point of attachment nearer to the corneal margin ; and the results of such an operation are less under command than those of tenotomy. The muscle may not attach itself firmly in the new position, or the connecting medium may stretch

after a short time. The operation may be undertaken more hopefully, the better the vision of the divergent eye; and it is often very successful. It is nevertheless most prudent, in every instance, to prepare the patient for the possibility of failure, or of only partial success. It is in no case likely that the defect will be increased by failure of the operation; and, as the chief motive for its performance is usually the improvement of appearance, it may be undertaken with propriety in almost every case.

3. **Complex Squint.**—The forms of strabismus in which the deviation is either upwards or downwards are not sufficiently numerous to be brought under general rule. They depend either upon spasm of the muscle producing the deviation, or upon paralysis or paresis of its antagonist; and every case must be investigated and treated upon its merits, by tenotomy or electrification, or both combined, according to the particular circumstances. Various irregular forms of strabismus are also seen, in the course of certain acute and chronic diseases of the nervous system, which entail loss or impairment of muscular co-ordination, such as meningitis and tabes dorsalis; but such forms are usually easily to be distinguished as symptoms of the general disorder, requiring no treatment or consideration apart from it. In chronic diseases, such as tabes dorsalis, it may be conducive to comfort to exclude the squinting eye from vision, for the purpose of obviating the inconveniences incidental to double images.

R. BRUDENELL CARTER.

STRANGULATION (*strangulo*, I choke).—

In pathology this term is employed to express either the process or the condition of constriction of a tube or pedicle, when it is so complete that the passage of the contents, or the circulation of the blood, is prevented. See HERNIA; INTESTINAL OBSTRUCTION; and OVARIES, Diseases of.

STRANGULATION as a Mode of Death (*strangulo*, I choke).—SYNON.: Fr. *Strangulation*; Ger. *Erwürgung*.

DEFINITION.—The act and the effect of constriction of the neck and air-passages by means of a ligature or of manual pressure (throttling). Death results essentially from asphyxia.

ÆTIOLOGY.—Strangulation is chiefly homicidal, but it may be suicidal or accidental. Accidental strangulation may occur in a variety of ways, as in the case of a child by tightening of a cravat round the neck, from the end catching in the wheel of a perambulator; in the case of a drunken woman by fixation and tightening of her bonnet-strings; and in the case of a cripple by a rope attached to a weight accidentally becoming tightened in front of the neck.

It was at one time doubted whether suicide could be effected by strangulation, owing to the fact that the hands relax when insensibility comes on, rendering it impossible to keep up sufficient tension on the ends of the ligature. But when the ligature is wound more than once round the neck, or some method is adopted by which the ligature can be tightened like a tourniquet, as by the insertion of a piece of stick which catches behind the ear or elsewhere, it is quite possible; and numerous instances are on record of suicide so effected. In most cases, however, the presumption is in favour of homicide, and in all cases of strangulation by manual pressure this may be looked upon as certain.

SIGNS.—In addition to the general indications of asphyxia (see ASPHYXIA) there are special signs of strangulation which vary with the degree of force employed, and the amount of resistance offered by the victim.

To strangle an individual of normal strength, and in full possession of all his faculties, is barely possible, without causing evident signs of violence on various parts of the body. The existence of injuries of this kind is valuable evidence of the mode of death. Very often cranial injuries are found, from the individual having been first knocked down by a blow on the head. Ecchymoses, abrasions, and other signs of mechanical violence are generally to be found in various parts of the body. If the strangulation has been effected by manual pressure, the front or sides of the neck exhibit bruised marks, corresponding to the thumb and fingers, with, perhaps, curved excoriations corresponding to the nails. The relative size of the marks produced by the thumb and fingers, and the direction of the nail marks, indicate the way in which the pressure has been exerted, and whether with the right or left hand.

When a ligature has been employed a mark is left on the neck, which varies with the nature of the ligature and the way it has been disposed. Usually it is a transverse, shallow furrow; single, double, or multiple, according to the number of folds; and continuous, or interrupted in places; differing from that of hanging, which is generally single and oblique, and higher up in the neck. The bottom of the groove is generally pale, and not parchmented as in hanging, owing to the pressure not being kept up so long as to lead to desiccation. Ecchymoses in the course of the groove are met with more frequently than in hanging, owing to the great violence frequently exerted.

Very commonly punctate ecchymoses are visible on the conjunctivæ, face, neck, and chest. They are considered by Tardieu to be more frequent in strangulation than in asphyxia from other causes, or than in cases of over-straining, which likewise may lead to them. In the subcutaneous cellular tissue, and in the fasciæ of the muscles above and below the hyoid bone, extravasations are frequently found, as well as on the external surface of the thyroid cartilage and trachea. The lungs vary as regards their vascularity; but on the surface it is common to find pseudo-membranous patches, which are due to the rupture of some of the superficial air-cells and collection of air-bubbles under the pleura. In the substance of the lungs congested patches, or apoplectic extravasations, are often found, varying in size, according to Tardieu's description, from half a franc up to a five-franc piece—extravasations, therefore, much larger than those usually found in suffocation.

TREATMENT.—The treatment of asphyxia from strangulation is that of asphyxia in general. See ARTIFICIAL RESPIRATION; ASPHYXIA; and RESUSCITATION.

D. FERRIER.

STRANGURY (*σπράγξ*, a drop; and *οὔρον*, urine).—SYNON.: *Stillicidium Urinæ*; Fr. *Strangurie*; Ger. *Harnstrenge*.

DEFINITION.—A spasmodic condition characterised by a frequent and urgent desire to pass urine, which is voided in drops or in very small quantities, with a sense of painful spasm in the perinæum and anus, and often unaccompanied by feeling of relief.

ÆTIOLOGY.—Strangury occurs in acute nephritis, in tubercular disease of the kidney, in renal colic, and in cases of intense congestion of the kidneys, however induced. It is also a diagnostic symptom of poisoning by cantharides, either from the internal use of the drug, or the external application of cantharides-plaster or of blistering fluid (see **CANTHARIDES**, Poisoning by). It is also met with after the administration of large doses of turpentine and its allies. Many morbid states of the kidneys, ureters, bladder, prostate, and urethra own strangury as a symptom. Especially is it a symptom of acute inflammations of the prostate (abscess in particular); acute inflammations of the bladder; or when the trigone is involved by morbid conditions, such as vesical calculus, growths, and tubercular disease. When acute gonorrhoea involves the *deep* urethra, this symptom is likewise met with. It must therefore be remembered that strangury may be produced by any condition which, directly or indirectly, leads to inflammatory affections of the trigone, or deep urethra; and it is in this way that the affection accompanies stricture of the urethra, enlarged prostate, foreign bodies in the bladder introduced from without, or fecal fistula.

Apart from inflammatory causes, morbid conditions of the urine, such as are met with in the oxalic-acid and uric-acid diatheses, may occasion strangury. Gouty prostatitis is therefore another factor in its causation.

TREATMENT.—The treatment of strangury is either preventive or curative. If it occurs during the administration or other use of drugs, such as turpentine or cantharides, it is imperative to discontinue their employment.

If we consider strangury as but a symptom of some other morbid condition, we must endeavour to remove the condition on which it depends. To relieve the more urgent and distressing local symptoms, we may have recourse to hot fomentations to the perineum, warm sitz-baths, suppositories of morphine and belladonna, or the cautious use of hypodermic injection of morphine.

JOHN HAROLD.

STRATHPEFFER, in Ross-shire.—Sulphur-waters. See **MINERAL WATERS**.

STREPTOTHRIX - INFECTIONS.—The *Streptotrichæ* are a group of micro-organisms, the exact position of which has given rise to some controversy. They seem to be somewhere intermediate between the fission-fungi or true bacteria, and the moulds, having probably a nearer affinity to the latter, among which they are placed by some writers. The genus itself has had various appellations, e.g. *streptothrix*, *cladotrich*, *actinomyces*, *oospora*. They are characterised by forming a network or mycelium of tangled filaments; these undergo true, though not dichotomous, branching. Spore-formation occurs, and in the tissues the more or less spherical nodules of the growth are often encased at their periphery within a palisade of radially disposed club-shaped structures, which are the swollen terminations of the mycelial filaments, and which in some instances seem to divide transversely and to form spores.

The best-known member of the group is the *actinomyces* or 'ray-fungus' (see **ACTINOMYCOSIS**), of which there seem to be several varieties or species. Another well-known condition due to a *streptothrix*

is the white variety of mycetoma or madura disease. See **MYCETOMA**.

The streptothrix-infections in their clinical characters generally resemble tuberculosis, from which they can be distinguished only by a microscopical or bacteriological examination of the tissues or discharges; hence it is not unlikely that they are of more frequent occurrence than has hitherto been supposed. Sooner or later chronic suppuration usually occurs. Flexner has described a case in which the clinical signs and symptoms were those of pulmonary tuberculosis.

Rarely, certain bacillary infections seem to form nodules with radiating filaments and clubs at the periphery. R. T. HEWLETT.

STRICTURE (*stringo*, I bind).—A contraction of a tube, duct, or orifice, for instance, of any part of the alimentary canal, or of the urethra. See **URETHRA**, Diseases of.

STRIDOR: STRIDULOUS (*strideo*, I creak). Stridor is the name given to a peculiar noisy form of breathing, produced in the larynx, trachea, or main bronchus; varying greatly in its character—being either harsh, musical, or crowing; and due to various forms of obstruction. The term *stridulous* is applicable to the respiration, the cough, or the voice, when they possess the characters of stridor. See **CROUP**; **LARYNX**; **PNEUMOGASTRIC NERVE**; **TRACHEA**; and **VOICE**.

STROKE.—A popular synonym for an attack of apoplexy or sudden paralysis. It is also used in the compound words, *sun-stroke*, *heat-stroke*, and *wind-stroke*, to indicate severally the sudden effects of these agents.

STRONGYLUS (*στρογγύλος*, cylindrical).—**SYNON.**: Fr. *Strongle*; Ger. *Pallisadenwurm*.—A genus comprising many species of nematoid worms. See **ENTOZOA**.

STROPHULUS.—The term is applied to a form of sweat-eruption occurring in infants and in children. It consists of small vesicles and papules, often appearing on the face, but also on other parts of the body. Thus it may occur on the side of the face in contact with the nurse, or elsewhere if the clothing is too warm or is allowed to remain wet. Occasionally it makes its appearance in febrile conditions, and if the digestion is disturbed, as during dentition, when the eruption is more universal, and its relation to miliaria becomes more evident. The eruption is the 'red gum-rash' of nurses. Probably in all cases the eruption is caused by retention of sweat, and the formation of superficial retention-cysts.

TREATMENT.—The eruption is usually trivial, but care should be taken to prevent irritation or infection of the eruption, by which eczematous conditions may readily be excited. The food and digestion of the infant should be attended to, and the site of the eruption kept dry and clean. The application of a dusting-powder containing oxide of zinc, talc, and, if necessary, a small quantity of boric acid, is useful, or a lotion of limewater, glycerine and oxide of zinc if the parts are reddened.

JAMES GALLOWAY.

STRUMA: STRUMOUS (*struma*, a scrofulous swelling).—Synonyms for scrofula and scrofulous. See **SCROFULA**.

STRYCHNINE, Poisoning by. — **SYNON. :** Fr. *Empoisonnement par la Strychnine*; Ger. *Strychninvergiftung*.—The seeds of *Strychnos nux vomica*, commonly known as *nux vomica*, as well as several other plants, owe their powerful toxic (excitomotor) properties to an alkaloid, *strychnine*; and in a minor degree to another alkaloid, *brucine*, which is said to produce the same physiological effects as strychnine. Strychnine is a white crystalline substance, very sparingly soluble in aqueous liquids, to which, however, it communicates an intolerably bitter taste. It is more freely soluble in acid and alcoholic liquids. When mixed with flour and sugar, and coloured by admixture with either soot or Prussian blue, strychnine forms the basis of several well-known forms of 'vermin-killer.' In spite of its repulsively bitter taste, strychnine has been administered with homicidal intent in such liquids as infusions of tea and cocoa, and in other media.

ANATOMICAL CHARACTERS.—The anatomical characters after death by strychnine-poisoning are very ill-marked, and at most consist of some congestion of the vessels of the spinal cord; and even this may be wanting.

SYMPTOMS.—Except when taken in the form of pill, strychnine and all substances containing it produce an immediate and intensely bitter taste, which is also at the same time of a quasi-metallic character, and is very persistent. Since the fatal dose—half a grain of the alkaloid—is small, and the poison is readily soluble in the acid gastric fluid, its physiological effects are, as a rule, not long delayed. They may be unmistakable after the lapse of two minutes; but commonly they are not well-marked till five, ten, or even twenty minutes after administration. They begin with a stage of restlessness, excitement, and a vague sense of impending peril. The special senses, too, are often preternaturally sharpened. A feeling of choking or impending suffocation ensues; then there is a trembling of the whole body; jerkings of the head; and, often in a moment, the whole body becomes stiff and rigid, assuming a bow-like form (*opisthotonos*), that is, bent backwards and resting perhaps on the head and heels only. The muscles even of the chest and abdomen are tense and fixed, so that respiration is impeded, giving rise to more or less cyanosis. The feet are either incurvated or excurvated. The angles of the mouth are drawn down, so as to give rise to the well-known *risus sardonius* of tetanus. Attempts to administer medicine by either cup or spoon have been known to result in the patients biting the cup or spoon in two, in consequence of a violent spasmodic closing of the jaws. During the paroxysm, and indeed throughout the intoxication, the cerebral faculties are unimpaired, and the convulsions are purely of spinal origin. The pupils are dilated. In a few minutes, and often in half a minute, the muscular tension relaxes, and there is a complete remission of the spasms. The patient lies exhausted, and bathed in perspiration; the rapid pulse of excitement falls in frequency; respiration becomes more normal; and the dusky lividity of the countenance passes off. This remission is, however, of no long duration. A gentle touch, a footstep, even a breath of air impinging on the patient, results in a new crisis; and often with a wild, despairing cry, a renewed convulsion, similar to but more intense than the preceding one, is ushered in. The patient rarely dies during the first or second paroxysm, but the alternation of convulsions and quiet is repeated

again and again till death ensues, usually in half an hour or an hour; or in non-fatal cases the fits become less and less frequent, less intense, and eventually cease. Death takes place commonly during a paroxysm, from asphyxia; but it may also occur in the intervals between the paroxysms, from exhaustion.

DIAGNOSIS.—The characteristics of strychnine-convulsions are so well marked, as already described, that there is little likelihood of the nature of the case being overlooked; and the only disease with which strychnine-poisoning can readily be confounded is tetanus—traumatic, idiopathic, or hysterical. In the hysterical form of the disease, as described by some writers, the well-marked hysterical symptoms, the closed or half-closed eyes, the desire to be fanned, and the incomplete remissions of spasm, serve for diagnosis. Except in the history, there is nothing to distinguish between the traumatic and idiopathic forms of the disease, so that what is here stated with regard to the diagnosis between strychnine-tetanus and traumatic tetanus, applies also to the idiopathic form. In traumatic tetanus the muscular symptoms begin with pain and stiffness of the neck and jaws, gradually passing into spasms; and the jaw is one of the earliest parts affected. The strychnine-tetanus, on the other hand, develops rapidly, and begins in the back of the neck or the extremities, or a general convulsion at once seizes the whole body. Moreover, the jaw is usually last affected, and its muscles relax first. The strychnine-relaxation is complete, or rarely almost complete; while in traumatic tetanus there is permanent muscular rigidity, and no complete remission of spasm. Fatal strychnine-tetanus is an affair of minutes, or at most of half a dozen hours; while traumatic tetanus never kills within twelve hours, and generally extends over a few days. In strychnine-poisoning the most trivial movement or touch will set up a convulsion; while during the spasms firm grasping of the hands, and hard rubbing of the rigid muscles, will often afford grateful relief. This distinction is not marked in traumatic tetanus. An analysis of the urine by Stass's method, which often affords certain indications of strychnine, and may be roughly made in a few minutes, will, in doubtful cases, at once remove all uncertainty as to the nature of the disease.

PROGNOSIS.—The prognosis is at all times doubtful. The patient's life cannot be considered safe till the convulsions clearly exhibit marked decrease, both in frequency and intensity.

TREATMENT.—Should the convulsions have already set in, the use of the stomach-pump is out of the question. An emetic of warm water with mustard, or ammonium carbonate, should be given without a moment's delay. The free use of chloroform not only alleviates the pain and allays the spasms, but allows time for the elimination of the poison from the system, and the administration of remedies. The patient should be touched as little as possible, and absolute quiet observed in the sick-room. Excellent results have ensued from the administration of large doses of potassium bromide; even half an ounce in one dose has been given. The gastric irritation produced by such large doses of the bromide as are necessary militates, however, against its use. Chloral-hydrate in full doses, and the anæsthetic administration of chloroform-vapour, are the best remedies. The introduction into the stomach of a diluted solution of potassium permanganate has

been recommended. Nitrite of amyl has been advised by some. Strychnine-poisoning more often ends fatally either from the lateness with which remedies are applied, or their non-application, than from their inefficient character.

THOMAS STEVENSON.

STUPE (*stupa*, tow).—A synonym for a fomentation. See FOMENTATION.

STUPOR (Lat.).—SYNON.: Fr. *Stupeur*; Ger. *Stupor*; *Stumpfsinn*.—A partial loss of consciousness. See CONSCIOUSNESS, Disorders of.

STUTTERING.—See STAMMERING.

STY (Sax. *steigan*, to rise up).—SYNON.: *Hordolum*; Fr. *Compère-Loriot*; *Orgelet*; Ger. *Gerstenkorn*.—This term is applied to a boil on the margin of the eyelid. A sty does not differ in any essential respect from a boil in any other situation, but it is usually of small size, and commences in the follicle of an eyelash. See BOILS.

STYPTICS (στυψω, I contract, make firm).

DEFINITION.—Styptics are substances which arrest superficial bleeding by their local astringent action. They include many of the drugs which are known as internal astringents or hæmostatics.

ENUMERATION.—The chief styptics are: Cold; Pressure and other mechanical measures; the Actual Cautery; Perchloride of Iron; Alum; Tannic Acid and Hamamelis; Acetate of Lead; Nitrate of Silver; Extract of supra-renal bodies; and Collodion.

ACTIONS AND USES.—Styptics act in various ways, and assist the natural modes of arrest, such as retraction and contraction of vessels and coagulation of the blood. Some arrest hæmorrhage by aiding the rapid formation of a coagulum, others by contracting the smaller vessels, and a third class by condensing and coagulating the albuminous tissues around the vessels. Some styptic substances act in more than one direction.

All mechanical measures which promote the coagulation of the blood will obviously tend to arrest bleeding by plugging the wounded vessels. Cotton-wool and similar materials are useful for this purpose, and a pledget of cotton-wool soaked in the liquid extract of Hamamelis (Hazeline) is a well-known remedy for bleeding piles. Collodium, also, acts mechanically by exerting pressure over the surface and thus preventing the blood from issuing. Alum, acetate of lead, and perchloride of iron cause coagulation of the blood. The actual cautery at a dull heat seals up small bleeding points. Pressure to the surface, ice or cold sponges, cause the vessels to contract, and thus prevent the blood-flow in superficial hæmorrhage. Tannic acid and substances containing it act more directly on the tissues around the vessels, and also assist in the formation of blood-clot.

The use of styptics is usually limited to the general oozing which may follow the application of leeches or the infliction of small wounds by accident or for surgical purposes. In some cases of *post-partum* hæmorrhage the injection of hot water into the vagina and uterus has a powerful action in arresting hæmorrhage, probably due to reflex contraction of the vessels and of the uterus itself (see PUERPERAL DISEASES). As adjuvants to the action of styptics all measures which lessen the local blood-pressure, such as complete quiescence, cold

food, elevation of a wounded limb, and the like, are of the first importance; and internal medication by ergot and other drugs which contract the blood-vessels is also indicated. If the oozing is severe and continuous, recourse must be finally had to surgical interference by local ligation of vessels when practicable.

FREDERICK WILLCOCKS.

SUBCUTANEOUS INJECTION.—See HYPODERMIC MEDICATION.

SUBCUTANEOUS NODULES.—See RHEUMATISM, Acute, p. 1412.

SUBPHRENIC ABSCESS.—See p. 1620.

SUBSULTUS TENDINUM (Lat.).—A twitching movement of the tendons, caused by sudden momentary contractions of the muscles to which they belong. This is especially apt to show itself in the tendons about the wrist in the later stages of many low fevers. It manifests itself principally in states of great prostration, and is often associated with delirium or other signs of cerebral irritation. See TYPHUS FEVER.

SUCCUSSION (*succussio*, a shaking).—A method of physical examination, which consists in suddenly shaking the trunk of the patient, so that certain sensations or sounds may be elicited, which are indicative of the presence of gas and fluid in a hollow space, such as the pleural cavity. See PHYSICAL EXAMINATION; and p. 1588.

SUDAMINA.—See MILIARIA; and SUDORIPAROUS GLANDS, Diseases of.

SUDORIFICS (*sudor*, sweat; and *facio*, I make).—A synonym for diaphoretics. See DIAPHORETICS.

SUDORIPAROUS GLANDS, Diseases of.—

The sweat-glands are liable to diseases of structure and of function, which are often difficult to elucidate on account of the close relation of the sweat-coils and ducts with the epithelium of the integument and sebaceous glands.

DISEASES OF STRUCTURE.—As a result of the position of the sweat-coils which lie deep in the cutis, and the length and tortuous course of their ducts through the cutis and epidermis, the sweat-glands are very liable to cystic dilatations. These dilatations may be due simply to excessive action of the sweat-coil, or perhaps more usually to some obstruction in the course of the duct. The obstruction may be of temporary character only, or due to chronic forms of dermatitis; in the latter case the cystic changes become permanent and often of peculiar character.

It is rare to find the coil itself suffering from cystic change, but the duct readily becomes distended in its course both through the cutis and through the epithelium.

Hidrocystoma is one of the most characteristic of the diseases caused by sweat-cysts. It occurs most commonly on the face, appearing as a multiple eruption of small thick-walled hemispherical vesicles, without obvious signs of inflammation, which last for some time and disappear without breaking. They are larger and the eruption more extensive in hot weather or during sweating due to hard work. The disease has been specially noted in the case of

washerwomen, cooks, and others liable to hyperidrosis. The cyst in this case appears to occur in the subepithelial portion of the duct.

The terms *Miliaria*, *Miliaria crystallina*, *Crystallina*, *Sudamina*, have been applied to small collections of clear fluid occurring in the upper layers of the epithelium and in relation to the course of the sweat-duct through the epithelium. They occur in cases of profuse sweating, as in fevers, and are characterised by their perfectly clear contents and non-inflammatory characters to the naked eye.

Miliaria rubra, *Miliaria papulosa* are names given to the lesions occurring in the eruption known as *prickly heat*. The evidence is not perfect, but it seems most probable that the lesion consists of a dilatation of the sweat-duct in the lower horny layers and below this level. Inflammation of the epidermis and the immediately underlying cutis occurs, and the profuse, intensely irritable eruption occurring even in this country in hot weather, but much more commonly in the tropics, results. The eruption affects large areas of the body, and as the result of scratching is apt to lead on to various secondary eruptions of eczematous or presenting purulent characters.

Miliaria vesiculosa, *Miliaria alba* (see STROPHULUS) are names occasionally applied to sweat-cyst eruptions with less violent symptoms. When the cyst occurs in the sweat-pore and involves the horny layer mainly or altogether, its contents may become firm and epithelial cells collect in it, and small concretions may be at length produced (see MILIUM). It is very rare to find actual *suppuration* in a sweat-gland, but certain small abscesses in such positions as the axilla and perinæum are said to arise in this way. A rare condition of multiple suppurative necrosis of sweat-glands has been described (*Spiradenitis vel Hidroadenitis disseminata suppurativa*, Dubreuilh, Unna, and others).

Adenoma of the sweat-glands (*Spiradenoma*; *Syringadenoma*) is described, but the cases recorded are few and the histological descriptions not very convincing. *Carcinoma* commencing in the sweat-glands has been more definitely described, and there can be little doubt that some of the unusual forms of superficial carcinoma are actually sweat-gland cancers. They may appear as single growths, but in some cases a multiple eruption of small malignant tumours with ulceration has been traced to the coil-glands. At present the diagnosis of this type of malignant disease cannot be made with certainty apart from careful histological study.

DISEASES OF FUNCTION.—Hyperidrosis.—Excessive sweating occurs as a concomitant of pyrexia, and associated with conditions of severe debility and collapse. It is also found to occur in cases of nervous and emotional disturbance. In such cases it is usually general, and as a rule requires no special treatment. Precautions should be taken to cleanse the surface of the skin by sponging or baths, so as to prevent decomposition of the sweat especially in the axillæ, groins and flexures, and the development of troublesome dermatitis. Occasionally cases are seen of localised sweating, such as on one side of the face or one side of the body. These cases are often due to injury or disease of the nervous system, but may be excited reflexly by the stimulation of sensory nerves. Thus in some cases mastication—for example, eating anything

sour, such as an apple—invariably produces profuse sweating on one side of the face.

More trouble and suffering is experienced by patients who suffer from hyperidrosis in ordinary health. The whole body may be affected, but usually certain portions sweat most profusely, especially the scalp, face, axilla, groin and perinæum, and the hands and feet. The sweating may produce a moist surface or be so profuse as to roll in drops and streams from the affected parts. In the case of a young lady, whenever she concentrates attention on her hands, e.g. by taking up a needle to sew, the hands become moist, and in a few seconds the sweat pours off them so as to render work impossible. In many patients the condition is chronic, so that the usually affected parts are in a constant state of unpleasant wetness. In such cases the epithelium of the palms and soles becomes sodden, thickened, and corrugated, the skin on the feet becomes tender, easily chafed, and blistered, and in all situations may become reddened and inflamed, thus producing eruptions resembling intertrigo and eczema. The liability of such a surface to become infected with bacteria is great, and consequently pustular eruptions in the axilla and about the genitals arise; but most troublesome is the condition of *Bromidrosis*, produced by the growth of bacteria, which emit foul odours. The ordinary white staphylococcus of the skin is capable of producing the unpleasant odour of butyric acid, and is the organism mainly concerned in the production of bromidrosis, but in all probability other organisms may also produce this effect. In the case of persons careless about personal cleanliness this condition is common, but even in others the greatest care as to cleanliness is necessary to prevent the pungent odour arising to such an extent as to render their presence in a room at once noticeable and unpleasant.

TREATMENT.—In cases of hyperidrosis care should be taken to secure as good a state of health as possible whenever debility is ascertained. In many cases a condition of feeble circulation through the extremities, with cold and congested hands and feet, is noticeable. For such patients suitable clothing, exercise, massage, and bathing are of importance, and the administration of remedies acting on the vascular system, such as digitalis, strophanthus or strychnine, is of great service. In a few cases the carefully regulated administration of ergot has done much good. The internal administration of sulphur is said to produce very good results. Where the nervous system is at fault, especially in cases of hemi-hyperidrosis, specific remedies have proved of little service; in functional nervous disorders, especially of hysterical character, general treatment is often very valuable in checking and curing hyperidrosis. Belladonna and atropine, though frequently administered, are very disappointing in their results, and only cause much inconvenience and even danger.

In localised hyperidrosis the utmost precautions as to cleanliness must be observed, so as to prevent bromidrosis, or to cure this most offensive condition if it has occurred. The affected parts, especially the feet, should be carefully washed with warm water and soap once, twice, or even more frequently daily, and thoroughly dried. They should then be disinfected as thoroughly as possible—for this purpose solutions of boric acid are very effectual—and then dusted over with the fine powder of boric acid either pure or diluted as may be necessary with

oxide of zinc and talc-powder. Other antiseptics or astringents used for this purpose and found to be of service are carbolic acid, salicylic acid, solutions of formalin, trichloroacetic acid, alcohol, quinine, chromic acid, alum, and tannin. When much walking has to be done the feet are very liable to suffer injury readily, to chafe, and become badly affected. In addition to cleanliness, a lubricant for the skin is then necessary. Benzoated lard containing from 2 or 3 per cent. of salicylic acid rubbed into the stockings or feet regularly is one of the best precautionary measures in such circumstances.

Anidrosis.—Absence or diminution of sweat occurs in various degrees. It may be symptomatic as in fevers and diabetes, due to congenital defects such as ichthyosis even in slight degree, or the result of skin-diseases such as scleroderma, leprosy, &c. Persons in good health frequently sweat very slightly, even on exertion.

TREATMENT.—In some cases warm baths followed by shampooing are of service; but, as a rule, general 'tonic' treatment is indicated, with special reference to any defect of the health which may be discovered.

Chromidrosis.—Cases of coloured sweating are rare, and due to several causes. Such cases should be investigated with care so that imposture is not overlooked.

The word is perhaps especially used in connection with a peculiar and unexplained group of cases in which a pigmented material varying in colour from sepia to a tint of blue is deposited from the sweat on the forehead, cheeks, and sides of the nose, more rarely on other parts of the body. It occurs sometimes in large quantity, and may appear as a scaly or powdery deposit on the surface.

The condition occurs nearly always in females, and is usually associated with marked neurotic phenomena, but its exact aetiology is unknown.

Red sweat occasionally occurs in the axillæ and groin and elsewhere; blue tints are also noted; both are due to the presence of bacterial secretions. Green sweat occurs in copper-workers and others who have absorbed the metal in food. See p. 209.

Hæmidrosis or bloody sweat is very rare, and occurring among hysterical women should be investigated with scepticism to ascertain the exact source of the blood, and to avoid overlooking an artificial eruption. It has apparently occurred in infants, and perhaps in hæmophilic persons and others a certain amount of blood-pigment may occur in the sweat.

Phosphorescent sweat has been noted.

Uridrosis.—Urea is said to be occasionally excreted by the skin in more than the usual minute traces, and to be actually deposited on the surface as fine powder or scales. It has recently been ascertained that the sweat contains excretory matter, toxic on injection into the lower animals, and increased on muscular exertion.

See also **DYSIDROSIS**.

JAMES GALLOWAY.

SUFFOCATION (*suffoco*, I stifle).—SYNON. : Fr. *Suffocation*; Ger. *Erstickung*.

DEFINITION.—The term 'suffocation' is sometimes employed synonymously with asphyxia. In the strict medico-legal sense it signifies asphyxia induced by obstruction of the respiration otherwise than by direct pressure on the neck (hanging, strangulation), or submersion (drowning).

ÆTIOLOGY.—Death by suffocation is usually the result either of accident or of homicide, rarely of suicide.

Suicide by suffocation is indeed not unknown. Cases of suicide by immurement in a box or trunk, or by thrusting a pad or other obstruction down the throat, have been reported; and it has been averred that slaves, both in ancient and modern times, have committed suicide by rolling the tongue back into the pharynx.

Accidental suffocation is very common in diseases causing occlusion of the air-passages; it may be due to the impaction of pieces of food or other obstacles in the pharynx; to the entry of foreign bodies into the larynx, as a seed, coin, or food, in cases of bulbar or general paralysis, or matters vomited during a state of insensibility; to mechanical pressure on the chest and abdomen, as in crowds, or in falls of earth or heavy bodies; to various diseases preventing the expansion of the lungs; to diseases of the lungs themselves; or to obstruction of the pulmonary circulation. Suffocation of new-born children by smothering under bed-clothes, non-removal of maternal envelopes, or overlying, may happen from carelessness as well as from intent. See **OVERLYING**.

Homicidal suffocation is resorted to chiefly in infants, or in the case of persons feeble and infirm, or rendered powerless or insensible by intoxication or narcotics. Closure of the mouth and nostrils by the hands, or obstruction of the mouth and nostrils by a pillow, mattress, or the like, perhaps combined with pressure on the chest, is the method usually adopted. Formerly suffocation by mechanical pressure on the chest was a judicial punishment—the *peine forte et dure*.

SYMPTOMS AND SIGNS.—The mode of death, and the general *post-mortem* indications, are those of asphyxia (see **ASPHYXIA**). The special indications of suffocation, and the way in which it has been brought about, may be evident from the place where the body is found, and its surroundings; or foreign bodies, or disease obstructing the air-passages or respiratory mechanism, may be clearly evident on *post-mortem* dissection; or there may be marks of violence and indications of pressure on the chest, flattening of the nose, &c., pointing to homicidal violence. The absence of marks of constriction of the neck excludes strangulation and hanging.

But in the absence of all such indications as have been enumerated above—and they may all be absent, especially in cases of infanticide—the question is whether any trustworthy conclusion can be formed as to asphyxia by suffocation.

The condition of the lungs is of especial importance in this relation. The lungs may be congested, or pale, or congested only posteriorly; but the surface is often uneven, owing to an emphysematous condition of some of the superficial air-cells; and in particular the lung looks as if it had been sprinkled with minute drops of a dark purple fluid. These spots, not much larger than a pin's head, are known as 'Tardieu's spots,' and are due to minute capillary extravasations under the pleura. They are not, however, confined to the surface of the lungs, but are found also in considerable numbers on the thymus gland, the base of the great vessels, under the parietal pleura, and also under the pericranium. Tardieu, who first called special attention to these spots, considered them absolutely diagnostic of

death by suffocation, as distinguished from other modes of asphyxia. But numerous other observations have shown that this cannot be accepted as correct, inasmuch as similar extravasations have been found in cases of hanging, strangulation, drowning, and deaths from cerebral injuries. It seems, however, fairly well established that they occur most frequently, and in largest number, in suffocation, especially in infants. Their formation depends on excessive vascular tension during the asphyxiating process. Similar spots have been found in the lungs of still-born foetuses, conditioned by obstruction of the placental circulation; and in the lungs of new-born children, perishing from other causes, extravasations of a like nature have been observed. It would, therefore, be unsafe to rely absolutely on Tardieu's spots as indications of suffocation, though, in the absence of other causes of death, and in presence of these spots in large numbers and in clusters, the opinion of death by suffocation would be fairly justified.

TREATMENT.—The treatment of impending suffocation is that of asphyxia. *See* ARTIFICIAL RESPIRATION; ASPHYXIA; and RESUSCITATION. D. FERRIER.

SUFFOCATIVE BREAST-PANG.—A synonym for angina pectoris. *See* ANGINA PECTORIS.

SUFFUSION (*suffundo*, I pour down).—The process or the result of the unnatural pouring out of a fluid into the tissues; closely analogous to effusion and extravasation. *See* EXTRAVASATION.

SUICIDAL INSANITY.—*See* INSANITY; and MELANCHOLIA.

SULPHONALISM.—**DEFINITION.**—A group of symptoms said to be occasioned by the prolonged administration of sulphonal.

Sulphonal is one of the favourite hypnotics in institutions for the insane. Being tasteless and odourless, fairly soluble in such vehicles as hot soups, not productive of digestive derangements, and obtainable without medical prescription, it has become very generally known to the laity; and thus a 'sulphonal-habit' has been met with which demands recognition and treatment.

Similar habits have been noted in the case of antipyrine and trional.

SYMPTOMS.—The prominent symptoms noted in the recorded cases of poisoning by sulphonal are vomiting, abdominal discomfort, gastro-intestinal disturbance, obstinate constipation, cephalalgia, tinnitus aurium, drowsiness, inco-ordination, diminution of reflex excitability, puffiness of the eyelids, ptosis, and more or less mental, physical, and cardiac weakness. The urine, which decomposes slowly, becomes of a port-wine or Burgundy-red colour, possibly with coincident evidences of renal inflammation. This peculiar colour of the renal excretion, which is said to be due to the presence of non-ferrous hæmatin or hæmatoporphyrin (*see* SPECTROSCOPE IN MEDICINE; and HÆMATOPORPHYRINURIA), resulting from extensive disorganisation of hæmoglobin, is thus of clinical significance, serving as a means of recognising the abuse of the drug, and to be regarded as an index for its immediate temporary discontinuance. Of rarer occurrence is a papular, measly, erythematous, or scarlatiniform eruption. Possibly many of the phenomena noted in the recorded cases were symptoms of the disease

from which the patient was suffering, and ought not to have been accredited to the drug. *See* HABITS; and DRUG-ERUPTIONS.

Antipyrine may give rise to various affections of the skin (p. 421); trional produces but few after-effects, though its continued use leads to mental and moral deterioration.

TREATMENT.—The treatment of sulphonalism consists in suspending the administration of the sulphonal until all unfavourable symptoms have disappeared; and by the use of diuretics, promoting the elimination of the drug, at least in cases where it has been taken in large doses. If it should have to be taken regularly for a lengthened period, the use of it should be occasionally intermitted for a few days, another suitable hypnotic being substituted temporarily.

JOHN HAROLD.

SULPHUR-WATERS.—*See* MINERAL WATERS.

SUNBURN.—**DEFINITION.**—Under this designation are included the superficial local effects of exposure to the sun's rays.

Such effects vary greatly with the susceptibility of the individual, the surrounding circumstances and conditions, and the duration or repetition of the exposure. They may be comparatively slight and transient, as is commonly the case; or they may be very severe, and involve considerable and prolonged suffering, and sometimes serious constitutional disturbance.

ÆTIOLOGY.—Delicate, thin-skinned, fair-complexioned subjects are most liable to suffer from sunburn; the thick-skinned and swarthy much less so. The rays reflected from snow or ice (especially through rarefied atmosphere), as experienced by Alpine climbers, or from water-surface (sea or river), are most hurtful. Exposure to the rays from powerful electric arc-lights may be followed by effects more or less similar to those resulting from exposure to the solar rays (Tyndall, Hewetson).

There is evidence to suggest, if not to prove, that sunburn is due not to the heat-rays alone, but rather to other influences, especially to those of the violet and ultra-violet rays. A beam of sunlight on striking the skin is, to a great extent, filtered of its red and calorific rays by the epithelial layer, so leaving the violet and ultra-violet rays free to begin their work on the blood and the vaso-motor nerves lying in their path. Active and inflammatory changes of very varying intensity follow, and, not infrequently, local necrosis as well—effects almost identical with those produced by Röntgen Rays, with which, physiologically, these rays of short vibration, especially the reflected rays, may in some way be associated.

SIGNS AND SYMPTOMS.—First, in the slight, familiar cases, there is redness of the skin from vascular congestion (*erythema solare*), accompanied by tingling and sense of heat. This is followed by desquamation and subsequent pigmentation, either uniformly diffused ('tanning') or especially localised in spots, giving rise to freckles (*ephelis*). All these subside more or less speedily, and are the only points to be noted. Pigmentation may occur without previous noticeable erythema, as is evidenced by the 'browning' of patients who have wintered at Davos or other Alpine resorts, or who have been otherwise exposed to snow-reflected sun-rays.

Secondly, in the more severe cases, the erythema is followed by vesication, and more or less deeply

extending inflammation of the skin. An erysipematoid condition may ensue, with œdema and considerable swelling of the part, severe pain, and great tenderness. This may be accompanied by constitutional disturbance.

Thirdly, in the worst cases, happily very rare, sloughing and ulceration to greater or less extent occurs. See HEAT, Effects of Severe and Extreme; and SUNSTROKE.

TREATMENT.—In the slighter cases of sunburn little or no treatment is required. Simple powdering with starch, oxide of zinc, bismuth or boric acid, or dabbing with elder-flower or rose-water, with a little eau-de-Cologne or solution of acetate of ammonium, may be pleasant. The more severe cases must be treated on general principles. Lead-lotion with morphine or cocaine will relieve the heat and pain. The solution of subacetate of lead with glycerine and elder-flower or rose-water is also a good application.

It is, however, almost more important to prevent than to cure. The preventive treatment obviously consists in protecting exposed parts from the deleterious effects of the sun's rays. When sunshades, veils, and masks are inconvenient—especially in cases of Alpine climbers and others—the writer recommends that the face, arms, and other exposed parts should be painted over with the 'grease paints' used by actors for 'making up.' Brown is the best colour, but flesh colour will serve. Pigments mixed with glycerine of starch may be used. For sunshades, veils, and similar protections, brown or some shade of red or yellow is the best colour. The 'tanning' of the skin, which naturally takes place, is the best protective against suffering from subsequent exposure.

In those who have been year by year subject to 'sunburn,' the skin becomes dry and wrinkled, from the effect upon the sudoriparous and sebaceous follicles, as well as browned by pigmentation. Such result may be to some extent prevented by the ancient practice of oiling the skin.

For the freckling and browning of the skin after sunburn, lotions of perchloride of mercury or boric acid, with emulsion of almonds, and glycerine, or juice of cucumber, are extensively used with more or less beneficial effect.

ROBERT L. BOWLES.

SUNSTROKE.—**SYNON.** : Insolation ; Heat-stroke ; Fr. *Coup de Soleil* ; Ger. *Sonnenstich*.

DEFINITION.—Certain pathological conditions resulting from exposure to solar or artificial heat.

Three well-marked varieties of sunstroke are recognised, namely: (1) Exhaustion and failure of the heart's action in *syncope*; (2) A condition like shock, in which the nerve-centres, and especially the *respiratory*, are affected, causing rapid failure of the respiration and circulation; and (3) Intense *pyrexia*, due to vaso-motor paralysis, and to the nerve-centres being over-stimulated and then exhausted by the action of heat on the body generally.

ÆTIOLOGY AND PATHOLOGY.—These morbid conditions being due to heat alone, are not peculiar to any country or climate, and are liable to occur wherever persons are exposed under any circumstances to great heat, whether solar or artificial. Soldiers marching or fighting, when oppressed by weight of clothing and accoutrements, are apt to suffer either from simple heat-exhaustion, or from that form of insolation which results from direct action

of the sun on the head and neck. This is common enough in India during the hot season, in other tropical countries, and in America; and is not unknown in Europe or even in England during the heat-of summer. Workmen, artificers, stokers, and other persons employed in heated rooms, hospitals, barracks, tents, and even ships, especially in hot climates, are liable to suffer from heat-exhaustion, which may pass into the dangerous condition of fever or insolation.

But the most frequent cases are those which occur in houses, barracks, tents, ships, by night or in the day, away from the direct solar rays. A form of disease sometimes described as 'ardent fever' in India is this condition supervening on the ordinary phenomena of ephemeral fever. It seems pretty well understood that heat alone is the effective cause of the so-called sunstroke.

A dry air, such as that of North India, with hot winds, is much better tolerated at a high temperature, than the damp atmosphere of Bengal at a much lower one; for the dry hot air favours evaporation from the surface, and thus keeps the body cool, while in the damp, heavy atmosphere the natural cooling function is almost in abeyance. Defective ventilation, stillness of air, crowded habitations, and close valleys and ravines are conditions in which heat-shock and heat-fever are prone to occur. Vigorous, healthy persons of moderately spare frame, possessing sound viscera, and leading temperate and regular lives, can tolerate a great amount of heat, in an otherwise pure atmosphere, and are much less liable to suffer from it than those whose environment is unfavourable and power of resistance impaired. Acclimatisation has also considerable influence in conferring toleration. New arrivals are more prone to suffer than those who have become accustomed to the climate. It is well known that the native can bear an amount of sun on his shorn head, neck, and half-naked body with indifference, if not pleasure, that would very soon prostrate a European. But to a temperature of the air rising above a certain standard, all succumb; and the natives of India suffer like others, and die in numbers every year from *loomarna* or 'hot-wind stroke.'

The exact amount and duration of toleration of a high temperature depend to a great extent, therefore, on the vigour of constitution and the present state of health. The natural refrigerating powers of the body, when in health, are such as to enable men to support very high temperatures, much above that of the normal state of the body. Disordered health, dissipation, over-fatigue, anything in fact that depresses nerve-power, reduces the normal physiological capacity, and consequently renders a man more liable to succumb. Persons who habitually indulge in alcohol to excess are peculiarly vulnerable by heat, and fevers by disturbing the thermotactic arrangements of the body are apt to predispose to the injurious effects of high temperatures.

ANATOMICAL CHARACTERS.—In cases where death has taken place suddenly, as from *shock*, there is no very remarkable *post-mortem* appearance. The heart may be found firmly contracted, but not always so—it may be flaccid. The lungs and the brain and its membranes may be somewhat congested, but not invariably. As in cases of shock, the venous trunks, specially those of the abdomen and the right side of the heart, may be too full of blood, and the pulmonary vessels overloaded; but

the lungs in some cases are blanched from absence of blood, owing to contraction of the pulmonary arterioles. The blood itself is dark and grumous, and is found effused in patches of ecchymosis, indeed rendering the body more or less livid; the coagulability of the blood is also impaired, and it is wanting in oxygen.

In death from ordinary cases of *thermic fever*, the lungs and respiratory organs are often deeply congested; the heart is firmly contracted from coagulation of myosin; the whole venous system is engorged; and the body even before death is marked by petechial patches, or extensive ecchymoses of a livid appearance. The blood is generally more fluid and grumous than natural; its coagulability is impaired; and it is acid in reaction. The red corpuscles, though generally presenting no abnormal change, are somewhat crenated, and have less tendency to form rouleaux than in health; and the quantity of oxygen is much diminished. The body for some time after death retains a high temperature; when first opened, the viscera feel pungently hot, and the incisions drip dark blood. *Rigor mortis* comes on very rapidly, from early coagulation of myosin.

The brain and membranes may be found congested, and in some cases there may be evidence of meningitis. Serous effusions into the ventricles, or hæmorrhage into the brain-substance, may have occurred, and are not improbable in the congested condition sometimes existing in the head; but the cause of death is asphyxia, not apoplexy, and the most important changes are found in connection with the thoracic viscera.

SYMPTOMS.—(1) Syncopal form.—**SYNON.** : Heat-exhaustion.—Simple exhaustion and syncope may occur under great fatigue or over-exertion, or depression from any cause, during exposure to a high temperature. There is depression of nerve-force, and prostration of muscular power; the skin is pale, cold, and moist; and the pulse is quick and feeble. Death may occur rapidly in the state of collapse from failure of the heart. Complete recovery is frequent.

(2) Asphyxial form.—**SYNON.** : Sunstroke proper.—Asphyxia and apnoea may come on very rapidly, after certain premonitory symptoms of depression and weakness, though occasionally without prodromata, during exposure, especially of the head and spine, to the direct rays of a powerful sun, when the atmosphere is much heated, and the nervous energy has been depressed by over-fatigue, dissipation, or illness. The brain and nerve-centres, especially the respiratory, are overwhelmed by the sudden elevation of temperature, and respiration and circulation fail, the failure of the latter being probably due to the inhibitory influence of the vagus. When death takes place, as it does sometimes very suddenly, during great excitement or exertion, it has been attributed to rapid *ante-mortem* coagulation of the cardiac myosin, which takes place at a temperature of 113° F. or a little below that level in cases of over-fatigue. This, however, though it may occur occasionally, is generally a *post-mortem* change, the heart's action being brought to a close by the heat; in the same manner as it has been shown by Claude Bernard and Lauder Brunton that the effect of high temperature on animals is first to accelerate and finally to stop the heart, and especially the ventricles, in a state of contraction. Recovery is frequently com-

plete, but sometimes tedious, and in many cases imperfect, ending in serious impairment of health or intellect, indicative of structural changes caused in the nerve-centres. The symptoms of this form of insolation, the real *coup de soleil*, are those of sudden and violent injury to the nerve-centres—unconsciousness, cold skin, feeble pulse, and all the symptoms of depression; death resulting from rapid failure of the respiration and circulation. If not fatal, reaction may result in a variety of conditions indicative of the injury done to the cerebro-spinal system.

(3) Hyperpyrexial form.—**SYNON.** : Heat-fever.—An intense state of fever, the result of the influence of heat on the nerve-centres, and through them on the vaso-motor nerves, and of the heating of the body generally, by the direct action of either artificial or solar heat, may occur, quite independently of the immediate operation of the sun's rays. It comes on as frequently at night, or in the shade, as in the day or in the sunshine, especially in persons who are exhausted by fatigue, overcrowding, depression from any cause, such as dissipation, want of rest, present or recent illness, and notably when the atmosphere is impure from overcrowding or want of cubic space.

The temperature of the body rises to 108° , 110° F., or higher. The brain, medulla, and cord, the nerve-centres generally, and especially the respiratory, suffer from over-stimulation, followed by exhaustion. Respiration and circulation fail; there is dyspnoea, with hurried, gasping breathing; great restlessness; thirst; fever; frequent micturition; and a pungent burning heat of skin, which is sometimes dry, sometimes moist. The pulse varies; in some it is full and laboured, in others quick and jerking. The face, head, and neck are congested to lividity, and the carotid pulsations are visible. The pupils, contracted at first, may dilate widely before death. Delirium with convulsions, frequently epileptiform in character, coma, relaxation of the sphincters, and suppression of urine, come on, and are frequently the precursors of death. Partial recovery not infrequently occurs, to be followed by relapse and death; or secondary consequences result in meningitis or cerebral changes, which may destroy life or intellect at a later period, or permanently compromise the whole health or that of some important function.

The premonitory symptoms of this form of insolation often manifest themselves for some hours, and it may be days, before they culminate in the dangerous condition just described. These premonitory symptoms are general malaise; disordered alvine or other secretions; profuse and frequent micturition; restlessness; sleeplessness, and apprehension of impending evil; hurried and shallow breathing; præcordial anxiety; giddiness and headache; occasionally nausea or vomiting; thirst and anorexia; and feverishness, which soon amounts to a pungent heat of skin with high temperature. These symptoms vary considerably, but they point to a profoundly disturbed state of the cerebro-spinal nerve-centres, and to pathological changes in the organs or structures whose functions have been so gravely disturbed. Recovery is often incomplete; or is followed by permanent impairment of health, and generally by intolerance of heat and exposure to the sun.

TERMINATIONS.—The mortality from sunstroke is about 45 to 50 per cent.; but of those who re-

cover many are permanently injured, and remain invalids for the remainder of life, which is often shortened by the changes induced. There may be some weakness, due to obscure structural change in the cerebrum, or to a chronic form of meningitis which affects the sufferer in various degrees of intensity; or epilepsy, impairment of memory, great nervous irritability, headache, insanity, partial paraplegia, partial or complete blindness, and extreme intolerance of heat—especially of the sun's heat—rendering the person utterly incapable of serving or living in a hot climate, or of enduring exposure to the sun. Or the case may gradually end in complete fatuity, insanity, or meningitis, which accounts for the intense cephalic pain; or, in a lesser degree, in disordered innervation and derangement of the functions generally, thus seriously compromising the general health. See INSANITY IN SPECIAL DISEASES.

Prophylaxis.—The protection of the nervous centres from the direct rays of the sun by a suitable helmet and spinal pad is a matter of prime importance in tropical countries. Light, easy clothing is also necessary. The avoidance of all the conditions which have been indicated as predisposing or auxiliary causes, especially of alcohol and over-fatigue, is also of great consequence. In houses, barracks, and hospitals plenty of space and the freest possible ventilation should be adopted. Ravines and hollows ought to be avoided. Soldiers should be marched in the early morning by short stages, in open order, and frequent halts for rest and refreshment made.

TREATMENT.—(1) In cases of *simple exhaustion* mild treatment is all that is needed. Removal to a cooler locality, the cold douche (but not too much prolonged), or the administration of stimulants may be beneficial. Tight or oppressive clothing should be removed, and the patient treated as in syncope from other causes. See RESUSCITATION.

Rest, and freedom from exposure to over-exertion, fatigue, or great heat, should afterwards be enjoined.

(2) In that form of sunstroke where the person is *struck down* suddenly by a hot sun, the patient should be removed into the shade. Here a douche of cold water must be allowed to fall in a stream on the head and body, from a pump (or as in India from the mussack, or other similar contrivance), the object being twofold—to reduce the temperature of the over-heated centres, and to rouse them into action. During the assault on the White House picket in the second Burmese war, numbers of men were struck down by the direct action of the sun during the month of April. They were laid out perfectly unconscious, in their red coats and stocks (worn in 1852), but were revived by the cold douche freely applied by the mussack over the head and body. In some cases flagellation with a broom was added; and all recovered with the exception of two cases, both of which had been bled on the spot where they fell. Mustard plasters and purgative enemata may also be useful.

If recovery be imperfect, and followed by any indication of injury to the nerve-centres, or by the supervention of meningitis, other treatment may be necessary, according to the indications. Much exposure to the sun should be carefully guarded against; and unless recovery be complete and rapid, the sufferer should be removed to a cooler climate, the most perfect rest and tranquillity of mind and

body enjoined, and the greatest care observed with regard to extreme moderation in the use of stimulants.

(3) In the cases of *thermic fever*, heat being the essential cause of the disease, the object is to reduce the temperature of the body as quickly as possible, and before tissue-changes have resulted. As the hyperpyrexia is due not only to the direct operation of heat, but to fever set up, remedies such as may influence this disturbed condition have been suggested. The results have appeared in some cases to justify the theory, and the hypodermic injection of quinine has been considered to produce good results.

Bleeding has now happily been almost abandoned. The congested livid surface, coma, and stertor, which formerly suggested it, are not now so treated. There are cases in which it may still be practised with advantage; but they are the exception and not the rule. In cases where venesection has appeared at first to give relief and mitigate the symptoms, the improvement has been often transient, and followed by relapse into a more dangerous condition, which has terminated fatally. At the same time no absolute rule can be laid down in this disease with reference to the abstraction of blood; and it is quite possible that greater immediate danger to life may exist in an over-distended right heart than in the loss of an amount of blood which might have tided the patient over that state of peril. Each case must in this respect be treated on its merits. The treatment generally consists in the judicious use of cold, either by affusion or by the application of ice to the surface; the reduction of the temperature being watched with a thermometer in the axilla, mouth, or rectum.

Care should be taken not to continue the cold application too long, as danger arises from depressing the temperature below the normal standard. The bowels should be relieved; and quinine may be given internally or in the form of hypodermic injection.

In the epileptiform convulsions that occur so frequently, the inhalation of chloroform or of ether may be of benefit, but their administration must be carefully watched. The earliest and most severe symptoms having subsided, the febrile condition that follows is treated on ordinary principles—salines and aperients being given, but not to the extent of depressing the patient. The diet must be carefully regulated, and of the blandest and most nourishing nature.

As improvement progresses, other symptoms may supervene, pointing to intracranial mischief. Where they are indicative of meningitis, iodide of potassium and counter-irritants may be used with advantage. Removal to a cooler climate is essential. As a general rule, it is desirable that the sufferer should not, for a long period at least, return to a hot or tropical climate; and he should be guarded against all undue exposure to heat, work, or mental anxiety of any kind.

The sequelæ of sunstroke are frequently from such causes most distressing, rendering the patient a source of suffering to himself and of anxiety to his friends.

The less severe symptoms—those, probably, indicative of the slighter forms of meningitis, or of lesions of the brain or nervous system—occasionally pass away after protracted residence in a cool climate; but they not infrequently also cause much

suffering, and shorten life. As they point to permanently disturbed, if not structurally injured, cerebro-spinal centres, the treatment required is as varied as the symptoms presented.

JOSEPH FAYRER.

KENNETH MACLEOD.

SUPPOSITORY (*suppono*, I place below).—

SYNON.: Fr. *Suppositoire*; Ger. *Stuhlzäpfchen*.—A suppository is a solid mass, which is introduced through the anus into the rectum for certain therapeutic purposes. The material of which it is made should be capable either of being dissolved, or of melting at the temperature to which it is exposed in the rectum.

Suppositories may be divided into *simple, medicated, and nutrient*. Simple suppositories may be exemplified by pieces of soap or tallow-candle, which are in popular use as aperients. The British Pharmacopœia now recognises seven suppositories, one of which may be regarded as simple, the remainder being medicated. The latter are made up with oil of theobroma, in one instance white beeswax also being used. Each suppository is cast into a mould of a conical or other suitable shape, so as to facilitate its introduction into the bowel. It may be well to give a list of these official preparations, with the proportions of their active ingredients, as follows:—

S. Glycerini=70 per cent. by weight of Glycerine with gelatin and water. *S. Belladonnæ*=Alcoholic Extract gr. 1½. *S. Plumbi & Opio*=Acetate of Lead gr. 3, Opium gr. 1. *S. Acidi Carbolic*=Carbolic Acid gr. 1. *S. Iodoformi*=Iodoform gr. 3. *S. Acidi Tannici*=Tannic Acid gr. 3. *S. Morphina*=Hydrochloride of Morphine gr. 4.

Besides these official suppositories, others are often prepared and used of different strengths from those mentioned, or containing other ingredients; and the practitioner may employ many drugs in this way with advantage, according to his own judgment.

Nutrient suppositories usually consist of lean meat that has been finely minced and peptonised.

APPLICATION.—A suppository must be introduced well into the rectum beyond the sphincter ani. At first this should be done by the practitioner, or by a competent nurse; but subsequently most patients learn to use suppositories for themselves without any difficulty. The suppository should be oiled, and passed in gradually and gently with a screwing movement and without any undue force. It may be necessary to keep the finger applied for a moment over the anal aperture, until the tendency to expulsive action on the part of the rectum has subsided.

USES.—A suppository may be used for the following purposes: (1) As a mere aperient, by exciting the expulsive action of the bowel through local irritation, which also has a reflex effect upon the intestine above. (2) On the other hand, to subdue excessive action of the bowel, and thus check diarrhoea. (3) To bring medicinal agents into contact with the rectum in a suitable form, in order to affect some local disease. Astringents and antiseptics are thus used. (4) To influence adjacent organs, the active ingredients of the suppository being absorbed. For instance, a morphine suppository will often produce a marked effect upon the

bladder and generative organs. (5) To produce the general effects of a drug upon the system, particularly when it cannot be given by the mouth. This of course occurs only after its absorption through the mucous membrane, and may be exemplified by the effects of morphine or mercury. (6) To nourish patients when rectal feeding is called for.

SUPRARENAL GLANDS, Diseases of.—

In the article on Addison's disease (p. 23) the well-known association between its characteristic symptoms and morbid changes in the suprarenal glands was described. Addison's disease is much the most important morbid entity connected with these glands, and is essentially a chronic disease; occasionally acute symptoms rapidly develop and prove fatal to a patient known to be the subject of the disease. In some instances similar acute toxic symptoms, collapse, vomiting, and convulsions suddenly occur, and lead to the death of a person previously in fair health and not suspected of any disease, and after death lesions such as hæmorrhage, suppuration, or tubercle are found in the suprarenal glands. These are cases of toxæmia due to acute suprarenal insufficiency, and are extremely difficult to recognise during life.

Morbid changes of various kinds are frequently found after death in the suprarenal glands, but as a rule without any corresponding clinical manifestations. This latency may be due to the lesion being localised, and thus leaving a sufficient amount of suprarenal substance in a state of functional activity, or possibly to compensatory hyperplasia of accessory adrenal bodies. Extreme want of development of the suprarenal glands is sometimes associated with anencephaly, while almost complete atrophy has been found in some instances of Addison's disease. The glands may undergo various forms of degeneration; amyloid change, chiefly in the cortex, is not very rare; cloudy swelling and fatty change are commonly seen in toxic and infective conditions. Gummata and syphilitic fibrosis are very rare, but tuberculosis without any associated signs of Addison's disease is fairly common. Small suppurative foci may occur in pyæmia or infective endocarditis, but primary abscess-formation is almost a pathological curiosity.

Hæmorrhage into the substance of the medulla of the suprarenal glands occurs under a number of conditions, such as traumatism more especially in infants during difficult delivery, in chronic venous engorgement (for example, in asphyxia) and in some septic and toxic conditions, such as purpura. Small hæmorrhages, as a result of embolism in pyæmia, may occur in the cortex, while considerable extravasation may take place into the substance of primary suprarenal tumours.

H. D. ROLLESTON.

SUPRARENAL GLANDS, Tumours of.—

Tumours of the suprarenal glands may be innocent or malignant.

Innocent Tumours.—Adenomata formed of encapsuled masses of suprarenal cells are not uncommon; they usually arise from the cortex, are

multiple and small in size, in a condition of fatty change, and are only discovered after death. Occasionally large adenomata occur; they may be bilateral and tend to degenerate and soften down in the centre into a hæmorrhagic pseudocyst; in rare instances they are palpable during life. Exceptionally other simple growths, fibroma, lymphangioma, angioma, &c., have been met with. Cysts are very infrequent, and when met with are generally due to secondary changes of a degenerative nature in an adenoma. Isolated cases of hydatid and dermoid cysts have been reported. Innocent tumours of the suprarenal glands are of little or no clinical interest.

Malignant Tumours may be primary or secondary. Secondary malignant tumours may be either carcinomatous or sarcomatous. As a rule no special symptoms can be correlated with their presence, but occasionally some of the phenomena of Addison's disease occur. Primary malignant disease is rare. It may be either sarcoma or carcinoma, and in undoubted instances of malignant disease, as proved by the presence of secondary growths, difficulty may arise, from the anomalous microscopic appearances, in settling the precise nature of the neoplasm. It is met with rather more commonly in males, and most often in early middle-age. The growth forms a large tumour with a special tendency to caseate and soften; a hæmorrhagic cavity in the centre may thus result. During life it usually resembles a tumour of the kidney; in fact a correct diagnosis is always difficult and often impossible. The clinical features are not those typical of Addison's disease, but in some instances of exceptional nature overgrowth of hair and pigmentation have been met with. Weakness and debility are marked features, and the disease runs a rapid course. It may imitate not only renal growths but tumours of the liver or pancreas, and retroperitoneal sarcomata. The prognosis is that of malignant disease elsewhere, but is worse from the difficulty of complete removal before metastatic infection has taken place. Removal is of course the only treatment; it has been successful in a few instances.

The accessory suprarenal glands may be the site of new-growth. When accessory suprarenal glands become embedded in the substance of the kidney, a not uncommon event, they are spoken of as suprarenal 'rests.' Primary malignant disease may start in these 'rests' and give rise to malignant disease in, though not strictly speaking of, the kidney. Though of great pathological interest, these cases of malignant disease of suprarenal 'rests' in the kidney are clinically indistinguishable from primary malignant growths of the kidney (p. 836).

SYCOSIS. — SYNON. : *Acne Mentagra*; Fr. *Sycose*; Ger. *Barbfinne*.

DEFINITION. — A form of folliculitis confined to the hairy parts of the face.

SYMPTOMS. — Sycosis is a somewhat rare disease. It usually begins on the chin or upper lip,

where it is apt to occupy the central part; it is, however, by no means limited to these regions. A similar form of follicular inflammation may attack the whiskers, eyebrows, and eyelashes. In an early stage the eruption consists of acneiform papules or nodules, which sooner or later develop into pustules with a hair passing through the centre of each. As the number of these increases, the skin assumes a swollen and thickened appearance. In acute cases the infiltration and thickening are considerable, in more chronic forms but slight. In most instances the hairs are not very easily extracted, unless the free supuration extends deep down into the follicle. In cases of long standing the inflammation leads to a complete destruction of the sac, and the formation of scars and permanently bald spots. In all the pustular forms staphylococci are present.

DIAGNOSIS. — In the diagnosis of this disease the following points should be especially remembered: (1) It is chiefly met with in adult males. (2) It generally attacks in the first instance the upper lip or chin, but occasionally the region of the whisker. (3) It is strictly confined to the hairy parts. (4) The papules, nodules, or pustules each have a hair running through them. (5) It is usually a very chronic affection, spreading slowly and lasting for months or years. (6) The inflammation is attended by pain and burning sensations, but by little or no itching. (7) Ultimately, the disease, if not cured, leads to permanently bald patches of scar-like tissue; this, however, is prevented by steady epilation.

Sycosis may be easily confounded with impetigo of the chin, especially when the latter is confined to the hairy parts. Impetigo has, however, a much more rapid development than sycosis, and the discharge and crusts are much more abundant. Moreover, the disease is not usually limited to the hairy parts, as is always the case with sycosis. Another disease for which sycosis may be mistaken is tinea tonsurans of the beard. The chief points of distinction are that tinea generally begins with a circinate patch, and spreads much more rapidly than does sycosis. Subsequently, when supuration is free, the differential diagnosis is more difficult. The hairs, however, in tinea barbæ present some of the characters of tinea tonsurans of the scalp, and their microscopical examination will readily determine the presence of the fungus.

TREATMENT. — There is only one way of curing chronic sycosis with any certainty, and that is by steady epilation. The best plan is first to remove all crusts with oil and fomentations. This softens the skin and renders epilation less painful. The hair of the part affected should be cut rather short with a pair of scissors, and then, wherever a yellow point is seen, the hair passing through its centre should be pulled out with a pair of depilatory forceps. These hairs usually come out with their sheaths attached. When this has been done over a limited area, dilute citrine ointment should be applied. At first, epilation should be confined to extracting those hairs only which pass through pustules; afterwards, however, the parts affected should be completely denuded of hairs by the extraction of a small number every day. This process is attended by considerable pain, and the patience and perseverance of the patient are severely taxed. The young hairs which appear

some time after epilation should be also removed, and the process continued until the skin is healthy; after each removal mild citrine ointment may be applied. Perseverance in this plan of treatment invariably cures the disease; whereas, if left to itself, it leads in the end to the total destruction of the hair and the formation of permanent cicatrices. The process of cure, however, is extremely tedious. ROBERT LIVEING.

SYMPATHETIC (σύν, with; and πάθος, suffering).—This term implies that a part or organ suffers 'in sympathy' with some other part or organ which is diseased. Most disorders which are popularly supposed to arise in this way admit of an obvious pathological explanation. Thus, a morbid process may extend directly along blood-vessels, lymphatics, or other tissues; a morbid agent may be conveyed by the blood or lymph from one part to another; or a secondary lesion may be produced by direct nervous influence. The 'sympathetic' disturbance may be indicated by pain or other subjective sensations; by functional derangements, as of secretions or actions; or by positive organic lesions. The occurrence of such phenomena in corresponding parts on both sides of the body, when a disease has commenced on one side, is sometimes very curious, especially as regards organic lesions. As illustrative of the associations in which the word 'sympathetic' is employed may be mentioned *sympathetic pain*, *sympathetic headache*, *sympathetic ophthalmitis*, *sympathetic vomiting*, *sympathetic bubo*.

FREDERICK T. ROBERTS.

SYMPATHETIC SYSTEM, Disorders of.—

SYNON.: Fr. *Maladies du Nerf Sympathique*; Ger. *Krankheiten der Nervus Sympathicus*.

1. Diseases of the Sympathetic System in connection with the Cerebro-spinal System.

(a) *The Spinal Cord*.—Lesions of the cervical region of the spinal cord may be associated with extreme contraction or extreme dilatation of the pupil on one or both sides; with increased heat and redness, or the reverse, of the head and neck; with perverted respiration; with perverted action of the heart; and possibly with an exalted febrile heat of the whole body (see SPINAL CORD, Diseases of, pp. 1526, 1527). Though we regard these phenomena as signs of disease in this particular portion of the spinal cord, it is none the less true that such phenomena are due to altered activities in those root-portions of the sympathetic system of nerves which take origin in, or traverse, this region of the cord. This is shown by the fact that similar sets of symptoms are produced by injuries, tumours, or other morbid processes implicating the cervical sympathetic itself.

It will be well to cite here the phenomena commonly associated with *irritation* or *paralysis* of the cervical sympathetic nerve, on account of their importance as diagnostic indications.

The signs dependent upon *irritation* of the cervical sympathetic in its *oculo-pupillary* fibres are—dilatation of the corresponding pupil with sluggish action, widening of the palpebral fissure, prominence of the eyeball, feeling of tension in the eye (as in glaucoma), and a scanty secretion of tears and mucus; while in its *vaso-motor* fibres they are

—lowering of temperature of the side of the face and head, diminution of sensibility, an absence of perspiration, with (if the irritation continue) a tendency to slight atrophy of the side of the face. The signs of *paralysis* of the cervical sympathetic in its two sets of fibres are the direct opposites of those just cited, so that it is not necessary to enumerate them. Of these signs, those dependent upon irritation or paralysis of the oculo-pupillary fibres are usually much more constant and durable than those which depend upon irritation or paralysis of the vaso-motor fibres. These latter signs are, for reasons at present unknown, often transitory and fitful. Sometimes there may be signs of paralysis of oculo-pupillary fibres co-existing with signs of irritation of the vaso-motor fibres, or *vice versa*. It has been definitely determined that injury in the lower cervical region of the cord, and as far down as the level of the *second dorsal* nerve, may give rise to the oculo-pupillary signs of one or other kind; and, on the other hand, that damage to the cord in these same parts, or as low down as the *fourth dorsal* nerve, may give rise to the above-mentioned vaso-motor signs.

When the *dorsal* and *lumbar* regions of the spinal cord are the seats of disease, other groups of phenomena will doubtless, after a time, be more fully recognised as results of irritation or paralysis of those roots of the sympathetic system which have their origin in or which traverse these particular regions of the spinal cord. It is therefore important to bear in mind the place of origin and the distribution of the different internal branches from the lateral sympathetic cords, which proceed from these regions to the different glandular organs or hollow viscera. Diarrhœa, sickness, obstinate constipation, sexual defects, and bladder-troubles, are among the symptoms which have such an origin, as well as undue heat or unnatural coldness of the lower extremities. See also PAIN IN VISCERAL DISEASE, p. 1137.

(b) *The Brain*.—In different portions of the brain some of the signs and symptoms of disease are also referable to direct or indirect interference with the functions of the sympathetic system of nerves; but they constitute (apart from vaso-motor derangements, which are very common and often well-marked) far less distinctive aggregates, owing to the fact that the sympathetic system of nerves has a much less extensive relation with the brain than with the spinal cord. In this direction, however, and in connection especially with diseases of the medulla oblongata, we have to bear in mind the occasional occurrence of diabetes, polyuria, or albuminuria; also of some cardiac and respiratory derangements.

2. *Diseases of the Sympathetic System proper*.—Where disease exists in the ganglia of the sympathetic system itself, or where it involves them, we get groups of symptoms more clearly referable to disordered activity of this system of nerves alone.

These will differ in particular cases, according to the nature of the morbid change, that is, according as it is destructive or merely irritative; and according to the number or particular combinations of ganglia and fibres affected. The ganglia and related plexuses may either be affected by *intrinsic* morbid processes, or may be variously involved from without by morbid processes having their origin in adjacent tissues.

(a) *Intrinsic changes*.—The principal intrinsic morbid processes which have been hitherto recognised *post mortem* in some one or other of the sympathetic ganglia are: Pigmentary degeneration; irritable overgrowth of their connective tissues, with or without secondary atrophy (the ganglia in such cases being either smaller or larger than natural); a highly congested and varicose state of their blood-vessels; effusion of blood into their substance; new-growths starting from their substance; and fatty degeneration, with more or less marked atrophy.

(b) *Extrinsic disease*.—Different parts of the sympathetic system may become involved in new-growths or in abscesses; or they may be simply pressed upon by aneurysmal or other tumours occurring in contiguous regions of the body.

Besides the pathological conditions already enumerated, it should be borne in mind that in altered blood-states, whether cachectic or of febrile origin, we commonly have, and especially in the latter class of cases, a greatly perverted activity of the sympathetic system throughout the body—as evidenced by the altered vascular conditions, increased tissue-metamorphosis and body-heat, together with the perverted activity of most of the glands in the body. *See* FEVER.

The principal disorders apart from those due to structural diseases of the cord and of the brain, in which derangements of the sympathetic system of nerves exist, or are believed to exist, and in which such derangements have either wholly or in part a causal relationship to the principal signs and symptoms of the respective disorders, are as follows: Epilepsy; convulsions; megrim (hemicrania); ophthalmic goitre; unilateral hyperidrosis; progressive facial hemiatrophy; angina pectoris; asthma; diabetes mellitus; Addison's disease; astralgia; enteralgia (colic); neuralgia cœliaca; neuralgia spermatica; and uterine neuralgia. Among the affections more doubtfully or partially related to disorders of the sympathetic, we may mention glaucoma; neuro-retinitis; progressive muscular atrophy; pseudo-hypertrophic paralysis; locomotor ataxy; diphtheritic paralysis; and so-called 'reflex paralysis.' In the special articles on most of the first group of affections, the reader will find references to the dependence of such conditions upon disorders in one or other department of the sympathetic system.

H. CHARLTON BASTIAN.

SYNCOPE (συνκοπή, a faint).—*SYNON.*: Fainting; *Fr.* *Syncope*; *Ger.* *Ohnmacht*.

DEFINITION.—A state of suspended animation, due to sudden failure of the action of the heart.

ÆTIOLOGY.—Syncope may be due to any condition which interferes with the action of the heart, whether acting (a) *intrinsically*; (b) through the *nervous system*; (c) through the *blood*; (d) through *gravity*; (e) through *more than one* of these channels.

(a) Syncope due to *intrinsic* cardiac conditions is chiefly seen in structural diseases of the heart, especially fatty degeneration. Among other instances of this class of causes may be mentioned compression of the heart by morbid growths, products or processes, or by tight articles of dress; excessive heat, whether natural or artificial, as in sunstroke and the hot bath; lightning; and certain drugs and poisons, including alcohol, chloroform, tobacco and ptomaines.

(b) The most common *nervous* causes of fainting are of an emotional kind, such as fear, grief or joy, in nervous or hysterical individuals. Sudden injury of the central nervous system, as in concussion of the brain, has partly the same effect. In a larger number of instances the nervous causes of syncope act reflexly, and are to be found in conditions of the stomach or intestines (corrosive and irritant poisoning, heavy meals, indigestion, worms, scybala); in the liver, kidneys, or uterus (injuries, calculi, displacements); or in the limbs or body generally (painful injuries or operations of any kind). Spasm of the arteries, due to reflex irritation of the vaso-motor nerves (cold and certain poisons), also may lead to syncope.

(c) Of the causes of syncope connected with the *blood* the most frequent is hæmorrhage. Chronic anæmia, as seen in idiopathic and pernicious cases, or accompanying chronic constitutional diseases, is a common cause of serious fainting.

(d) Syncope produced by disturbances of the force of *gravity* in the circulation is familiar in the faintness which may occur when patients first assume the erect posture in convalescence.

(e) In a large number of instances, the causes of syncope are *complex*. Thus in fainting from hunger and exhaustion the heart is depressed directly, as well as through the nervous system, and through the blood; and in severe injuries, such as railway accidents, there may be a combination of depressing causes, including fear and grief, hæmorrhage, painful lesions, cerebral concussion and shock. Fainting in a hot impure atmosphere appears to be due partly to the direct effect of heat upon the circulation; partly to the interference with respiration, and indirectly with the heart, produced by carbonic acid and other excrementitious products.

In the subject of any of the predisposing causes of syncope already mentioned, the occurrence of fainting may be determined by a very slight exciting circumstance. It is thus that in serious cardiac disease, in hysterical subjects, in delicate overgrown adolescents, and in persons suffering from anæmia, the smallest excitement or exertion, unpleasant sights or smells, or exposure to an impure and heated atmosphere, may cause faintness, and in some instances even fatal syncope.

ANATOMICAL CHARACTERS.—In death by syncope the organs generally are found to be anæmic; and this condition is particularly marked if hæmorrhage have occurred. The state of the heart varies with the cause of its failure, the ventricles being either dilated and full of blood, or empty, as in cases of fatal hæmorrhage, and possibly contracted.

SYMPTOMS.—A syncopal attack presents three stages, namely: (1) *a period preceding loss of consciousness*; (2) *a condition characterised by insensibility*; (3) *a period of recovery* from the fainting state.

(1) A person about to faint is observed to turn suddenly pale; he staggers, or leans against the nearest support; the eyes roll upwards, while the eyelids tremble or close; and consciousness and general sensibility are impaired. The pulse fails, generally becoming weak, small, and frequent; in other instances it is infrequent, irregular, or intermittent. The respiration is irregular and feeble. Vomiting may possibly occur.

At the same time the patient has a number of subjective sensations. The most urgent of these are a sense of 'sinking' in the epigastrium, a feeling

of increasing debility, 'giddiness' in the head, and a tendency to fall. Vision becomes indistinct; the hearing is usually impaired or 'distant'—rarely more acute; and tinnitus may be present. Mentally there is a rapid fading of sensory impressions and of consciousness; while in cases of fainting from loss of blood there may be restlessness, agitation and delirium.

(2) The first stage is now complete. Thereupon the muscles are relaxed; the patient falls; and consciousness is completely lost. The surface is pallid, and possibly cold and clammy; the eyes are closed, and the pupils dilated; the pulse and the cardiac impulse and sounds are nearly or quite imperceptible; respiration is indistinguishable, or occurs as occasional weak sighs; and the vital functions generally appear to have ceased. In syncope due to severe hæmorrhage general convulsions may occur.

(3) The third stage, that of recovery from syncope, is marked by signs of gradually returning consciousness, increase of the pulse at the wrist, and restoration of the functions generally. Usually the first evidences of improvement are slight movements of the hands and features, and deep sighing. The pulse now becomes more distinct; the cardiac impulse and sounds are found to be stronger; the senses of sight and hearing can be excited; colour returns to the face and lips, and warmth to the extremities; and intelligence is gradually restored. Very shortly the patient may be able to resume the sitting posture; and the seizure is at an end.

DURATION AND TERMINATIONS.—The duration of the several stages of syncope varies greatly, from a few seconds even to hours. In many instances the attack does not pass beyond the first stage; in rarer cases insensibility may last for an almost indefinite time. The most common termination is in recovery; but syncope is one of the ordinary modes of death, especially in hæmorrhage and structural disease of the heart. In nervous subjects partial recovery may be quickly followed by return of the fainting state, the patient being said to 'pass out of one faint into another.' Where referable to structural disease or to hysteria, syncope may recur at intervals for many years.

PATHOLOGY.—Syncope consists essentially in sudden failure of the action of the heart, originating in any of the causes already mentioned, and leading to a condition of acute general anæmia. Whether from some affection of the heart itself, from sudden interference with the nervous impulses which regulate its action, from failure in the supply of blood within its cavities and in its substance, or from a combination of such causes, the systolic contraction suddenly becomes short and feeble. If there has been no hæmorrhage nor vaso-motor paralysis, the cardiac cavities are distended with blood, and further embarrassed; if profuse hæmorrhage has occurred, the heart is deprived of blood, and thus of the natural stimulus to contraction, and the same effect will follow failure of compensation for the hydrostatic effect of gravity by vaso-motor activity. In either case fatal cardiac paralysis may be the result, unless the contractile power of the heart be speedily restored.

The acute general anæmia that results specially affects the central nervous system. In the erect posture the circulation fails first within the cerebrum, producing rapid disturbance and then loss of

consciousness, and depressing the centres that regulate the heart, vessels, respiration and stomach. The general muscular paralysis which occurs at the same time is also partly of central origin. Similarly, the convulsions which may ensue in cases of hæmorrhage are probably referable to sudden circulatory disturbance within the basal ganglia and cord. The senses are further obscured by anæmia of their special organs; the heart is more depressed by failure of the coronary circulation; the paralysis of the muscles is increased by want of blood within them; and the temperature falls from failure of the circulation generally.

In non-fatal cases recovery naturally occurs by restoration of the cerebral circulation in the recumbent position, and consequent stimulation of the cardiac centre. Other circumstances favour the recovery of the general circulation, such as the relaxation of the arteries, and the partial restoration of the respiratory and other functions, which quickly re-act upon the heart.

DIAGNOSIS.—Syncope has to be diagnosed from other conditions or events in which loss of consciousness is a prominent symptom; and chiefly from epilepsy, apoplexy from any cause, vertigo, concussion of the brain, shock, and poisoning of many kinds, including suffocation by certain gases and drunkenness. From such of these conditions as commence in the brain, and from poisoning (unless the poisons act as cardiac depressants) syncope is distinguished by the characters of the pulse. Certain cases of hysterical faints, which are strictly cerebral, not cardiac, in origin, are also readily diagnosed by the pulse, which may be of good volume and force. The diagnosis of shock, which usually produces a degree of syncope, is described in the article on that subject. *See SHOCK.*

PROGNOSIS.—The prognosis of syncope depends upon its cause, and upon the practicability of immediate treatment. If due to structural disease of the organs of circulation, or to serious injury, acute poisoning, excessive heat, or profuse hæmorrhage, the case may be serious, and prove fatal unless treatment be instantly applied. If, on the other hand, the cause of the faintness lie in an excitable nervous system, momentarily depressed by some passing emotional disturbance, by impurity of the atmosphere, or by digestive derangement, the attack may be pronounced free from danger, although liable to recur.

TREATMENT.—In the treatment of syncope two indications are equally urgent, namely, removal of the cause of faintness, and restoration of the action of the heart. If the patient should not have fallen, he must be immediately laid flat on his back; the atmosphere should be rendered as pure as possible, by throwing open the windows and doors, or by removing the patient to the open air, and preventing people from crowding round him; at the same time the dress should be loosened about the neck, chest, and abdomen. If hæmorrhage have occurred, means must be taken to stop it. Cardiac stimulants, direct or indirect, must then be employed. The most available and powerful of these is alcohol, in the form of brandy or other spirit; and this may be given either pure or in water, and in an amount which will vary with the individual case, as estimated by the immediate result. *Sal volatile*, ether and *eau-de-Cologne* are equally valuable cardiac stimulants, if available. Should the patient be

unable to swallow, these substances, as well as warm liquids, must be given at once as enemata; or ether may be injected under the skin. Ammonium carbonate ('smelling salts') and other strong smelling compounds, including perfumes, fanning, cold douches, and refrigerant applications of eau-de-Cologne or other spirit to the temples and hands, are other ready means of exciting the heart reflexly through the nervous centres. If these measures fail after a fair trial, the condition of the patient is very serious. The systematic employment of efficient means of resuscitation must then be had recourse to, including friction of the limbs and trunk, inversion, galvanisation of the region of the heart, and even transfusion. See RESUSCITATION (A); and ANÆSTHETICS.

In cases ending favourably the patient must be careful not to assume the erect position too hastily, or to undergo much exertion, until some rest has been obtained, or some stimulant or nourishment administered.

The occurrence of syncope is sometimes the first indication of the existence of serious structural disease of the heart or other organ; and it should suggest a careful examination of the patient, and the adoption of measures likely to prevent the return of such a dangerous event, that is, the avoidance of the principal causes already mentioned, as far as they are avoidable.

SYNOVIAL MEMBRANES, Diseases of.—
See JOINTS, Diseases of.

SYPHILIS (etymology uncertain. Perhaps from 'Syphilus,' the title of a Latin poem by Fracastorius, published in 1530; or from *σῦς*, a swine; and *φιλέω*, I love).—SYNON.: Vulg., Pox; Fr. *Vérole*; Ger. *Lustseuche*.

DEFINITION.—An infective general disease; communicable by contact of a specific virus with a breach of surface, or by hereditary transmission. Syphilis is characterised by a period of incubation; and, in the acquired form, by certain changes at the seat of inoculation, and in the proximate lymphatic glands. These are followed by an eruption on the skin and mucous membrane, and sometimes by lesions of the deeper tissues and viscera.

ÆTIOLOGY.—The various phenomena of syphilis are caused by the absorption of an infective virus into the blood, and its diffusion throughout the body. It is now generally agreed that the 'soft chancre' is a local affection, quite distinct from syphilis. From this point of view the present account is written. The local suppurating sore or soft chancre is described elsewhere. See VENEREAL SORE.

One attack of syphilis usually affords protection against a second throughout the lifetime of the individual, but in rare instances, as in other infectious diseases, the same person suffers more than once.

Besides being capable of contaminating others by inoculation, the subject of acquired syphilis is also liable, during a variable period, to transmit the disease to the offspring; but whether the inherited form of syphilis be further transmissible to the next generation remains doubtful.

PATHOLOGY AND ANATOMICAL CHARACTERS.—The essential nature of the syphilitic virus is unknown. Various micro-organisms have been reported from time to time as found exclusively in the

blood or tissues of syphilitic persons; but evidence is still wanting to settle the question, one difficulty in the way being that syphilis seems not to be communicable to the lower animals. Syphilis resembles the exanthemata in having a period of incubation, in the development of a rash, and in the protection commonly afforded by one attack against subsequent infection; but it differs from them in its long duration and liability to relapse, and in not being communicable through the atmosphere.

When the syphilitic poison has been absorbed, it multiplies until the whole body becomes pervaded by it. How soon this absorption takes place is not known. Excision of the initial lesion has been extensively practised with the object of preventing further development of the disease; but the evidence at present available, from observation as well as from experiment, indicates that by the time the initial lesion appears the virus has already passed far beyond its boundaries.

The changes produced by syphilis have been well described by Gowers as depending partly on a process of inflammation, and partly on a process of tissue-formation. These two are generally combined in varying degree according to the lesion and according to the stage of the disease. The inflammatory element is most marked in the early eruptions of the skin and mucous membrane, and is also probably the chief factor in causing certain early functional disorders of the internal organs. The process of new growth is most distinct in what is called the *syphiloma* or *gumma*. The change begins by the production of a small-celled growth, which at first resembles granulation-tissue—hence named by Virchow *granuloma*—but which soon shows a marked tendency to vascular occlusion and consequent degeneration.

The new-growth may develop in a diffused infiltrating form, or in the circumscribed masses known as *gummata*. Any of the structures of the body may be attacked, most commonly, perhaps, the skin and subcutaneous connective tissue; but bone, muscle, glands, and the viscera are all liable to suffer, the change probably beginning in the blood-vessels of the affected part; and although the morbid growth is essentially the same wherever it is developed, it presents differences in appearance, as well as in behaviour, according to the tissue or organ affected, and the period at which it occurs.

A *gumma*, which is the most characteristic product of syphilis, in its typical form appears as a yellowish, tough, somewhat elastic, and sharply defined mass, which is often caseous in the middle. *Gummata* vary greatly, from a mere granule to the size of a duck's egg, or even larger still. They may be single or multiple, and are frequently associated with the diffused form of growth, which after a time becomes converted into a tough fibrous tissue; this finally contracts, and thus puckers, deforms, and often seriously affects the functions of the organ in which it grows.

Besides the specific effects of syphilis there are certain degenerative diseases of the nervous system, notably *tabes dorsalis* and *general paralysis*, which are thought to be chiefly caused by syphilis, as there is evidence of that disease in over 70 per cent. of such cases.

A syphilitic origin has also been claimed by certain authors for a variety of maladies connected with malnutrition—rickets, for example—when they occur in the children or even grandchildren of syphilitic

parents. There is considerable difference of opinion concerning these so-called 'para-syphilitic' affections, but all are agreed that *amyloid disease* may be caused by syphilis, especially, but not exclusively, in cases where long-standing suppuration has been present. See AMYLOID DISEASE.

INFECTION.—Before considering the different ways in which syphilis may be propagated, it is necessary to mention the vehicles of the virus. These are—

1. The discharge of the initial lesion.
2. The secretions of all the secondary eruptive lesions, especially of those known as mucous patches or tubercles.
3. The blood, during the earlier stages of the disease.

The secretions of the later or tertiary affections have not been proved to be inoculable, nor have the physiological secretions of a syphilitic person—for example, the saliva, sweat, tears, milk—unless mixed with the secretions of syphilitic lesions or with the blood, even though the disease be in an early stage. The semen, however, though apparently not inoculable in the ordinary way, seems to be capable of infecting the ovum during a period which probably varies considerably in different cases. Lastly, the secretions of other diseases from which a syphilitic person may be suffering are not always infectious. This at least is the case with regard to vaccinia; for healthy children have often been vaccinated from syphilitic subjects without contracting syphilis.

Modes of Communication.—The sources of infection being so numerous, it is easy to understand that the modes of communication must be so also. They may be described under three heads: (1) *direct communication*; (2) *mediate communication*; and (3) *hereditary transmission*.

1. *Direct communication.*—In the great majority of cases syphilis is imparted during sexual intercourse—first, because the genital organs are the most frequent seat of the infectious lesions; secondly, because the delicate epithelium of these organs is especially liable to abrasion during coitus. Hence syphilis is usually described as a venereal disease, but it should always be remembered that it is not necessarily so. Wherever the poison comes in contact with a broken surface, it may thence be absorbed, and general infection follow. Instances of syphilis being conveyed quite independently of sexual relations are unfortunately far from rare. Perhaps the most frequent form of extra-genital infection is that of a nurse by a syphilitic child, or of a child by its nurse. The disease may also be spread by kissing, syphilitic lesions being very common about the lips and in the mouth. Again, medical men and midwives not infrequently contract syphilis by attending diseased women in labour; and surgeons by examining or operating upon syphilitic persons.

2. *Mediate communication.*—When syphilis is communicated indirectly, the medium may be of almost endless variety. Articles which are used in common by different persons, such as spoons, drinking-vessels, and pipes, are perhaps the commonest media; implements used in various trades—shaving and glass-blowing, for example—have also acted in the same way. Again, through the performance of tattooing, cupping, catheterisation of the Eustachian tube, and other operations, chiefly by ignorant persons and quacks, the disease has been communicated; and it has also happened during vaccination; but now that calf-lymph only is used there should be

no danger whatever. The mode of communication in which the foetus is believed to be the medium between husband and wife is noticed under the next heading.

3. *Hereditary transmission.*—Our knowledge concerning the transmission of syphilis from parent to child is still imperfect in many respects, and the questions involved are much too wide for discussion in this article. Consequently, no attempt will be made to do more than state briefly the points which are generally accepted, and the usual course of events when syphilitic persons become parents.

In the first place, it must be remembered that a child born of syphilitic parents does not always show signs of the disease. When the infection of both parents is recent, however, the offspring almost invariably suffers, and this is also the case if the mother alone be diseased. In such circumstances abortion or premature birth is common. When the father alone is syphilitic, and especially if his disease be not of recent date, both mother and child may escape.

Syphilitic infection of the offspring may be either germinal, from one or both of the parents, or in the case of the mother it may be post-conceptual, that is, through the placental circulation.

When a previously healthy woman bears a syphilitic child to a syphilitic father, and shows no sign of infection herself, she is supposed to have gained immunity from her foetus *in utero*. The most weighty evidence in support of the view that she is really immune is that known as Colles's Law, namely, that the mother of a syphilitic child, although she may suckle it, does not acquire syphilis from it after its birth.

But if in similar circumstances the mother suffers afterwards from some of the later signs of syphilis without having previously shown any of the earlier signs of acquired syphilis, she is supposed to have been infected by her foetus *in utero* (syphilis by conception, or *choc en retour*).

Again, if, as more rarely happens, a syphilitic woman bears a child which shows no sign of infection, the child is supposed to have gained immunity through the placental circulation. But neither in the case of the mother nor of the child is it known how long the immunity lasts.

On the supposition that syphilis is due to a microbe, these phenomena have been explained as follows: Under normal conditions, as is well known, there is no direct communication between the blood-vessels of the placenta and those of the foetus, and if those conditions remain unaltered in spite of the syphilitic infection of mother or foetus, then whichever of the two is healthy will by diffusion of the toxins gain immunity from the other. On the other hand, if the continuity of the walls of the blood-vessels be broken—which is probably most frequently the case in syphilis—then the micro-organisms themselves will pass, and mother or child, as the case may be, will be infected by the other.

If the mother acquire syphilis during the earlier months of pregnancy the child commonly suffers. If she be infected after the seventh month it is said that the child may escape, but further and more exact evidence on this point is required.

The duration of the transmissive power varies in different cases, according to the influence of treatment and other circumstances; but the liability to transmit syphilis to the offspring seems to last longer than the ability to infect by inoculation. In the

absence of treatment the child or children born nearest to the date of parental infection usually suffer more severely than those born later, which gradually suffer less and less severely as time goes on; but this is not always the case. A healthy child may be born under the influence of mercury; but a subsequent one may be tainted, if treatment have been discontinued, and the disease have resumed activity. There are also periods of quiescence in syphilis independent of treatment, during which apparently healthy children are sometimes born.

SYMPTOMS.—The symptoms of syphilis are usually divided into three groups—*primary, secondary, and tertiary*. And although such division is really artificial, it is useful to retain these terms for the purpose of description; but it must be borne in mind that in the great majority of cases tertiary symptoms do not occur at all; that they sometimes appear quite early in the disease; and that the signs proper to all three periods may be present at the same time.

1. Primary Syphilis.—A patient is said to be suffering from primary syphilis as long as the initial manifestation, and the accompanying glandular enlargement, remain the sole signs of the disease.

When the syphilitic poison, unminged with any irritating matter, has been inoculated, the abrasion quickly heals, and no further change is observed for three or four weeks. This interval is called the period of *incubation*. Its average length, judging from cases of experimental inoculation, is about twenty-four days; but it may perhaps be as short as ten, or as long as forty-six days, or even longer still. After this a small red spot appears at the site of inoculation, which is called the *initial or primary lesion*. Later, this may assume one of several forms, and is then often termed a hard or infecting chancre, and sometimes, incorrectly, a Hunterian chancre. The initial lesion presents certain differences in appearance, according to its position, and the presence or absence of irritation. Its chief characteristic is the presence of induration at its base; and the aspect of the sore is much affected by the degree to which this hardness is developed. Sometimes the lesion is observed as a hard desquamating papule; sometimes as a prominent ulcer, having a hard well-defined base and thickened adherent margins; but most commonly as an erosion or shallow ulcer, with an amount of induration which varies much in different cases, and which is liable to be overlooked unless care be taken. Sometimes the induration develops in a thin layer, like a piece of parchment, or even paper; hence the term ‘*parchment sore*’ often applied to this form of the initial lesion. In rare instances, especially in women, induration appears to be absent. The secretion is thin, scanty, non-purulent; and though not readily inoculable on the bearer, it has nevertheless been successfully inoculated in certain cases during the primary stage. The syphilitic primary lesion is usually *single*, contrasting strongly in this respect with the local venereal sore, in which multiplicity is the rule. It is also indolent, often painless, tends to disappear spontaneously, and does not necessarily leave a scar.

The *seat* of the initial lesion is most frequently the genital organs, but, as has already been stated, absorption of the poison may occur in any situation where a breach of surface exists. Consequently the initial lesion may be found on any part of the body, as about the lips or mouth in children, on the breast

in nurses, or on the hand or finger in the case of doctors and midwives.

If, as frequently happens in practice, irritating matter of any kind have been inoculated as well as the syphilitic poison, the course of events will vary according to the nature of the irritant. For example, if the pus of the local chancre have also been absorbed, the incubation-period of syphilis will be occupied by the course of the suppurating sore, which may or may not have healed at the time the change peculiar to syphilis occurs. If the sore be still present, induration will develop, and the lesion will for a time assume the characters of both kinds of sore; but if it have healed, the cicatrix will harden and eventually assume more or less closely the appearance of one or other of the forms of initial lesion which have just been mentioned.

The initial lesion in rare instances may disappear in a few days, but its duration usually varies from two or three weeks to several months, according to its size and the influence of treatment. It sometimes breaks out again after cicatrization; and induration may reappear, even repeatedly, without fresh infection. If the sore, from irritation of any kind, be made to suppurate, the secretion may become freely inoculable on the bearer. When the chancrous and syphilitic poisons have both been inoculated, the resulting lesion has been termed by Rollet a ‘*mixed chancre*.’

Glandular Enlargement.—On whatever part of the body the initial lesion may be situated, the nearest lymphatic gland or glands become perceptibly enlarged in from seven to fourteen days after its appearance. Where the glands themselves are multiple, the whole group is usually more or less affected; but the gland most directly connected with the point of inoculation enlarges first, and often attains a greater size than the others. In the absence of inflammation of the surrounding parts, each gland can be felt as a separate distinct indolent swelling, usually about the size of a marble, the cellular tissue and skin remaining free. At this time the enlargement commonly remains limited to the nearest group, but later it is sometimes general. When the genital region is the seat of the initial lesion the glands of both groins are in most cases enlarged, though often to an unequal extent. Suppuration of the glands probably never occurs unless there be some source of irritation in addition to the syphilitic poison.

Besides the glands, the *lymphatic vessels* leading to them—those of the penis, for example—can sometimes be felt as hard cords, freely movable beneath the skin. These cords have also been found to contain thickened blood-vessels.

2. Secondary Syphilis.—After the development of the initial manifestation, with its accompanying adenopathy, another interval occurs before further signs appear. This is sometimes called the *second incubation*, to distinguish it from that which intervenes between infection and the appearance of the initial lesion. This second period of quiescence, counting from the appearance of the initial lesion to the appearance of the general eruption, is usually about six weeks. Thus, as a general rule, it may be stated that, in the absence of specific treatment, the rash appears from sixty to seventy days after infection; from forty to fifty after the initial lesion; and from thirty to forty after enlargement of the nearest lymphatic glands.

During the earlier part of this period the patient

commonly does not feel ill; but towards its close, and shortly before the appearance of the eruption, some patients, especially women, if they be not already under the influence of mercury, develop certain symptoms of constitutional derangement which have received the name of *prodromata*. Thus the patient may become pale and anæmic, and may suffer from shortness of breath and lassitude. In addition, headache, loss of appetite, pains in the limbs and back, rise of temperature, and other symptoms known under the name of 'syphilitic fever,' may be present. During this period also, as was first pointed out by Ricord and Grassi, the proportion of red blood-corpuscles is diminished. The prodromata are usually mild in degree, but occasionally they are severe. Thus, headache may be agonising, and in rare instances the amount of constitutional disturbance is so great that the onset of one of the acute fevers may be suspected.

Cutaneous System.—At the end of this second interval of apparent quiescence, then, and having been preceded or not by some of the symptoms just mentioned, the first eruption appears. This, in the great majority of cases, consists of irregularly scattered red spots (*Erythematous Syphilide*, *Syphilitic Roseola*) varying in size from a hemp-seed to a shilling, not raised above the surface, fading on pressure at first and often throughout. The rash is unattended by itching or any other subjective sign, so that it is often overlooked by the patient. The spots vary in colour, being often at first of a paler or deeper red according to the complexion of the bearer; but if they last long they usually become dull red or brownish, and then may not fade on pressure. Finally they disappear completely, and occasionally slight desquamation follows. The spots usually appear first about the flanks and abdomen. The face and hands generally escape. The extent and duration of the eruption vary much in different persons. It may be limited to a few faint spots on the trunk, or the whole body may be covered with the rash, in which case it often resembles that of measles. The erythematous syphilide may appear suddenly and disappear quickly; or it may last for several weeks, and indeed occasionally for months, if untreated. It sometimes recurs, but in that case is usually, though not invariably, limited to a few blotches or rings on the trunk or limbs.

As the macular eruption fades, papules not uncommonly appear, or some of the spots may be papular from the first, so that a maculo-papular eruption is often seen in early syphilis. The papules are bright red at first, but later often assume a colour resembling that of raw ham, and later still a 'coppery' hue. The papules are very liable to relapse, and to become scaly. When they fade, a brown stain is often left, which gradually disappears completely. At this time also crusts are frequently present on the scalp among the hair, which itself becomes dry and withered, and at a later period often falls out, either generally or in patches. Syphilitic alopecia is in most cases limited to a temporary general thinning of the hair of the head, but all the hairy regions of the body may suffer. The nails also are liable to be attacked in several ways. See NAILS, Diseases of.

Though the macular and papular syphilides are by far the most frequent forms of early rash, vesicular, pustular, rupial, and ulcerating eruptions sometimes appear during the secondary stage, the last two being most common in patients of bad constitution.

The earlier eruptions are usually superficial, and widely spread. Except perhaps in the case of the earliest rash, the papule forms the basis of the spots. Irritation and itching are usually absent. The eruption has certain favourite seats, namely, the anterior and lateral surface of the trunk, the flexor surface of the limbs, the border of the hairy scalp, and the neighbourhood of the various orifices of the body. Several forms of eruption are often present at the same time; most commonly maculæ and papules, but sometimes papules and pustules. They all tend to disappear spontaneously, and, except the pustular form, without leaving any scar.

Pigmentary changes in the skin are common in syphilis. Temporary excess of pigment may follow any syphilide, and this again may be followed by its loss, so that sometimes yellow or brown stains are seen, and sometimes white-spots. A much rarer change, which differs from those just mentioned in that it does not follow another lesion on the same site, is that known as the *pigmentary syphilide*. It consists of irregular brownish patches situated chiefly about the sides of the neck, and observed mostly in women. Opinions are divided as to whether this is an essentially syphilitic affection or not. It lasts a long time, and is but little affected by antisymphilitic remedies.

Mucous Membrane.—Besides the affections of the skin, lesions of the mucous membrane, particularly that of the mouth and throat, are nearly always present during the secondary stage of syphilis. Erythema, excoriations, or shallow ulcers are very common about the fauces and tonsils, as well as on the buccal surface and tongue, during the early portion of this stage; and the nasal and laryngeal mucous membrane is also liable to be affected. Equally common, though usually somewhat later, are mucous patches or tubercles (see MUCOUS PATCH). They may occur on any moist surface, but are most frequently seen about the mouth, genital organs, and anus. The initial lesion also sometimes assumes the appearance of a mucous patch or tubercle, especially in women.

These affections of the skin and mucous surfaces are often accompanied by more or less deterioration of the general health, with pallor, lassitude, and loss of weight. Aching in the muscles, bones, or joints (*osteocopic pains*), and sometimes periosteal swellings or synovial effusions, also occur, as well as more or less general enlargement of remote lymphatic glands, particularly those of the neck and beneath the jaw; but the axillary, epitrochlear, and indeed all the glands within reach, may be enlarged. Iritis is also liable to come on about this time, and, later, choroiditis. Sometimes, but more rarely, affections of the auditory apparatus are present. See EYE; and EAR.

Enlargement of the *epididymis*, chiefly its head, is another, though rare, phenomenon in secondary syphilis. Temporary albuminuria and jaundice also sometimes occur during this stage.

The number, extent, and severity of the secondary manifestations vary greatly in different persons. In some cases erythema on the skin and slight redness and excoriation of the throat are the only signs that are discovered. In other instances the erythematous rash is succeeded by papular and scaly syphilides, and by obstinately recurring lesions of the mouth, throat, genital organs, or other parts of the body.

After the lapse of a period which varies usually

from six to eighteen months, the secondary stage comes to an end, and in most cases the disease troubles the patient no longer. But supposing this not to be the case, there may be an interval of months or years during which no symptoms appear. Sometimes, however, symptoms continue to develop from time to time, which partake of the characters of both the secondary and tertiary stages, and which gradually merge into the latter without any strict line of demarcation between the two. Examples of these intermediate signs are thickened scaly patches on the skin, which often take a circular or serpiginous form, and sometimes ulcerate; obstinate eruptions of the soles and palms; ulcers and induration of the tongue; periosteal swellings; orchitis; and affections of the choroid and retina.

3. Tertiary Syphilis.—While the secondary stage of syphilis is mainly characterised by the occurrence of superficial lesions, more or less widely spread over the surface, and tending to spontaneous disappearance; the main features of tertiary affections, on the other hand, are that they usually attack only a limited area, that they have a tendency to extend and to cause destruction of tissue with consequent contraction and scarring, and that they do not tend to spontaneous recovery.

The lesions classed as tertiary are due to invasion of some part of the body by the granulomatous or gummy growth which has been already described. The tertiary period, also, is sometimes, but by no means always, attended by severe cachexia, with a peculiar pallor of the skin.

Whether the syphilitic growth assumes a diffused or a circumscribed form, unless it be checked by treatment, degeneration is often rapid, leading to obstinate ulceration when the superficial structures are attacked, and to the production of tough contractile fibrous tissue when the viscera are the seat of the new-formation. Of the internal organs those belonging to the nervous system are probably most frequently affected.

When the gummy growth attacks the skin or mucous membrane in a diffused form, it produces hard, flat plaques of varying extent. The skin after a time becomes purplish-red and adherent, and finally breaks down at one or more points; an ulcer is left, which sometimes creeps over the surface (serpiginous ulceration), healing in the middle and extending at the margins, until a considerable amount of tissue is destroyed. When this diffused infiltration occurs in the pharynx, air-passages, or rectum, the disease is very obstinate, unless actively treated at an early stage, and the subsequent contraction may produce incurable and fatal stricture in any of those situations.

When gummata develop in the skin itself, the result is often called a *nodular syphilide*. Gummata in the cellular tissue, when discovered early, appear as small hard nodules, movable beneath the skin; but after a time, unless treated, they enlarge, soften, and become adherent to the discoloured integument, which finally gives way, exposing a mass of yellowish-white material, which is gradually cast off in the form of shreddy matter. The cavity then heals by granulation, leaving a depressed scar.

Local irritation or injury seems often to determine both the appearance and the site of some of the manifestations of syphilis; for example, the effects of smoking and broken teeth in the case of the throat and tongue, and a blow or squeeze in the case of the bones and testes.

The syphilitic affections of the other tissues, and of the various organs of the body, will be found described along with the other diseases of the several parts under their proper headings. See BRAIN, Syphilis of; BONE, Diseases of; LIVER, Syphilitic Disease of; TESTES, Diseases of, &c.

Malignant Syphilis.—It has already been mentioned that the division of syphilis into a secondary and a tertiary stage is to a great extent artificial; indeed, it is sometimes impossible to say under which title certain lesions ought to be classed. There are again cases, fortunately not common, to which the term 'malignant' or 'galloping syphilis' has been applied, in which the disease from the first pursues a rapid, destructive, and sometimes uncontrollable course. Skin-eruptions, which partake of the secondary stage in their wide-spread character, and of the tertiary in their tendency to ulcerate—*rupia*, for example—appear early, even while the initial lesion is still present. Deep ulcers form also in the mucous membrane, and the gummy growth may develop in the internal organs, and cause death; or the patient may die worn out by exhaustion, or from some intercurrent inflammation.

Inherited Syphilis.—Syphilis is a very frequent cause of *abortion*, especially if the parental infection be of recent date, or treatment have been neglected. If the child be carried the full term, it may be born dead, with or without signs of syphilis; most commonly, however, if the child be born alive, it does not show any signs of the disease at birth.

In inherited syphilis the initial manifestation is presumably absent, and after birth the disease appears to begin at the secondary stage. So far as is at present known there is no difference in the clinical signs of infantile syphilis, whether the infection be derived from one or both parents, or whether it be germinal or placentar. The symptoms of the inherited are in their main features similar to those of the acquired disease, allowance being made for the difference between the actively growing tissues of the child and the fully developed organs of the adult. There are, however, some points that deserve notice. The first is the frequency with which the nasal mucous membrane is attacked, the rhinitis giving rise to one of the earliest and most characteristic symptoms, namely, snuffling. If the inflammation extend to the deeper structures, flattening or other deformity of the nose may follow. Another peculiarity is a tendency, much more marked in inherited than in acquired syphilis, to early mingling of secondary and tertiary symptoms. Lesions of the bones and viscera, for instance, may occur, not only with the earlier skin-eruptions, but even during intra-uterine life. The bones most liable to be attacked are those of the cranial vault, and the long bones of the extremities. *Craniotabes*, especially of the occipital region, seems to be frequently, though not always, due to syphilis. See BONE, Diseases of; and SKULL, Diseases of.

Supposing the child to have been born alive, it usually shows no evidence of disease for a period ranging between two and six weeks, sometimes longer, after birth. It then, as a rule, gradually loses its healthy appearance, begins to snuffle, becomes fretful, and wastes more or less rapidly. The child's skin assumes a dull dirty colour, and, though loose and wrinkled, is very brittle and easily breaks round the mouth and nose into chaps and

fissures, the scars of which often form a characteristic sign in after-life, if the child survive.

The *erythematous syphilide* in inherited syphilis shows a marked difference from that of acquired syphilis. Instead of numerous small spots spread widely over the surface, it usually consists of larger dusky patches, which generally appear first about the buttocks and genital region, and often extend down the lower extremities. The soles and palms also are frequently affected, and sometimes the eruption spreads over the whole body. Desquamation very often follows. Papular or pustular rashes, resembling those seen in the adult, may also appear; and mucous patches are nearly always present, sooner or later, about the orifices of the body. Affections of the hair, the nails, the testes, and the viscera, similar to those of acquired syphilis, are also found in young children. A bullous eruption is seen only in severe cases; it appears very early, and is frequently fatal. Though it has been asserted recently that infection from a child who has inherited syphilis is very rare, still in practice it will be wise to look upon the earlier lesions as equally infectious with those of the acquired form of the disease.

Though a large majority of those who suffer in infancy show no signs afterwards, yet later on, usually from about the fifth to the fifteenth year of life, inherited syphilis may manifest itself by a number of symptoms which were formerly ascribed to 'scrofula.' The growth is checked, the individual being stunted, weakly, ill-nourished, and of low vitality. The forehead is prominent, and the bridge of the nose sunken. The skin is pallid, and perhaps ulcerated, or scarred by previous ulceration. The permanent teeth, especially the central upper incisors, as was first pointed out by Hutchinson, may be dwarfed, narrowed towards the cutting edge, and notched at the centre of the free border (see *TEETH*). The cornea is liable to a form of diffuse inflammation (interstitial keratitis), leading to more or less opacity and impairment of vision; the iris and the deeper structures are also liable to be invaded; and deafness is sometimes present. These affections of the eye and ear are, according to Hutchinson, much more common in girls than in boys (see *EYE*; and *EAR*). The bones of the palate and nose may be diseased; and nodes may appear in various situations; as well as a form of chronic synovitis, most frequently affecting the knee-joints. The fingers and toes also, and, more rarely, the metacarpal and metatarsal bones, may become enlarged. This form of dactylitis is most common in early life; but it has been observed after puberty, as well as rarely in connection with acquired syphilis. The soft palate and pharynx may be the seat of ulceration, which sometimes becomes phagedænic. The deeper tissues and the viscera are also liable to be attacked by processes similar to those which occur in the acquired disease, giving rise to a variety of symptoms, and sometimes leading to a fatal issue. Some authors believe that early life may be passed without symptoms, and that these later affections may constitute the first signs of inherited taint.

COURSE, DURATION, AND TERMINATIONS.—The course of syphilis varies very much, according to the individual, and according to the treatment adopted. In the majority of cases of acquired syphilis the disease runs its course within a year and a half or two years; but in certain rare

cases it appears to end with the first eruption; sometimes, perhaps, even earlier than this. When tertiary symptoms ensue, the commonest period for their appearance is probably from three to five years after infection; but they may be delayed for ten or twenty years, or even longer. On the other hand, as has been already stated, the secondary may run on into the tertiary stage without any appreciable interval. When tertiary symptoms have once appeared, the duration of the disease is uncertain, depending greatly on the constitution and habits of the patient, and on the effects of treatment. In some cases the patient continues to suffer throughout his life.

Besides what, for want of knowledge, we call idiosyncrasy, the course and duration of syphilis are also influenced by many other circumstances—for example, climate, age, pregnancy, and the hygienic surroundings of the patient.

The greater or less severity of the disease, or the stage at which it may have arrived in the person from whom it is contracted, does not appear to have any appreciable influence on the course of acquired syphilis.

The usual termination of syphilis is in recovery, and this in many cases probably without treatment, if the patient suffer only from the more superficial forms of disease. In syphilitic disease of the viscera, unless it be recognised and treated at an early stage, the termination is frequently fatal.

In *inherited syphilis*, if the child be born with signs of syphilis it usually dies; but when it remains healthy for some weeks after birth, the disease mostly ends in recovery within a year, provided proper treatment be carried out. In later childhood, however, or in adolescence, even up to the thirtieth year according to Hutchinson, further symptoms may develop; in which case the duration and termination will depend greatly upon their due recognition and appropriate treatment. When the disease is neglected, death is a frequent termination, especially among the ill-fed children of the poor.

COMPLICATIONS.—*Phagedæna* is an occasional complication of the initial lesion, but more frequently of the later ulcerating syphilides. The *local chancre* is another complication, giving rise to what has been termed the 'mixed chancre.' *Erysipelas* sometimes attacks syphilitic patients, and it is said to act beneficially in causing the disappearance of certain obstinate eruptions. This influence, however, is only seen in some chronic cases when the patient is otherwise in fair health. If erysipelas attack a cachectic person, with rapidly spreading lesions, the complication is a serious one, and may prove fatal. In *tuberculous* patients syphilis is often obstinate and severe. The skin-affections in such persons are prone to ulcerate, and syphilis seems in some cases to rouse the tuberculosis into activity. The *gouty* diathesis also influences the course of syphilis. The skin-eruptions often assume the scaly form, and sometimes resist treatment obstinately. *Bright's disease* is a serious complication. Patients whose kidneys are diseased are liable to suffer severely both as regards the superficial tissues and the internal organs. *Ague*, especially if recent and severe, is also a serious complication. *Alcoholism* is detrimental in two ways: first, by its injurious influence on the system generally; secondly, preventing the proper action of specific remedies.

DIAGNOSIS.—In the diagnosis of syphilis much will depend on the stage at which the disease has arrived when the patient comes under observation. Before the incubation-period has come to an end the diagnosis will of course be impossible; but when the initial lesion with its accompanying glandular enlargement has appeared, there is usually no difficulty, unless some local complication be present, or unless the diagnostic signs have been obscured by giving mercury too soon. The initial lesion is distinguished by its indurated base, the indolent superficial character of the ulceration when that is present, the thin serous discharge, and the indolent painless enlargement of the nearest lymphatic glands. Other points in connection with the diagnosis of primary syphilis are considered elsewhere. See VENEREAL SORE.

The diagnosis of the early syphilides does not, as a rule, present much difficulty, if the general characters already mentioned be attended to. In some cases, however, when pyrexia and general constitutional disturbance precede or accompany the outbreak of the eruption, the symptoms may be mistaken for those of some other disease. The erythematous syphilide has been mistaken for measles or scarlatina, and a pustular syphilide for small-pox. The various forms of drug-eruption, especially that due to copaiba, as well as other rashes due to toxæmia of various kinds, should also be borne in mind. In doubtful cases, careful attention to the temperature, and the condition of the tongue, throat, and air-passages, together with the history and the presence or absence of other signs of syphilis, will usually decide the question in a few days. The colour of a syphilide or scar, no matter how coppery it may be, is by itself of little value from a diagnostic point of view.

It is, however, at a later stage—perhaps many years after infection, and long after the disappearance of outward signs of the disease—that the diagnosis presents most difficulty to the physician. For example, a patient comes with obscure symptoms, pointing to some lesion of the nervous system, heart, liver, or other viscus. In such cases the skin and mucous membrane, particularly of the genital organs, mouth and throat, should be carefully inspected, and the bones and testes examined for irregularity or swelling. The eyes may afford important aid, by the detection of iritic adhesions or changes in the deeper structures. The presence of local paralyses, especially of the ocular muscles, is a valuable diagnostic sign. The absence of signs or characters distinctive of other diseases—cancer or tuberculosis, for example—is often also of value in doubtful cases.

When no conclusive information can be gained from any of these sources, the history becomes of the greatest importance. A venereal sore with lumps in the groins, and followed by a rash on the skin, sore throat or tongue, loss of hair, pains in the bones worse at night, and bad eyes, are some of the points that should be inquired into, and in women the occurrence of abortion or of still-birth. Symptoms of fever, either continued, remittent or intermittent, may occur both early and late in syphilis, and with or without obvious signs of the disease. In obscure cases of fever, therefore, syphilis should be thought of as a possible cause.

In investigating the history of a supposed syphilitic person, it should be borne in mind that syphilis is not necessarily a venereal disease, and that conse-

quently the initial lesion may have been far away from the genital organs, and thus mistaken or overlooked; also that the early manifestations, particularly in women, may be so slight and so evanescent as to escape observation. Again, some may have forgotten that they have suffered from earlier signs; and others who do remember obstinately conceal the fact. However this may be, the practitioner frequently fails to elicit any clear history of earlier manifestations in those who suffer from visceral syphilis. Sometimes also, for various reasons, the history is not available. If neither the symptoms present at the time, nor inspection of the patient's body, nor the method of exclusion, nor the history of the case, separately or combined, suffice to render the diagnosis clear, specific remedies should be administered, and their effect awaited before an opinion is given. But it is well to be cautious in drawing conclusions from such evidence. The failure of specifics, in an affection of the nervous system for instance, does not prove that the case is not syphilitic, for they may have not been given early enough to check the disease. Again, improvement may occur under mercury or iodides in cases where there is no syphilis.

In the diagnosis of *inherited syphilis* at an early age, snuffling and coryza, when persistent and well-marked, are of much importance. Radiating cracks around the mouth and nostrils are also valuable signs. Besides the eruption on the skin, especially that of the buttocks and soles of the feet, mucous patches should be looked for about the mouth, anus, and genital organs. A bullous eruption of the palms and soles is nearly always syphilitic, but it is rare. Enlargement of the spleen is a valuable corroborative sign. The bones of the skull should always be examined for nodes and cranio-tabes, and those of the limbs for nodes and epiphysal enlargement. Nodes on the skull occur most frequently on the frontal and parietal bones, especially near the anterior fontanelle (Parrot's nodes). As a distinction from rickets it has been pointed out that while the frontal and parietal eminences themselves are affected by rickets they are not affected by syphilis. Pallor and wasting are common; indeed wasting alone, without other discoverable cause, points towards syphilis; but it must be remembered also that a syphilitic child who suffers but slightly may retain a healthy appearance throughout.

In later childhood and adolescence the most valuable diagnostic signs are the low stature and puny development; the dull, pasty complexion; radiating scars about the mouth; the prominent forehead; the broad and sunken bridge of the nose; signs of present or past mischief in the cornea, iris, or choroid; dwarfed and notched median upper incisors; deafness of high degree, symmetrical, and without otorrhœa; nodes on the bones; unhealthy ulceration, often closely resembling lupus, or its scars, especially of the face or throat. Here, again, if no conclusive signs be present, the history becomes most important, both of the patient himself and of his immediate relations, and here also the diagnosis has occasionally to be postponed until antisyphilitic remedies have been administered. Lastly, it is too often forgotten that syphilis in children is not necessarily inherited, but that it may have been acquired by suckling or in some other way. In the diagnosis between acquired and inherited syphilis in children, the points to be attended to are the presence or absence of a primary

lesion, and of glandular enlargement, and the characters of any eruption that may appear, as well as the other signs already mentioned.

PROGNOSIS.—This, in the great majority of cases, is favourable, if the patient be otherwise in good health, of temperate habits, and especially if his disease be properly treated from an early period. The effect of other constitutional diseases has already been indicated among the *complications* of syphilis. Probably nothing tends more to prolong and aggravate the course of syphilis than habits of drinking. In persons given to alcohol, therefore, the prognosis should always be guarded.

An interesting question, and one on which further information is needed, is whether any trustworthy data as regards prognosis can be gained from the character of the early manifestations. Neither the length of incubation, nor the amount of induration or ulceration of the initial lesion, has been shown to afford any trustworthy evidence as regards prognosis. Early *general* glandular enlargement is often an unfavourable sign. Persons thus affected become anæmic, and consequently more liable to grave affections. As regards the early syphilides, it may be mentioned that the ordinary well-marked macular and papular eruptions appear to be less common precursors of late visceral affections than early rashes that are ill-marked and scanty. Obstinate, frequently recurring lesions of the skin and mucous membrane also seem to be rarely associated with visceral disease. In connection with this may be mentioned the frequent failure of the physician to elicit any history of early symptoms in those who suffer at a later period from grave visceral affections, especially from syphilis of the nervous system.

In the cases of malignant or galloping syphilis, in which ulcerating and rapidly spreading lesions attack the skin and mucous membranes, and are associated with a tendency to phagedæna and great prostration at an early period after infection, the prognosis should be guarded: the patient may die worn out by the pain and profuse discharge of the superficial lesions, or of some acute affection. In syphilitic disease of any of the internal organs, the prognosis will depend greatly on its early recognition and treatment.

One of the most important points to be considered in prognosis is the way in which the patient has been treated. For, although we do not yet know any certain sign—save re-infection—which proves that syphilis has come to an end, it may with much confidence be stated that if mercurial treatment have been begun at an early period, and continued a sufficient length of time, and if the patient be constitutionally healthy and of temperate habits, the chances are very greatly in favour of complete subsidence of the disease within two years.

When syphilis causes death it is usually through the so-called tertiary lesions, especially perhaps syphiloma of the blood-vessels and notably those of the brain and spinal cord. The proportion of cases in which tertiary affections occur is probably not more than 10 per cent., and in a large majority of these the vital organs escape. Much progress has been made of late years towards the better and earlier diagnosis of visceral syphilis, and it seems probable that the prognosis will become more and more favourable as time goes on.

Much of what has been said as to the prognosis

of acquired syphilis applies also to the inherited form of the disease. A child in whom symptoms do not appear until several weeks after birth, who is well cared for, properly fed, and who receives proper medical treatment, will probably recover; one who is ill-fed and neglected will most probably die. Indeed, among the children of the poor, syphilis is one of the most fatal diseases of infantile life.

TREATMENT.—I. **Preventive Treatment.**—At the present time there are unfortunately no State regulations to check the spreading of venereal diseases in this country.

Among individuals the strict daily observance of cleanliness, too often neglected by both sexes, constitutes the best protection against disease, and by preserving the epithelial surface in a sound and healthy condition would of itself, if generally practised, do much towards reducing the prevalence of syphilis as well as of other venereal diseases.

There is no trustworthy evidence that syphilis can be cut short by removal or destruction of the initial lesion. Indeed, cauterisation within twelve hours after exposure has failed to prevent infection.

Every person who contracts syphilis should be warned of the danger of communicating it to others. Sexual intercourse should be prohibited while the disease remains active. This direction should never be omitted, as many patients are unaware that they are liable to communicate the disease after the primary sore has healed.

The infectious nature of the lesions of the mouth and throat should also be pointed out, and the consequent risk of infection by kissing, or by the use of drinking-vessels, pipes, towels, or other articles in common with other persons.

The question of *marriage* in relation to syphilis is one of great importance, and it is the duty of the practitioner to prevent the contamination of a healthy person, or the procreation of syphilitic children, whenever it is in his power to do so. No person who shows signs of active syphilis should marry, however long a time may have elapsed since infection; for although communication of the disease is probably rare after two years have gone by, it may take place after ten years, or even longer in neglected cases. It has already been stated that syphilis usually ceases to be active within two years; but this is not always so. After the last symptoms have disappeared, there should be an interval of at least a year before marriage takes place; but the period between infection and marriage should never be less than three years. If the treatment during the early stages have not been systematic and prolonged, it will often be advisable to subject the candidate for marriage to a course of mercury for about three months, and after this to keep him under observation for a year before the marriage takes place.

If a syphilitic man have a relapse after marriage with a healthy woman, he ought at once to desist from intercourse—indeed, from contact of every kind—and undergo thorough treatment. The wife also should be watched, that treatment may be begun as early as possible, if she have contracted the disease. A woman who has borne a syphilitic child should as a rule be treated with mercury whether she show signs herself or not.

The spread of syphilis from children to nurses, and *vice versa*, must also be guarded against, and the practitioner should never allow a syphilitic child

to be entrusted to a healthy wet-nurse, nor a syphilitic nurse to suckle a healthy child.

2. Curative Treatment.—The treatment of syphilis may be divided into (a) *general*; (b) *specific*; and (c) *local treatment*.

(a) *General treatment.*—Syphilis is essentially a debilitating disease; hence it is important that the general health of the patient should be supported by nourishing diet, good air, warm clothing, extreme moderation as regards alcoholic liquors, cleanliness, cheerful society, and moderate exercise in the open air. In most cases the patient may follow his usual employment, unless it involve prolonged exposure to damp and cold. The skin should be made to act freely, by the frequent use of soap and water, and an occasional vapour- or Turkish bath if thought desirable. Some woollen material should be worn next the skin, and chills avoided as much as possible. Smoking in moderation may be allowed as long as the mouth and throat remain free; but when syphilitic lesions are present, it should always be discontinued, and if they show a tendency to recur smoking should be abandoned altogether. Regular action of the bowels is also important.

(b) *Specific treatment.*—Besides attention to the general health of the patient on ordinary principles, the administration of certain drugs which are known to have special influence over syphilis should never be omitted, however mild the earlier manifestations of the disease may be. The subcutaneous injection of serum both from inoculated animals and from syphilitic persons has been practised to some extent during recent years; but nothing can be definitely stated at present as to the value of this mode of treatment.

The special drugs now almost exclusively used in the treatment of syphilis are *mercury* and the various salts of *iodine*. Probably the former only can be looked on as a permanent remedy. The iodides are of great value in some of the earlier as well as in most of the later manifestations of syphilis; but the effects are not always lasting, and therefore they cannot be trusted to alone.

Much of the prejudice against the use of *mercury* has arisen from the fact that in former times its administration was carried to a poisonous extent. It is now known that if the drug be administered in suitable doses, it acts as a tonic, syphilitic patients rapidly improving in health and gaining weight under its use.

As soon as a diagnosis of syphilis has been made mercury should be given. It is sometimes advised that the rash should be waited for 'to clinch the diagnosis'; but in most cases the diagnosis can and ought to be made before that, and it must be remembered also that the rash may be mistaken or overlooked as well as the earlier signs. But the strongest argument in favour of early treatment is to be found in the fact that grave and sometimes fatal lesions may occur within a few months after infection. For all the lesions both of the primary and of the secondary stage mercury is appropriate, and in the later stages it should be used in conjunction with iodides, as well as in cases where the iodides fail to relieve. Mercury may be given to almost all persons when its use is indicated, but its effect must be carefully watched if the patient be in feeble health or the subject of disease of the kidneys. Mercury is sometimes said to be contra-indicated in tuberculous patients, but in the writer's experience

they bear the drug as well as others if care be taken in its administration.

Before a mercurial course is begun the mouth should, as far as possible, be put in a healthy condition. Unsound teeth should be stopped or removed, and tartar got rid of. If the gums are spongy, an astringent mouth-wash should be used frequently. The *urine* should always be examined before treatment is begun, and at intervals afterwards. At present it is by no means clear how much of the renal irregularity indicated by albuminuria in syphilis is due to the disease and how much to other causes, including possibly the drugs employed in its treatment. The *weight* of a syphilitic patient under treatment should also be noted from time to time. The patient should also be warned that fruit and green vegetables may cause diarrhoea during a course of mercury. Milk usually agrees well, and may be taken freely.

When mercury is taken in syphilis, the patient usually improves rapidly. If a rash be present it soon begins to fade, and ulcerated surfaces begin to heal. All the necessary results are in most cases attained without any, or with only the slightest, visible effect on the gums.

Every case of acquired syphilis in an adult should be treated by mercury for at least a year. During this period it will be necessary to omit the drug from time to time, and perhaps to vary its form and mode of administration; but what should be the length of each course, and what the length of the intervals, are questions that must be decided according to the symptoms that appear, and according to the effects of mercury in each case. After the first year no fixed rules can be laid down. As long as there are signs of syphilis treatment must of course be carried out; but the particular drug to be chosen, its dose, and the length of time it should be continued, ought to depend on what has been learned beforehand about the patient and his malady, as well as on the treatment he has already undergone.

Mercury may be introduced into the system in various ways—by the stomach, rectum, vagina, skin, or subcutaneous tissues; but its action is essentially the same by whatever channel it is administered.

Mercury is most conveniently given by the mouth, and in ordinary cases the results are probably quite as good as under any other mode of administration. In early syphilis *blue pill* usually fulfils all the requirements of the case; and the writer has found this more generally useful and less likely to disagree than grey powder. If no urgent symptoms be present, a grain of one or other of these preparations may be given, with a little extract of gentian, three or four times a day, immediately after meals. Quinine or reduced iron may be added, if thought desirable, but opium is usually unnecessary. In such doses mercury rarely causes either stomatitis or purging, but the possibility of both should always be mentioned to the patient. If, however, a rapid effect be desired—in *iritis*, for example—2 or 3 grains of blue pill, with $\frac{1}{4}$ or $\frac{1}{3}$ grain of opium, may be given three or four times a day, the patient being kept indoors, until the requisite effect is produced, after which the drug should be given less frequently, or be reduced in quantity. If salivation be inadvertently set up, the mercury should be discontinued for a time, a purge administered, and the mouth washed out frequently with a gargle of alum or chlorate of potassium. See MERCURY, Diseases arising from; and SALIVATION.

The green iodide of mercury is an active salt, which is largely used on the Continent, especially in France, but it is more liable to decomposition and to cause irritation than the forms just mentioned. It may be given in doses of $\frac{1}{4}$ to 1 grain, with a little opium, twice or thrice a day.

The perchloride of mercury is mostly given in the later and more chronic forms of syphilis, but in the early stages it is sometimes better borne than almost any other preparation. It may be prescribed in doses of $\frac{1}{16}$ to $\frac{1}{8}$ grain, either in a mixture with iodide of potassium or with perchloride of iron, or in a pill, according to circumstances. The red iodide is also useful, especially in cases of relapsing scaly syphilides.

When other preparations purge or otherwise disagree, the *tannate of mercury* in 1 or 1½ grain doses sometimes answers well.

A mixture of sarsaparilla and aromatics with antimony or mercury, known as *Zittmann's decoction*, is sometimes useful in tertiary syphilis.

Inunction is very effective, but it is troublesome to the patient; hence he may neglect to carry it out properly. Provided the skin be in a suitable condition, it may be employed whenever mercury is indicated, especially when for any reason it is deemed inadvisable to give the drug by the mouth. See INUNCTION.

The mercurial vapour-bath is not a convenient routine method of treatment, but is beneficial in certain cases, especially those of widespread rash. See FUMIGATION.

Subcutaneous or intra-muscular injection is probably the quickest way of obtaining the effects of mercury, but it is more or less painful, and not altogether free from risk; hence it is only to be recommended when other means fail, or in very urgent cases, or perhaps in the case of the Army and Navy if it be found that the men cannot be trusted to carry out their treatment in the ordinary way. As a rule this method should not be employed on a patient who has not previously taken mercury, lest he chance to be peculiarly susceptible to the drug, and so in danger of being poisoned. Mercurial injections are usually best made deeply into the muscles of the buttock or back. Nearly every known preparation of mercury, soluble and insoluble, has in turn been employed, but there is no general agreement as to which is the best. A solution containing 1 part of the red iodide with sufficient iodide of sodium to dissolve it in 64 parts of water answers well. The dose is from 4 to 8 minims, and it may be repeated daily or less often according to the case and the effects produced.

The *intravenous* injection of mercury has been advocated by a very few surgeons. The writer has no experience of it.

The salts of *iodine* are principally used in the treatment of tertiary syphilis; but it is a mistake to look upon them as adapted only for that stage. In the secondary period, and in cases where the lesions partake of the character of both stages, the iodides may often be advantageously combined with mercury. Speaking generally, the writer believes that the iodides are indicated when there is evidence of a marked tendency to new-growth at any time after the primary stage. In cases where the symptoms have been controlled by iodine, mercury should, as a rule, be given to complete the cure.

Iodide of potassium is the salt most frequently used; but the iodides of *sodium* and of *ammonium*

are also employed. The action of all is similar, but the sodium and ammonium salts appear to be less depressing. They may be given separately or combined. The dose of the iodides varies from 2 or 3 to 100 grains or even more. In ordinary circumstances it is best to begin with 3 or 4 grains, with a little ammonia, three times a day, and to increase the dose if necessary. In urgent cases, such as those of naso-pharyngeal disease, in which deformity is threatened, as well as in some cases of visceral disease, particularly in syphilitic affections of the nervous system, from 10 to 20 grains may be given at first, and the dose rapidly increased until some effect is produced. In such cases, also, it will often be prudent to carry out inunction, or the subcutaneous injection of mercury, at the same time. The iodides should be given well diluted; and any of the bitter infusions, or the citrate of iron and ammonia, may be added when their use is indicated. Milk is an excellent vehicle, especially for children. Iodides may also be effectively administered *per rectum*.

Donovan's solution (Liquor arsenii et hydrargyri iodidi) acts well in many of the later affections of the skin and mucous membranes. The dose is from 5 to 30 minims.

Iodoform is occasionally given internally in the later stages of syphilis; but it frequently causes gastric and intestinal irritation. The dose is about a grain, in the form of a pill.

The *bromides* of potassium, sodium, and ammonium are serviceable in certain cases of syphilitic affection of the nervous system. They may be given alone or with iodides, according to circumstances.

Besides the foregoing remedies, many others may be required in the treatment of syphilis. Iron and nux vomica or strychnine are drugs that are frequently of the greatest value, either in conjunction with specifics or with quinine. Cod-liver oil also is valuable in many cases. Sarsaparilla is sometimes useful during or after a prolonged course of specifics. Mineral acids and vegetable bitters are often of service during the intervals of specific treatment. Opium is sometimes necessary to prevent the purgative action of mercury, especially when large doses are taken, as well as to relieve pain in some of the affections produced by syphilis.

Certain bathing-resorts which possess *sulphur-springs*—Aix-la-Chapelle, for example—have become noted for the cure of syphilis; and there can be no doubt that great benefit is often derived from the course of treatment pursued at such places. The good results, however, are due rather to a combination of specific remedies with strict attention to diet and general hygiene, than to any special virtues of the waters. As far as the writer's observation goes cure is not more certain, and relapse is not less liable to occur after treatment at Aix than elsewhere.

When syphilis is complicated with tuberculosis, gout, rheumatism, or other disease, the appropriate remedies should be given with those proper for syphilis, or temporarily substituted for them according to circumstances.

A certain number of persons are either unusually susceptible or unusually insusceptible to mercury or iodides in ordinary doses. Nearly all such cases, however, can be managed by making the dose small enough or large enough as the case may be, by combining tonics or sedatives with the specific, or by altering the mode of administration, together

with strict attention to diet and the manner of living generally.

(c) *Local treatment.*—The uncomplicated initial lesion of syphilis usually requires only cleanliness, and the application of a little calomel-powder or black wash. If the sore suppurate, it should be cleaned, dried, and dressed with finely-powdered iodoform. Phagedæna must be treated by immersion, caustics, or the actual cautery, while the general health receives attention (*see* VENEREAL SORE). If the lymphatic glands become tender or inflamed, warm fomentations should be applied, and the patient kept lying down. If an abscess form, it must be treated according to the directions given in the article on BUBO.

The early eruptions on the skin rarely require local treatment; oleate-of-mercury ointment may be used for conspicuous spots. Erosions or fissures may be dressed with an ointment of calomel and vaseline, or with iodoform. In the scaly affections of the palms and soles, an ointment of ammoniated mercury and oxide of zinc may be well rubbed in at bedtime, gloves being worn during the night. Mercurial plaster also is a useful application. Mucous patches should be cleansed and dried several times daily, powdered with calomel (1 part) and oxide of zinc (3 parts), and covered with dry lint. If they are large and prominent, pure carbolic acid or acid nitrate of mercury may be applied from time to time. Cracks and ulcers about the nails should be dressed with ointment of red oxide of mercury.

Ulcers or fissures, or mucous patches of the tongue, mouth, and throat should be touched with carbolic acid, and a chlorate of potassium and borax gargle or spray used frequently, especially after eating. Other valuable applications are a mouth-wash of perchloride of mercury, $\frac{1}{8}$ to $\frac{1}{4}$ grain to the ounce, or a stronger solution applied with a mop; and a solution of chromic acid, from 10 to 20 grains to the ounce of water. For the later ulcers internal treatment is of the first importance.

Ulcers about the lips and nostrils should be kept moist with ointment of red oxide of mercury and vaseline. When necrosis of the nasal or palatal bones has occurred, a lotion of permanganate of potassium or chlorinated soda should be used frequently with a syringe or as a coarse spray, and the fragments removed as soon as they become loose. The early affections of the larynx usually disappear without local treatment. In the later affections general treatment is most important, but tracheotomy may sometimes be required.

Ulcers about the anus require careful cleansing and the application of calomel- or iodoform-ointment. For ulceration within the rectum iodoform suppositories and antiseptic injections should be used. In stricture of the rectum careful dilatation by means of bougies may be tried. In extreme cases proctotomy, or even colotomy, may have to be performed.

As regards the bones, the pain produced by early nodes is relieved by painting with a solution of iodine. As a rule, nodes should not be incised. If necrosis take place, the dead bone should be removed as soon as it becomes loose.

In iritis, besides the prompt administration of mercury, a solution of sulphate of atropine (1 grain to 2 drachms of distilled water) should be dropped

into the eye every two hours till the pupil is well dilated. Afterwards a weaker solution may be used less frequently to keep up the effect. In interstitial keratitis also atropine should be used. Iridectomy is occasionally necessary. In choroiditis and retinitis leeching is sometimes useful when there is much pain, but constitutional treatment is most important.

In syphilitic orchitis a suspensory bandage should be worn, but other local treatment is usually unnecessary, unless a gumma break down and fungous protrusion occur, in which case support should be given by strapping. Syphilides of the female genital organs should be dressed with iodoform, and the application of strong carbolic acid is also often beneficial. If the cervix uteri be affected, vaginal injections will be needed as well.

Treatment of Inherited Syphilis.—In the case of a syphilitic child, whether the disease has been acquired or inherited, mercurial treatment should always be adopted as soon as symptoms appear. Grey powder may be given in one-grain doses twice a day; or a strip of flannel smeared with diluted mercurial ointment may be worn round the waist. The ointment should be renewed every night, and the skin cleansed every third day. Some preparations of iron and cod-liver oil are also often useful.

Iodide of potassium is most valuable in the later forms of the disease. The rules for its employment, alone or with mercury, are the same as in acquired syphilis, but the dose must of course be adapted to the age of the patient.

Opinions differ as to the length of time the treatment of a syphilitic child should be continued. Probably three months at least is usually advisable, and if symptoms then persist, it will be wise to continue treatment for several weeks after they have disappeared.

The *local treatment* of the syphilitic affections of children is similar to that recommended for adults. When the nostrils are obstructed by inspissated mucus, they must be carefully cleansed with a borax-and-glycerine lotion by means of a camel's-hair brush or a syringe, and sores dressed with dilute ointment of red oxide of mercury.

The *general management and diet* of syphilitic children are most important. Whenever the mother can suckle her child, she should do so. Though a very few exceptions to Colles's Law have been reported, this rule, in the writer's opinion, need not be altered; but if it be impracticable, a wet-nurse who has already suffered from the disease is the best substitute. If neither be available, ass's, goat's, or cow's milk must be given. Extreme cleanliness and fresh air are essential.

ARTHUR COOPER.

SYRINGOMYELIA (σὺριγγῆ, a pipe or tube; and μῦελος, the marrow).—A name under which Ollivier grouped numerous cases in which cavities of different kinds were met with within the substance of the spinal cord. *See* SPINAL CORD, p. 1559.

SYSTOLIC.—Of or belonging to the systole or contraction of the heart, and usually associated with the cardiac impulse or sounds, or with murmurs. *See* PHYSICAL EXAMINATION.

T

TABES (*tabes*, a consumption).—A term formerly employed to denote consumption or wasting of the body.

TABES DORSALIS.—SYNON.: Locomotor Ataxy; Fr. *Ataxie Locomotrice*; Ger. *Graue Degeneration der Hinterstränge des Rückenmarks*.

DEFINITION.—A disease of the spinal cord alone, or of the spinal cord and peripheral nerves; manifested, when considerable, by inco-ordination of movement, peculiar pains, defective sensibility, and loss of muscle-reflex action (myotatic irritability; 'tendon-reflexes').

ÆTIOLOGY.—Males suffer more frequently than females, the proportion being about ten to one. A neurotic heredity can occasionally be traced; seldom direct inheritance. Among individual causes one greatly exceeds the rest, namely, the influence of syphilis. When every allowance is made for accidental coincidence, it is found that in at least one-half the cases the coincidence must depend upon causal relationship, and it is probable that this is true of a much larger proportion. Many authorities, indeed, believe that is the almost constant antecedent. The interval between the primary manifestations of syphilis and the first symptoms of tabes varies from one to twenty years. It is rarely less than three years, although cases are met with in which the first symptoms occur during the active stage of syphilis. But syphilis is not the only cause, and in a few cases (less than 10 per cent. of the whole) it can be excluded with confidence. The other causes are traumatism, exposure to cold and wet, and over-exertion. Alcoholic and sexual excess are doubtful factors in its production; it has been said to occur as a sequel to certain acute diseases, such as acute rheumatism, typhoid fever, and diphtheria, and as a manifestation of a primary tendency to degeneration. Symptoms of tabes also occasionally succeed other diseases of the spinal cord, such as myelitis, such sequence being especially common in syphilitic subjects. This form has been called 'secondary tabes.'

ANATOMICAL CHARACTERS.—In most cases the spinal cord presents changes visible to the naked eye. These consist in a grey translucent appearance of the posterior columns. The whole of these columns may be thus changed or only parts of them, the extent of the changes being usually proportional to the severity and duration of the disease. With the microscope this change, or 'sclerosis' as it is called, is found to consist in an overgrowth of the interstitial elements, at the expense of the nervous elements in the areas affected. In the most common conditions the sclerosis occupies the whole of the posterior columns in the lumbar region, and becomes gradually restricted to the postero-median columns higher up, having thus the character of an ascending degeneration. In rare cases of severe character and long duration the posterior columns are occupied by connective tissue throughout the whole vertical extent of the cord. In slight cases the sclerosis may be limited in the lumbar region to the posterior root-zone, affecting the median column higher up. Sclerosis may also affect other areas of the cord. The fine fibres of the posterior

root, Lissauer's tract, are generally affected. The direct cerebellar and ascending antero-lateral tracts may also show degeneration. In rare cases complicated with paralysis even the pyramidal tracts are affected. Often in old cases there is a slight general increase of the connective tissue throughout the cord.

Changes in the grey matter are difficult to discover in the slighter cases. Some atrophy of the anterior cornual cells may be detected in cases complicated with true muscular atrophy. The column of Clarke may show distinct degeneration, and this is said to be associated with sclerosis of the direct cerebellar tract. The grey commissure also may be atrophied, and the nerve-cells and fibres in the posterior horn probably undergo changes which are difficult to detect.

The posterior nerve-roots are also atrophied, and the degree of atrophy depends upon the severity of the affection. The histological changes extend as far as the ganglion. The peripheral nerves are altered, the change consisting in a wasting of fibres, which seems to commence in the white substance and to extend to the axis-cylinders. There may be an increase of interstitial tissue, but the change is essentially one in the nerve-elements themselves. This degeneration is greatest in the terminal filaments, and usually lessens upwards, but may extend up to the posterior ganglion. The sensory fibres are alone affected. The changes in these have been chiefly found in the nerves supplying the skin, but Déjérine has demonstrated the presence of similar conditions in the sensory nerves of muscle.

SYMPTOMS.—The most common and characteristic symptom of tabes is the inco-ordination in walking which has given to the disease its common name. This varies in degree in different cases, and may be entirely absent. Before the condition is sufficiently marked to cause the characteristic disorder in movement, it may render standing difficult, especially if the eyes are closed ('Romberg's symptom'); and a still slighter degree may be evidenced only by the startings of tendons in the uncovered feet in the effort to maintain the equilibrium. As the defect progresses, it gradually impairs the patient's ability to walk; and finally locomotion is rendered impossible without assistance. As a rule, the affection of the lower limbs is earlier and much more severe, but the arms may be similarly affected, and, rarely, the ataxy in the arms is the earliest obtrusive symptom. There is often a difficulty in fine movements, such as buttoning the coat; the grasp is not sustained; and there are slow unintentional movements in the fingers, when these are kept in one posture with the eyes closed.

Among sensory symptoms the most obtrusive are pains, especially the severe and distressing 'lightning pains.' These are present in the majority of cases, and are characterised by their momentary, acute, stabbing character. The darts of pain recur in the same place for hours, and may be felt in another part the next time. Such attacks may alternate with periods of entire freedom, varying in duration. Their onset often seems to be determined by the changes in the weather. In some cases they are absent. There are also frequently

present dull aching pains or other acute pains, very various in character and sensory paræsthesiæ, such as numbness and tingling. The sharp pains are often superficial, and then render the skin extremely tender at the place. Another sensory symptom often complained of is a sense of constriction in some part of the trunk, usually round the waist—the so-called ‘girdle-sensation.’ A similar sensation may be present in the leg or thigh or knee, as if a band were tied tightly round it.

Sensory disturbance may also be manifested by impairment of cutaneous sensibility. This is most frequent in the legs and feet. Sensibility for pain and for temperature usually suffers first and most. The temperature-sense seldom escapes when sensibility to pain is much impaired. There is still more frequently delay in the transmission of painful sensations, which may amount to one or two seconds, seldom more. Sometimes there is a rhythmical recurrence of the sensation. Localisation may be disordered, so that a prick on one leg is referred to the other, or a prick at one spot may be felt in several (*allochiria*). Tactile sensation is often perfect when that to pain is almost lost. In rare cases it is impaired more than that to pain, and now and then affected alone. The same changes are met with on the trunk and arms, even sometimes on the head. Sensory loss may also be present in the muscles, so that their contraction on electrical stimulation may be unfelt, and the muscular sense may be so impaired that passive extension is unfelt and the position of the limbs is not known unless they are seen.

Reflex action is also impaired. Cutaneous reflex action is usually impaired in proportion to the loss of cutaneous sensibility. In some early cases there may be some cutaneous hyperæsthesia, and the reflex action from the skin may then be in excess. More important is the condition of the muscle-reflex action shown by the state of the knee-jerk, the loss of which, as Westphal first pointed out, is one of the earliest and most constant symptoms of tabes. It is very rare for the knee-jerk to be obtained in any case of true tabes; its loss may precede years the onset of ataxy, although cases are sometimes met with in which it is lost only on one side and diminished on the other.

Many ocular symptoms occur in connection with tabes. Of these, the most important is the loss of the reaction of the pupil to light, while it still continues to act with accommodation—the so-called Argyll-Robertson phenomenon.² This condition is present in about five-sixths of the cases of tabes. Often also the normal dilatation that occurs on painful stimulation of the skin of the neck cannot be produced. The pupils may be very small, but not infrequently they are of normal size. Paralysis of different ocular muscles may also be present, with accompanying diplopia. The muscles supplied by the third nerve are most frequently affected, especially the levator palpebræ, causing ptosis. This paralysis may be transient—lasting a few days or weeks—or permanent. The former is most common in the early stage, the latter in the late stage of the disease. There may be a condition identical with ‘progressive ophthalmoplegia.’ Other cranial nerves are rarely affected, with the exception of those of the larynx. Abductor palsy of the vocal cords is an occasional and grave symptom.

Among the more serious and troublesome effects of tabes the various so-called ‘crises’ must be

enumerated. These are named after the various viscera affected. Thus, the most common are the gastric crises, which are manifested by severe sickness and nausea, often associated with epigastric pain. Severe attacks of laryngeal cough and spasm are not uncommon (‘laryngeal crises’). These are often associated with bilateral weakness of the abductors of the vocal cords. There are also vesical, bronchial, and rectal ‘crises,’ manifested by pain and other symptoms referable to the various viscera indicated.

The action of the sphincters is usually impaired. Retention of urine may be followed by incontinence. The latter is not infrequently the result of over-distension, and is often associated with cystitis. Constipation is common; in the later stages incontinence of fæces may be present. The sexual functions are usually altered. In the early stage there is sometimes increased sexual activity, associated with excess of the cutaneous reflex action, but in most cases there is impaired or abolished sexual power, often as an early symptom, but sometimes deferred to a late stage.

Vaso-motor and trophic disturbances are important. Among them may be enumerated local sweatings, disappearance of hair from the skin, ecchymoses, and altered growth of hair in connection with attacks of pain. The so-called perforating ulcer of the foot is almost confined to tabes, and is usually excited by cutting a corn too deeply. Changes in the teeth and nails also occur, leading to partial decay or total loss. Changes in the joints and bones are especially important, and were carefully investigated by Charcot. The bones may become brittle, and so render the occurrence of spontaneous fractures easy; but the most important condition is the so-called ‘Charcot’s joint,’ consisting in an irregular enlargement of the ends of the bones, often with atrophy of the articular surfaces. The irregular outgrowth of bone may be extensive, and the fibrous tissue is often accompanied by œdema outside it. The larger joints are most commonly affected, especially the elbows, knees, ankles, and tarsal joints. It is often excited by a slight sprain, which causes an excessive inflammation, followed by the chronic alterations.

COURSE AND TERMINATIONS.—The course of the disease is extremely variable. There are usually three stages—the first one, in which the gait is not yet affected (*pre-ataxic*); the second, in which there is distinct inco-ordination (*ataxic*); and a third, in which the ability to walk alone is lost (*paralytic*). The first stage varies in duration from a few weeks or months to as long as twenty-five years; and if the patients are subjected to careful treatment there is no progressive tendency shown in probably as large a proportion as one-half the cases. Some patients in the second or third stage may even much improve, so that a patient at one time unable to walk becomes able to get about with a fair amount of ease. When optic-nerve atrophy is present, this and the loss of the knee-jerk may remain for many years the only evidence of the disease. There seems less tendency in such cases for the spinal symptoms to increase.

The dangers of locomotor ataxy consist not so much in the rapid spread of degenerative processes in the nervous system as in the occurrence of renal disease secondary to retention of urine, which is apt to develop insidiously. Laryngeal palsy also

constitutes an element of danger; and suddenly occurring trophic disturbances have been known to prove fatal. General paralysis of the insane is a not unusual complication, or rather cerebral development of the same degeneration; and it runs the usual course as a rule. Valvular heart-disease is an occasional complication of the disease, and is probably the result of a syphilitic process. This also may lead to a fatal termination.

PATHOLOGY.—In discussing the pathology of this disease it must be recognised that in tabes the main incidence of the marked change is upon the afferent nervous system, and that it is a primary degeneration of the nervous elements. Its incidence is on the neurons, which have their nutritional centre in the cells of the posterior spinal ganglia, and the primary incidence of the disease seems to be on the afferent nerves from the muscles, and the fibres which continue their path, from the posterior ganglia, in the posterior median columns of the cord. The symmetry of the lesions suggests a blood-state as the cause, and the very frequent antecedence of syphilis leaves little doubt of its dependence on a post-syphilitic toxin, acting especially on these neurons, diminishing their vital endurance, and entailing their subsequent degeneration. It has also an action on the fibres of the optic nerve, and, in extreme cases, on many other structures in the nervous system. But its primary influence on the afferent muscle-neurons explains the early loss of the knee-jerk and the dominant ataxy. Similar changes and symptoms have been proved to result from other toxic influences, especially from alcohol. This may cause loss of the knee-jerk and ataxy from its action on the peripheral nerves, in what has been termed 'alcoholic pseudo-tabes.' The long interval which elapses between the primary disease and its nervous sequel is only in proportion to the chronicity of the primary specific disease; and the general conditions of its occurrence suggest that the action of the toxin is to induce the premature decay of the nerve-elements specially affected. This explanation enables us to understand the inutility of antisyphilitic treatment in tabes.

The variability in the amount of ataxy and the affection of cutaneous sensibility sometimes transcends the usual limits of the disease. After syphilis characteristic tabetic pains may occur, with loss of the light-reflex but without ataxy or even loss of the knee-jerk. In such cases there is often slight impairment of sensation in the skin, especially retardation to pain, and such cases may be designated 'cutaneous neuro-tabes.'

DIAGNOSIS.—Tabes dorsalis may easily be confounded with alcoholic neuritis. In the latter, however, there is the tenderness along the nerve-trunks, and the sphincters and pupils are unaffected. The history of alcoholic excess will also help in the diagnosis. This last, and improvement when the cause is withdrawn, are the chief distinctions in 'alcoholic pseudo-tabes.' The so-called hereditary ataxy 'offers some points of resemblance to tabes, but is distinguished by the earlier age at which it occurs, and the absence of the usual cause and of attacks of pain.' Diphtheritic paralysis may also bear some resemblance, but the history of the onset will usually make it distinct. Other forms of unsteadiness, such as ataxic paraplegia, are distinguished by the presence of the knee-jerk. Injury affecting the posterior columns,

or a tumour pressing on them, may simulate tabes but have distinctive symptoms. A tumour in the cerebellum, by giving rise to unsteadiness, may raise a diagnostic doubt, but its own special symptoms are never absent.

PROGNOSIS.—This must be based upon the considerations mentioned in the description of the course of the disease. Some cases are obstinately progressive, but arrest occurs, under treatment, in at least half the cases. It may be obtained in any stage, but is more frequent in the first, or 'pre-ataxic,' stage, before inco-ordination has developed. The prognosis is usually fair as regards duration of life, for the malady does not itself kill; and the most serious dangers to life may be to a large extent avoided. Optic-nerve atrophy is usually progressive, but not invariably so. The prognosis in any case must largely depend upon the ability and willingness of the patient to carry out necessary instructions and treatment.

TREATMENT.—Much can be done by treatment in tabes, at least to relieve, apparently even to modify considerably the course of the disease. The influence of rest and hygienic surroundings is very great. The avoidance of mental worry and fatigue is of the first importance. Exercise should be gentle, and should always stop short of fatigue. The avoidance of sexual excess is of the greatest importance, since it may lead to a most disastrous increase in the symptoms. Care should be taken to avoid dyspepsia and constipation.

Much certainly may be done by drugs. The almost invariable inefficacy of antisyphilitic remedies finds an explanation in the pathology already enunciated. It is seldom that anything but harm results from the energetic treatment for syphilis so commonly adopted. Arsenic is one agent generally useful. It may be combined with minute doses of mercury, such as seem tonic to those who have had syphilis, and may be alternated with phosphorus, quinine, and strychnine. Others that have been recommended are nitrate of silver, and ergot. Physostigma in some cases, belladonna in others, seems to have a slight beneficial influence, and in such a disease no agent even slightly useful can be despised. The writer has found chloride of aluminium very useful in lessening the tendency to attacks of pain. Counter-irritation to the spine is beneficial in cases in which symptoms come on acutely. The best way to apply it is by means of the mild actual cautery. Electricity has little influence on the disease. The application of faradism to the muscles to stimulate the afferent nerves might be expected to diminish the ataxy, and sometimes, but not often, does seem to exert a slight influence. The use of voltaic electricity, in any method, has no beneficial effect. Gymnastic exercises for the feet in the recumbent posture have been recommended, but they have not much influence on the steadiness of locomotion. Regulated steps in footmarks is more effective. Nerve-stretching and suspension, although once fashionable, have passed out of use as valueless. The attacks of pain and the crises are usually temporarily relieved, and often arrested, by antipyrine (15 gr.) or acetanilide (10 gr.). Hypodermic injections of the hydrochloride of cocaine are useful for superficial pains with tenderness of the skin. These may also be relieved by the application of chloroform sprinkled on lint covered with oiled-silk. The most severe attacks may, however, yield only to the hypodermic injection of morphine. Gastric

crises need treatment for any exciting cause, such as an attack of dyspepsia or constipation. Simple food must be administered, and the agents which relieve the attacks of pain may arrest the crises. In some cases morphine is necessary, by hypodermic injection. Laryngeal crises are usually relieved by nitroglycerine or nitrite of amyl. The condition of the bladder must be attended to most carefully. No hesitation should be felt in using the catheter as often or as early as is necessary, if the bladder is imperfectly emptied; and it should be washed out with a weak solution of boric acid if there is turbidity of the urine. The general hygienic conditions should be the best possible. Over-exertion and exposure to cold and wet should be carefully avoided. The course of the disease depends very much on attention to small details.

TAPPING.—A popular name for paracentesis. *See* PARACENTESIS.

TARANTISM (*tarantula*, a ground-spider).—An epidemic dancing-mania, prevalent in Italy in the sixteenth and seventeenth centuries, originating in fear of the bite of the tarantula, as a remedy for which the dance was adopted. *See* ECSTASY.

TARASP-SCHULS, in Unterengadin, Switzerland.—Alkaline sulphated waters. *See* MINERAL WATERS.

TARTAR.—*See* TEETH; and CONCRETIONS.

TARTAR EMETIC, Poisoning by.—SYNON.: Fr. *Empoisonnement par l'Antimoine*; Ger. *Antimoniumvergiftung*.—Poisoning by tartar emetic, a soluble double tartrate of antimony and potassium, is not very common. The emetic properties of the salt generally ensure its speedy ejection from the stomach. Poisoning by the salt may be either (1) *acute*, from the ingestion of a large dose; or (2) *chronic*, the patient succumbing under the exhaustion consequent upon its prolonged administration.

1. **Acute poisoning**.—Shortly after taking a large dose of tartar emetic, the patient is seized with intense nausea and faintness, accompanied by depression of the force of the pulse, and increased perspiration. Violent vomiting and retching follow, with a burning pain and sense of constriction in the

mouth, throat, and gullet. Vomiting affords no relief to the nausea and pain, and is repeated, the vomited matters becoming bilious, and ultimately perhaps blood-tinged. A metallic taste is felt in the mouth; the abdomen becomes painful and tender; and profuse diarrhoea sets in, the fæces often containing a considerable quantity of blood. The urine is at first increased in quantity; but later it may be scanty, blood-tinged, or suppressed. The circulation is throughout depressed; and the skin cold, clammy, and bathed in profuse perspiration. The muscular system is relaxed; but cramps of the extremities may torture the patient. In rare cases a pustular rash appears, like that produced by the external medicinal application of the drug. In some cases neither vomiting nor purging has occurred, the symptoms being simply those of intense prostration, with embarrassed respiration. In fatal cases death occurs within a few hours.

2. **Chronic poisoning**.—The administration of repeated small doses of tartar emetic causes nausea, vomiting, purging, exhaustion, and debility, which not infrequently prove fatal. These symptoms are accompanied by depressed irregular circulation, profuse perspiration, and disturbances of respiration.

ANATOMICAL CHARACTERS.—These are somewhat variable, but on the whole are those of a metallic irritant poison. In most cases there is inflammation of the stomach and intestinal tract generally, not so patchy or marked by such bright redness as in arsenical poisoning. Not infrequently the stomach and small intestines escape, and the inflammation may be confined to the large bowel; even ulceration of the intestines may occur, accompanied by hæmorrhagic extravasations. Hypostatic congestion of the lungs is often prominent.

DIAGNOSIS.—Poisoning by tartar emetic may be diagnosed from that due to other irritants, especially arsenic, by the greater and earlier depression, the profuse perspiration, greater irregularity of pulse, and the more irregular respiration. An analysis of the ejecta or of the urine is always advisable, and often indispensable to complete the diagnosis. In chronic cases an analysis of the urine is the only satisfactory mode of determining the nature of the illness, where tartar emetic is not known to have been administered as a medicine.

PROGNOSIS.—This must always be grave, so long as the ejecta contain considerable quantities of the poison. In acute cases the patient cannot be considered out of danger till not only the vomiting has ceased, but an obvious return of strength has set in for some time.

Fatal dose.—Fifteen grains may prove fatal to an adult. Much larger doses may, however, as a rule, be taken with impunity. The danger is much increased if the poison be taken in conjunction with some substance, such as opium, which deadens the susceptibilities of the stomach.

TREATMENT.—The stomach-tube may be used, notwithstanding profuse vomiting. The elimination of the poison may be hastened by free administration of diluents, and the stomach protected by mucilaginous drinks, or the stomach may be washed out by means of the siphon-tube. The most effective antidote is tannic acid, which forms an insoluble tannate of antimony. For this purpose tincture of cinchona bark, decoction of oak-bark, or strong infusions of tea or coffee may be administered; or the stomach may be washed out with similar fluids, or with a solution of half a drachm of tannic acid.

Not till after this has been done, or the stomach well and repeatedly cleansed by free vomiting, should opium be administered. The after-treatment will depend upon the symptoms. The treatment of chronic cases consists in cessation of the administration of the poison; in the exhibition of ammonia, stimulants, and tonics; and in careful support of the strength. Nutrient and opiate enemata are of the greatest service.

TASTE, Disorders of.—SYNON.: Fr. *Troubles du Goût*; Ger. *Störungen des Geschmacks*.

INTRODUCTION.—Disorders of taste have to be carefully distinguished from those of smell, on which all perception of flavour depends. The chief sensations of taste are those called sweet, sour, salt, bitter, and metallic. Flavours are sensations of smell due to an agent which reaches the olfactory mucous membrane through the posterior nares; their cause usually at the same time acts upon the nerves of taste, so that the flavour blends with the gustatory sensation, and seems like a part of taste proper. But if the sense of smell is lost, or even if the passage of air into the nasal cavities by the posterior nares is prevented, no flavour is perceived and taste alone remains. It is also necessary to distinguish disorders of taste from altered appreciation of the sensation—increased or diminished enjoyment of, or disgust at, sensations which are themselves normal.

The sensation is subserved by structures in the mucous membrane on the back of the tongue, the palate and the palatine arches, and to a slighter extent by those on the tip and edges of the fore-part of the tongue. On the last sweet and sour, on the former salt and bitter, are best perceived; but, except for individual peculiarities, all the sensations can be perceived in each region. The sense is related especially to certain ‘papillæ’ on the back of the tongue, but elsewhere to less differentiated structures of the mucous membrane. Substances must be in solution to excite the sensation, but the solution may be effected by the moisture on the tongue. A knowledge of these facts is important for testing the sense of taste.

In the front of the tongue the sensation is certainly subserved by fibres from the lingual branch of the fifth, belonging to this nerve, but reaching its root by a circuitous path—the chorda tympani, facial, and Vidian nerves, sphenopalatine ganglion, and thence to the fifth by the petrosal nerve. The nerve-fibres connected with the papillæ at the back of the tongue are those of the terminal branches of the glosso-pharyngeal, but disease of this nerve within the skull does not impair taste, and destruction of the root of the fifth nerve abolishes it, not only on the back of the tongue, but also on the palate. Apparent exceptions to this rule are probably due to imperfect destruction of the root, or to the disease of its fibres being within the pons. Hence it seems that the taste-fibres ascending from the back of the tongue leave the glosso-pharyngeal, just as those from the front of the tongue leave the lingual, and reach the root of the fifth by an equally

circuitous path, probably (from other pathological facts) chiefly by the tympanic nerve of Jacobson.

Within the pons, the fibres for taste seem to take a course separate from the proper sensory root-fibres, and lie at first near the motor fibres or nucleus, since the writer has met with complete loss of taste and paralysis of the muscles of mastication on one side, without anæsthesia, from disease within the pons. The path ascends to the opposite hemisphere of the brain, but the position of its cortical centre is not known.

1. Increased Sensitiveness of the Nerves of Taste.—SYNON.: Gustatory Hyperæsthesia; *Hypergeusia*.—This condition is manifested by detection of a substance too minute in quantity to be perceived by normal taste, or by an abnormally intense impression when a given quantity of a substance is tasted. In excitable states of the nervous system, as in general malnutrition, substances in small quantities in the blood are tasted with great readiness; the bitterness of morphine injected beneath the skin may be at once noticed (Wernich), and, for a long time after a bitter substance has been taken, whatever is tasted may seem bitter. Gustatory hyperæsthesia is often met with in hysterical persons, and sometimes in the insane. It is not usually a symptom of sufficient prominence to demand special treatment.

2. Perverted Sense of Taste.—SYNON.: Gustatory Paræsthesia; *Parageusia*.—This is not uncommon in neurotic states. Substances excite a different taste from that to which they naturally give rise. A bitter flavour, for instance, is detected in a simple saline. This condition is commonly conjoined with altered appreciation of the taste which is recognised, so that substances commonly considered pleasant are disliked, and those are enjoyed which commonly excite disgust. It is seen in a slight degree in some toxic conditions, but more frequently in psychical disturbances. In hysteria it leads to strange tendencies in diet. It is also met with, as a rare symptom, in some degenerative diseases, such as locomotor ataxy.

3. Subjective Sensations of Taste.—These may occur from disorders of the central nervous system, in hysteria, insanity, and occasionally as the aura of epileptic attacks. The sensation is usually of an unpleasant description, and is probably produced in the region to which the taste-fibres are conveyed by the branches of the glosso-pharyngeal nerve. It is remarkable (as evidence of the association of the cerebral centres) that sensations of flavour and of taste are combined in the epileptic aura, but a subjective sense of smell is always distinguished from these.

Subjective sensations of taste occur also, very rarely, from irritation of the gustatory nerves. They have been produced experimentally by galvanising the chorda tympani, when this has been exposed by disease of the internal ear; and have also occurred in some cases of disease of the petrosal part of the facial nerve. These subjective sensations have to be distinguished from abnormal sensations due to substances in the blood, or to secretions of the mouth. The treatment of the symptom is that of its cause.

4. Loss of the Sense of Taste.—SYNON.: Gustatory Anæsthesia; *Ageusia*.

ÆTIOLOGY.—Diminished sense of taste may be produced by: (a) Thickening or other changes in the mucous membrane of the mouth, rendering the

nerve-endings less accessible to sapid solutions. This is, however, a rare cause. (b) Local applications lessening the irritability of the nerve-endings. Hot or cold applications may temporarily destroy the sense of taste. Cool substances cannot be tasted so well as those which are warm. (c) Hysterical and other functional nervous disturbances. It then forms part of 'hysterical hemianæsthesia,' the unilateral loss of the special senses, accompanied by hæsthesia of the limbs and half of the trunk on the corresponding side. (d) A similar loss, in the same association, has been met with in rare cases of organic disease of the opposite hemisphere. (e) Disease of the nerves which conduct the sensation to the sensory root of the fifth nerve, especially of the tympanic plexus, in consequence of caries of the temporal bone. It is also often produced, in the front of the tongue, by disease of the chorda tympani, when a neuritis of the facial nerve passes up its canal.

SYMPTOMS.—Loss of taste involves the perception of bitter, sweet, sour, saline, and metallic qualities. These may be lost in varying degrees, sometimes entirely; occasionally some are more impaired than others. The loss, from disease of the nerves, may be on the whole or part of one side, according to the relation of the several nerves to the function in different parts of the gustatory region, as already explained. Each part of the tongue possesses the power of recognising every quality, but not in the same degree; bitterness and sweetness are appreciated chiefly by the glosso-pharyngeal at the back, acidity and saltiness by the lingual in the fore-part of the tongue, chiefly at the tip and edges. The onset of the defect may be sudden, as in hysteria; or gradual, as in most forms of nerve-lesion. It is usually unilateral; in rare cases both sides are involved. It is associated with other symptoms of loss of function of the affected nerves.

DIAGNOSIS.—Loss of taste has always to be carefully distinguished from loss of smell. All flavours are recognised by the olfactory nerve, and it is commonly assumed that when these cease to be perceived taste is lost. The power of tasting must be ascertained by powders or colourless solutions which shall convey no information. Citric acid, quinine, sugar, and salt, in powder or solution, answer well. The tongue must be held out, and the substance or solution placed on the part of the tongue it is desired to test, and after each observation the mouth must be rinsed with water. It must be remembered also that the anterior part of the tongue is almost destitute of the sense of taste, except on the edges and tip. If the loss is unilateral, the powder may be rubbed on the side of the protruded tongue, near the tip, with the finger, and the patient should indicate, by nodding or shaking the head, whether it is tasted, before the tongue is withdrawn into the mouth. The moisture on the mucous membrane is sufficient to dissolve the substance and enable it to act upon the nervous structures.

PROGNOSIS.—This depends on the cause, and the extent to which the morbid condition can be influenced by treatment. It is good in hysteria, less favourable in nerve-affections. The loss due to affection of the facial nerve is frequently recovered from, but may persist even when the function of the latter is recovered. In intracranial disease of nerves the prognosis is, as a rule, unfavourable.

TREATMENT.—The treatment in nerve-disease is that of the cause of the symptom. Stimulation of

the nerves in the tongue may possibly aid the recovery of function, and for this faradisation may be employed. Hysterical loss of taste, part of hemianæsthesia, is best treated by neglect. Where the loss depends on an affection of the mucous membrane of the tongue, local measures alone are effective, in so far as the treatment can be influenced.

W. R. GOWERS.

TEETH, Diseases of.—**SYNON.** : Fr. *Maladies des Dents*; Ger. *Krankheiten der Zähne*.

The teeth fulfil two principal functions: they serve for articulation and for the mastication of food. The loss of the teeth leads to many forms of dyspepsia, and it must be remembered that the loss of even some of the teeth may, through throwing their opponent teeth out of work, render inefficient a set of teeth which at first glance might appear to be adequate for mastication. The restoration of the missing teeth will often bring about the cure of dyspeptic troubles which diet and drugs have failed to influence. Elaborate cooking, while rendering the food of such consistence that it may even without much mastication be accessible to the gastric juice, has the effect of rendering its sojourn in the mouth too short for the action of the salivary ferments to be complete, and has the further indirect effect of giving the teeth too little work for their well-being. Teeth which are not subjected to the normal amount of attrition are more prone to decay, so that it has even been contended that a principal factor in the causation of dental caries is the removal of all hard and fibrous elements from the food. Moreover, disease of the sockets of the teeth is more apt to occur when they are in comparative disuse, while the self-cleansing action of the mastication of hard foods diminishes the pabulum left about the interstices of the teeth, and hence has a beneficial effect in diminishing the numbers of micro-organisms which swarm in a dirty mouth. This is exemplified by the clean and healthy condition of the teeth in wild animals and in the lower races of mankind, notwithstanding that the latter do not use a tooth-brush. But among civilised people, consuming much softened food, the use of the tooth-brush, and indeed of some form of antiseptic wash or tooth-powder, is indispensable in order to keep the mouth in clean condition. No degree of care attainable in everyday life will render the mouth sterile, but the number of micro-organisms in the mouth can be immensely reduced by proper care.

A perfect set of teeth should be typical in form, in which case the points of contact of contiguous teeth are rounded and small in area, and the colour a yellowish-white; they should not look very transparent, and pearly: transparent, bluish-white teeth appear to be specially liable to early and rapid decay. It was formerly supposed that such teeth were deficient in calcium-salts, but, so far as the dentine at all events is concerned, this has been shown not to be the case. The enamel, owing to the difficulty of isolating it in sufficient quantity, has not been investigated with the same completeness, and it is possible that differences of chemical constitution may exist in this, the first line of defence. All that can safely be said is that there is no known difference in the chemical constitution of good and bad teeth, though they can be recognised by the eye.

Defects in the form of teeth are very common and predispose to caries; they may be of the nature

of pits almost or completely going through the enamel, in which case they afford a lodgment for particles of food. Other defects take the form of lines marking a check of growth at some period, somewhat like the similar lines which are seen upon the nails. If the history of the child be inquired into, it will generally be found that they correspond with the stage of development of the tooth appropriate to the age at which some acute illness occurred. According to some authorities they are invariably due to rickets. Stomatitic affections, especially such as have been due to the administration of mercury, leave their mark upon the teeth in the form of an irregular, craggy, or honeycombed condition of the enamel; and the poison of inherited syphilis produces a peculiar form of tooth, to be presently more exactly described, but which for the present may be designated as a stunting of the portions first formed. Teeth, from their exposed position, are subject to accident and to irregularities of position, which are not uncommonly due to a disproportion between the size of the teeth and of the jaws, it being a fact that the jaws are more readily affected and more subject to variation than the teeth, as is well exemplified in short-muzzled breeds of dogs, whose teeth are almost always crowded.

1. Absorption of Permanent Teeth.—A process similar to that by which the milk-teeth are shed may be set up on the roots of permanent teeth and lead to their loss. A tooth which has been knocked out and replanted is very apt to be ultimately shed in this way, and teeth, the roots of which have long been the subject of slight irritation, are apt to be more or less absorbed, though this rarely happens with otherwise sound teeth. The pressure of an erupting wisdom-tooth will cause absorption of the root of the tooth in front of it, and an erupting canine may cause damage to a lateral incisor in the same way. The only symptoms are the loosening of the teeth and some tenderness on vertical pressure, due to the sharpness and roughness of the root; nothing can be done in the way of treatment.

2. Accidents to the Teeth.—A tooth which has been knocked out will usually, if cleansed and replaced in its socket, become again fixed. Under these circumstances the cementum appears to remain alive, though the pulp is killed. Hence a tooth knocked out should be well washed in boiled water or in a weak antiseptic solution and replaced; temporary support may be afforded to it by tying it to its neighbours or by moulding some gutta-percha round it.

3. Bacteriology of the Mouth.—Warmth, moisture, and the presence of abundant pabulum in the form of the saliva and buccal mucus, as well as of introduced foods, render the mouth an excellent culture-chamber for bacteria, while its exposed position and the frequent introduction of uncooked material supply it with a great variety of forms of micrococci and bacilli. The nooks and crannies in the interstices of the teeth furnish places where they can flourish with little disturbance, while the constant removal of their products by the swallowing of the saliva prevents any interference with their free development. Hence it might have been expected, as is the case, that a great variety of forms, some of which go on to the formation of zoogloea-masses and others to the formation of thread-forms and masses of spores, have been de-

tected in the mouth. Some difficulty attends their investigation, as a good many of them have not been successfully cultivated, and are hence not known in pure culture; the identification of these therefore rests on the unsatisfactory basis of morphological character only, and their biological characters are unknown. Hence it is possible that some of the filamentous forms, such as *leptothrix*, may be stages in the growth of other described forms. Some half-dozen forms occur in almost every mouth, and recently Goadby has succeeded in cultivating some which others had previously failed to grow. These all grow best on an alkaline medium containing gelatine; those which liquefy gelatine do not always liquefy the decalcified dentine-matrix, but those which liquefy blood-serum generally do so; these organisms are mostly anaërobic and work in an alkaline medium only. This being the case it is pretty clear that the initial stages of dental caries, when decalcification is the prominent feature, and its subsequent stages, when the whole tissue breaks down, are either not accomplished by the same organisms, or at least are not affected by the organism working under similar conditions; hence it is not surprising that no specific organism of dental caries has been discovered, and that it is generally believed that many different organisms may be able to cause it. Besides the organisms more or less peculiar to the mouth, over a hundred different forms have been found in it, some of which are pathogenic and some not. It would be out of place to enter into any detailed account of the organisms of the mouth here, but it may be mentioned that although no mouth is free from organisms, yet they are enormously more abundant in unhealthy and ill-kept mouths, in which sundry vibrios of 'comma' and spiral form are always present. It is certain that dental caries is dependent upon the existence of micro-organisms, and it is in the highest degree probable that *pyorrhœa alveolaris* is due to bacterial infection; hence the two commonest diseases of the teeth owe their origin to infections of this kind. Apart from the bacteria directly concerned in the causation of dental disease, the principal pyogenic bacteria are often met with, even where no suppurative affection appears to exist, such as the various kinds of *Streptococci* and *Staphylococci*; and, with less frequency, species of *Sarcina* have been found in the surface-layers of carious dentine. Comma-bacilli, like but not identical with Koch's cholera-bacillus, are often seen, and pneumococci are also common. Hence there is much to favour the idea that the mouth is often the source of otherwise inexplicable infections, and it is therefore of great importance that the mouth and teeth should be kept in such condition as to minimise the risk of their forming a focus of infection (*see ANEMIA, PERNICIOUS*, p. 55). Suppurations in connection with the teeth are exceedingly common; carious dentine appears to form a pabulum for many bacterial forms, and there is a growing belief that infection from the mouth is the cause and the means of keeping up certain gastro-intestinal troubles of an intractable character, while it is more than suspected that many other infections, the origin of which has been obscure, have come from the mouth. Actinomycosis of the lung has been distinctly traced to infection from the mouth, and septic pneumonia is a common sequela of surgical operations on the jaws and tongue. And as pathogenic bacteria are frequently in the mouth, quite independently of any operation

wound, it is reasonable to suppose that they occasionally find their way to the stomach or the lung. Thus, symptoms attributed to carcinoma of the stomach have been known to disappear with the cure of pyorrhoea alveolaris, a condition in which small quantities of pus loaded with organisms are constantly being swallowed; and Godlee records cases of this disease in which mistaken diagnoses of serious lung-disease have been made. He also records a case of acute glossitis, apparently due to infection from this disease. Beside these cases in which the connection is well proved, it is by some believed that malignant endocarditis, the recurring attacks of putridity in bronchiectasis, and other infections difficult to explain, may turn out to have their origin in the mouth.

4. Dental Caries.—This disease has no relation to caries of a bone, and so is in this respect misnamed. It is exceedingly common, the milk-teeth rarely escaping entirely, while there are few adults in whom it is not found in some degree. It invariably starts from the outside, generally on the enamel-covered portion of the tooth, and progresses inwards with increasing rapidity and spreads wider when once the enamel has been penetrated. Occasionally on exposed positions, where the softened portions are rapidly worn away, a spontaneous cure occurs, and a hard brown polished surface is left. This is termed *arrested decay*, and in it the dentinal tubes appear to be blocked up, perhaps by calcification of their contents. A similar result may sometimes be attained in suitable positions by cutting away the affected parts and thoroughly polishing the surface. Various histological changes occur, into which it is out of place to enter here; but it may be mentioned that, not only is the disintegrating material loaded with micro-organisms, but micrococci and short bacilli penetrate the dentinal tubes to a considerable distance beyond the area which shows any naked-eye changes. The first step in the process is decalcification, the lime-salts being dissolved by acids; these acids are furnished by fermentations leading to the production of lactic and other organic acids, and for their formation there are required fermentable material and the bacteria capable of setting up these fermentations. Subsequently the decalcified organic matrix, the collagen, is softened and broken down by a species of peptonising action; but whether prior to its liquefaction it undergoes conversion into gelatine is not known, though this would appear probable. No specific bacteria of caries have been discovered; it is probable that many different forms are capable of producing it. From this it will readily be understood that experiments in the production of artificial caries in a flask fail completely if the fluid be sterilised; but if it be not sterilised the process can with proper precaution be very completely imitated. And although the mouth cannot be kept sterile, the nearer it approaches to this state, and the less food remains lodged in it, the less will the teeth be attacked by caries. A curious feature of dental caries is that it is very rife in young and adolescent persons, but that during middle life it is comparatively easily controlled; in aged persons, however, it not infrequently again becomes rife.

ÆTIOLOGY.—The *predisposing causes* are local and general. *Local.*—The most important of these are defects of structure, such as deep pits, irregular or crowded disposition of the teeth leading to

lodgment of food and want of cleanliness; abnormal condition of secretions of the mouth, such as scanty secretion of saliva, met with in various states of ill-health, and very notably in fevers; and unsuitable diet—for instance, prolonged sucking of sweets leads to a gummy deposit on the teeth, probably due to mannite, a product of the fermentation of cane-sugar. Dyspeptic conditions probably influence the teeth locally by vitiating the secretions of the mouth; with a furred tongue one often sees the saliva stringy, that is to say, the mucus is in excess of the watery secretion, and this has a very damaging effect by interfering with the cleanliness of the mouth.

General.—Though the precise connection is not at present understood, certain general constitutional conditions are associated with abundant decay of the teeth. Thus during pregnancy the teeth often suffer more than at other times, and it is observed that markedly anæmic women rarely escape, though here the question may arise whether the state of the teeth and the abundant micro-organisms which are being continually swallowed may not be the cause of the anæmia (*see p. 55*). At all events, putting the mouth in order by the extraction of very bad teeth and the filling of others often has the most beneficial result upon the anæmia, even where the teeth had been previously fairly adequate for mastication. The teeth of patients placed upon a milk-diet on account of acute dyspepsia also suffer markedly, though here again there is room for doubt whether the disuse of the teeth and the supply of very suitable pabulum for the growth of bacteria may not be the real cause rather than the dyspepsia. It is also very doubtful whether such disorders as gout, rheumatism, diabetes mellitus, and tuberculosis, &c., so influence the teeth that ill-effects can be attributed to them, at all events otherwise than by the interference with digestion, and so with the oral secretions. It is also open to doubt how far bad teeth are inherited; there is a strong general impression that they are, but on the other hand, the environment is likely to be similar in the same family, and the upsetting of the old idea that teeth liable to early decay are, so far as the dentine is concerned, less highly calcified renders it more difficult to see how inheritance affects them. But it must be remembered that our knowledge is very incomplete on this point; thus it is possible that the enamel may be different in good and bad teeth; and that the lime-salts, while in the aggregate of the same amount, may be in different combinations. Of the organic matrix, also, practically nothing is known save that it is collagen. It is an over-statement of the case to say that there is no difference in chemical composition between good and bad teeth, though it is true that none has been demonstrated. *The exciting causes* have already been alluded to. They are comparative disuse leading to a loss of natural cleansing, or the presence of acid-forming bacteria and their appropriate pabulum and the lodgment of particles of food.

Acid medicines are incapable *per se* of initiating caries, but they may do much mischief by superficial action on the enamel, whereby it is roughened and bacterial plaques the better enabled to adhere, while the decalcifying process is thereby commenced.

Caries invariably commences from the outside; when it has penetrated the enamel it spreads

rapidly along the direction of the dentinal tubes, but it is also able to spread laterally, and always does so as it approaches the pulp. Some attempt at defence is frequently made, especially when the progress is not very rapid, by new deposits of secondary dentine on the threatened side; but this is rarely of much avail unless the caries is arrested by other means. Rapid caries leaves the softened dentine almost white; whereas when its progress is slow the dentine takes on a brownish discolouration, which is believed to be due to pigment-forming bacteria rather than to any form of decomposition of the organic matrix. Carious dentine has a peculiar odour, which has been compared to that of gangrene of the lung, or to the scent of the little neuropterous insect, *Chrysopa*. If it be not checked the pulp becomes infected, exposed, and inflamed, often ultimately dying in consequence.

TREATMENT.—Prophylactic treatment has already been indicated, and will be further dealt with under the head 'Hygiene of the Mouth' (see p. 1669). Remedial treatment consists in the removal of the carious material and the filling of the cavity with some suitable material, except in the few cases where complete removal and polishing of the residual surface is feasible. As caries is dependent on external causes, a small amount of carious dentine may sometimes be left in the floor of the cavity, if it be well soaked with an antiseptic and thoroughly sealed in, rather than run a risk of exposing the pulp in its removal.

5. Enamel, Pitted. — **SYNON.**: Mercurial Teeth (Hutchinson); Stomatitic Teeth; Honey-combed Teeth.

It is of great importance to distinguish between syphilitic teeth and other malformed teeth which have no similar signification. Much unnecessary distress has been occasioned by confounding teeth having rocky and pitted enamel with those which were truly syphilitic in their origin; and many persons supposed themselves to inherit syphilis, who merely possessed teeth bearing marks upon them which registered a temporary illness or a condition of depressed nutrition in childhood when the affected teeth were forming. Teeth with rocky and pitted enamel vary indefinitely as to the extent of their defective formation, from a slight horizontal grooving in the enamel, to a condition in which the whole surface is rugged, and studded with pits like a thimble. In extreme cases the enamel may be almost entirely wanting; but there is *no narrowing of the apices of the crowns of the teeth, and no crescentic notch in the superior incisors*, as in syphilis. The defects of the enamel are nearly always horizontal in their disposition; and even the pits have such an arrangement in series. This condition is most frequently seen in the permanent teeth, though sometimes in the temporary. It is most manifest in the first molars, the incisors, and the canines. Rarely it affects the bicusps, near the apices of the cusps; and still more rarely the whole bicuspid crown suffers. But it will be observed that the malformation is symmetrical in the corresponding teeth, and that in the different teeth it has occurred at a point in its development which each tooth had attained at one particular date; and probably the mildest and severest cases are essentially the same in their pathological meaning, the difference being only one of degree. It has been supposed by Hutchinson that this condition of teeth is the result of the

constitutional influence of mercury given in childhood; but it is extremely rare for mercury to affect the mouth in children, and it occurs in persons not known to have been treated with mercurial teething-powders. The microscopical structure of teeth, thus degenerated, shows that the condition is essentially one of imperfect calcification of the enamel; and any influence or disease of childhood, suspending for a time or depressing the nutrition, may quite possibly be an efficient cause.

6. Erosion.—Erosion is the name given to the process by which saucer-shaped cavities or grooves are formed on the labial aspects of the necks of the teeth. They are generally placed transversely; and though at times attacking all teeth, are most frequently seen on front ones. The surface of erosion is hard, polished, and often not at all discoloured until the pulp is approached, wherein it differs from caries; and the teeth attacked frequently become so weakened as to break off. Erosion seems to be due to a chemical solvent, the source of which is probably the gum-margins.

Some doubt remains as to its ætiology; it may be a softening due to the same agencies as the commencement of caries, attrition constantly removing the softened portions; and it has been suggested that it may be due to some agent which primarily attacks the organic portion, leaving the lime-salts free to be rubbed away.

TREATMENT.—The cavities due to erosion should be filled if deep enough; otherwise the sensitiveness generally present should be treated by nitrate of silver in the form of the solid pencil, which, however, discolours the dentine deeply, or by chloride of zinc.

7. Eruption of Wisdom-Teeth, Difficult.—Insufficiency of room in the jaw for the advent of the wisdom-teeth is sometimes attended by very painful and even serious symptoms, especially in the lower jaw. The wisdom-tooth remains impacted at the base of the ascending ramus of the jaw, growing and pressing against the second molar. This gives rise to inflammation and pain, wandering down the neck and arm, the latter being often weakened in muscular power. In acute and neglected cases, abscess forms at the angle of the jaw, and burrows about the cheek. One remarkable symptom is trismus, which is very usual in these cases, and is characteristic; the masseter muscle becoming contracted and firmly set, so that the jaws can hardly be opened a quarter of an inch. This locking of the jaw sometimes occasions very unnecessary alarm.

Reflex nervous symptoms are sometimes occasioned by the resisted eruption of the lower wisdom-teeth, and cured by removal of the cause of irritation. Upper wisdom-teeth occasionally give trouble by growing into and causing ulceration of the cheek.

TREATMENT.—The treatment depends much on the degree of obstruction. Excision of the flap of ulcerated gum which overlies the wisdom-tooth is occasionally sufficient to relieve the symptoms; otherwise removal of the wisdom-tooth is the proper cure. Where there is trismus, it is necessary to force open the jaws with a gag under an anæsthetic, and then extract the tooth if possible. If it cannot be reached, the second molar should be extracted. The relief to pressure thus afforded will often give complete relief, though if there be much suppuration in association with an obstructed wisdom-tooth, the

removal of that tooth is usually advisable. The trismus vanishes on extraction of the tooth.

8. Extraction of Teeth.—In these days it might hardly appear necessary to say that forceps should be sterilised either by boiling or by dipping their jaws into strong carbolic acid, yet many who would not think of using any other surgically dirty instrument are careless about tooth-forceps, notwithstanding that several fatal cases of septicaemia have been traced almost certainly to dirty forceps. If a little concentrated carbolic acid remains upon the jaws of the instrument it does no harm. It is a matter of everyday observation that the more the bone of a socket is damaged in an extraction, the more do subsequent inflammatory conditions prevail, so that this should be avoided as far as possible; the interior of the socket is filled up with and protected by clot, but any lacerated portions of the edge of bone denuded of their gum-covering rarely heal kindly.

9. Hæmorrhage after Tooth-Extraction.

When a tooth is extracted the nutrient artery of the pulp is torn across and usually soon ceases to bleed. When troublesome hæmorrhage ensues it is commonly from this vessel and not from those of the socket that it proceeds. Primary hæmorrhage is that which commonly occurs, and if there be no great damage done to the bony walls of the socket, is rarely difficult to arrest. Very hot or very cold water generally stops the bleeding at once, or failing this, temporary arrest of the bleeding by pressure of the finger over the open mouth of the socket often succeeds by giving time for a clot to form. Failing this, a tent of matico-leaf rolled up rough side outwards and placed in the socket of each root assists in the formation of a firm clot, but it may sometimes be necessary to pack each socket firmly with graduated compresses of wool dipped in styptic colodion or some other astringent, or the tooth itself may be used as a plug. The objection to using any form of plug is that the natural process of healing is greatly retarded. If the sockets be much damaged there may be a difficulty in making an efficient plug. The routine use of applications such as perchloride of iron is much to be deprecated; if there be any strong hæmorrhagic tendency a much larger bleeding surface is thus created. If these measures fail, a firm compress should be placed over the plugged sockets and pressure made upon it by means of the opposing teeth, which may be maintained by the help of a four-tailed bandage. The patient, even if faint, should take no alcohol nor any hot drink; a very hot foot-bath is of service, and in some cases an emetic, by its depressant effect, arrests obstinate bleeding. Hæmostatics may be given internally, but, as a rule, are inefficient. If it become necessary to extract a tooth for a patient in whom hæmorrhagic tendencies are suspected or known to exist, it is safer to plug the socket at once without waiting; in one such case the writer had no trouble with the tooth though the patient nearly lost his life from epistaxis, which came on immediately after recovery from nitrous-oxide anaesthesia. A few fatal cases have occurred in which the difficulty has been greatly increased by caustic applications; the actual cautery is of little use, as it is impracticable to reach the bleeding point at the bottom of the socket. *See p. 617.*

10. Hygiene of the Mouth.—The established fact that dental caries is dependent upon micro-organisms, and the growing belief that other infec-

tions may be due to the micro-organisms of the mouth, render it important that intelligent care should be given to keeping the mouth in a condition as pure as possible. The use of foods which require considerable mastication tends in this direction, and in so far as elaborate cooking defeats this end, the tooth-brush must take its place. A tooth-powder should contain some soap, or a soap may contain a polishing powder. In addition there should be some antiseptic which is efficient, and at the same time is not injurious to the teeth, nor to health if a little be swallowed. These requirements are fairly well fulfilled by benzoic acid and saccharin, but many other substances might be employed, such as thymol and the various essential oils. Where the form of teeth is such that particles of food lodge easily, they should be removed either by drawing silk between the teeth or by the use of a wooden or quill toothpick. Nothing conduces so much to the growth of organisms and the occurrence of caries as the lodgment of food, and antiseptic washes fail to reach the matter packed in between teeth. And in mouths where there is any suppurating an antiseptic mouth-wash should be freely used several times a day. Mercuric chloride is too unpleasant and too poisonous for everyday use in the mouth, but experiment has shown that by its use the nearest approach to a sterile mouth has been obtained. Hence for special purposes, such as the preparation of the mouth for any operation, it should be employed in the strength of 1:2500. It need hardly be said that no untreated carious teeth should be allowed to remain, nor should any suppurating stumps. *See also p. 209.*

Too little attention is paid to the condition of the mouth during acute disease. At such times a diet requiring no use of the teeth and vitiated secretions call for more than the usual amount of care. Nurses should be instructed, in every case in which it is practicable, to brush the patient's teeth with a soft tooth-brush, and to use a mouth-wash for the purpose. An agreeable one consists of Thymol, gr. iij; Benzoic Acid, ʒss; Oil of Wintergreen, ʒss; Sp. Vini, ʒiij, enough to be dropped into a wine-glass of water to make it quite cloudy. Condy's Toilet Fluid much diluted is also often very refreshing when the patient's mouth is dry and an unpleasant taste is present.

11. Anomalies in Number, Shape, and Position of Teeth.—These are for the most part of interest to the dentist only. Total deficiency of teeth sometimes occurs, the subjects commonly having other abnormalities, such as hair all over the face and body, or sometimes partial deficiency of hair, or imperfect development of nasal bones, or of the external ear. Individual teeth are sometimes absent, the lateral incisor being the one most frequently suppressed, and this peculiarity sometimes occurs in so many members as to become almost a 'family mark.' Occasionally also a temporary tooth is retained and it becomes a question whether it should be extracted or not. The existence or non-existence of its permanent successor can often be determined by a skiagram. Excess in number is also met with, the added teeth being termed supernumerary teeth; they are usually abnormal in form and furnished with imperfect roots.

Wisdom-teeth seldom conform exactly to the form typical of the human molar, at least in the higher races of mankind, and together with their irregularity of form there is great uncertainty in the

date of their eruption. Hence it is argued that the wisdom-tooth is gradually disappearing in the higher races of mankind.

Anomalies in position are very common and are more often due to overcrowding than to any other cause, the growth of the jaws being inadequate to provide space for the teeth to occupy a regular arch. Apart from the disfigurement the crowding tends to the lodgment of food and so to the decay of the teeth, so that it should never be neglected. In children with 'adenoids' the habitually open mouth seems to lead to a transversely contracted arch so that the range of the teeth is more or less V-shaped, and thumb-sucking through continued pressure leads to a deformation of the jaw in which undue prominence of the front teeth is the most conspicuous effect. See p. 716.

12. Loosening of Teeth.—See 16. Periosteum, Diseases of Dental.

13. Necrosis of the Jaw and Teeth after the Eruptive Fevers.—Necrosis of the jaw and teeth is among the secondary maladies which are apt to occur after small-pox, scarlet fever, and measles in children, and the cases are all singularly alike. They usually occur between the third and eighth years, and the severity of the previous attack of fever is immaterial. The local symptoms, which usually appear from three to six weeks after the primary disease, consist in a separation of the gum around one or more of the temporary teeth; and this continues until the bare jaw is exposed to a depth which corresponds not only to the temporary teeth, but to the bony capsules of their immature successors. Transverse ulceration then usually follows; and the temporary teeth, their alveoli, the immature permanent teeth, and their bony capsules are shed. Frequently this occurs on both sides of the mouth symmetrically. There is no swelling or formation of supplemental bone. In the lower jaw, the base of the bone is rarely, if ever, involved; and the consequent disfigurement is singularly slight. These exfoliations occur much more frequently after scarlet fever than after measles; and they are rare after small-pox. Limited necrosis occurs sometimes in consequence of alveolar abscess, and sometimes thin flakes of the alveolus overlying the front teeth necrose without apparent cause. More severe necroses also occur when arsenical dressings have escaped from the tooth-cavity.

TREATMENT.—The treatment of these cases should consist in as little local interference as possible. Little need be done, beyond attention to cleanliness and deodorisation, and the removal of the sequestra when quite loose. The general condition of the patient will require careful treatment.

14. Phosphorus-Necrosis.—Workers in match-works are subject to necrosis of the jaws, sometimes of great severity. The accepted idea has been that they are only in danger of this when there are carious teeth, it being supposed that the poison obtains direct access to the bone through the tooth-cavity. There can be no doubt that it is important that the teeth in lucifer-match workers, notably where ordinary phosphorus is employed, should be carefully attended to, but it is open to doubt whether the common explanation of the causation of the lesion is correct. There is not the smallest reason to suppose that the existence of a carious cavity, before the pulp has become involved, can be a means of access; it is only when the pulp has become involved and is dying or dead that it can

be important. And in the majority of cases which have been sufficiently well recorded, the mischief has only happened when teeth were dead and suppurating. As there are cases of phosphorus-necrosis occurring long after the patients have ceased to work in match-factories, and as there is some evidence to show that in persons long exposed to the fumes of phosphorus (it being probably the lower oxides which are the most mischievous) other bones in no way exposed get affected, it seems probable that the frequent incidence upon the jaw-bones is rather to be explained by the supposition that the poison induces a general condition of pre-disposition to periostitis and necrosis, while the jaw-bones being through the medium of septic teeth infinitely more frequently affected with periostitis than any other bones naturally become the usual site of this form of necrosis. The treatment is to be conducted on general principles, premature interference being especially harmful. See p. 1113.

15. Nervous disorders caused by the Teeth.—The most frequent and the most familiar of these is pain of neuralgic type referred to spots at a distance from the teeth, and unaccompanied by localised pain in these organs. Thus pain may be felt in the eye, in the region of the ear, in the supra-orbital region, or even in the neck and upper arm; and this pain may come and go at definite times in the day, being temporarily cured by a meal, being induced by extra fatigue, and in fact behaving precisely like what we term a neuralgia. Hence a pain that is relieved by quinine and not felt in any tooth may nevertheless be due to disease of the teeth. The condition which is usually found in such cases is a very local but intense inflammation of the pulp of one of the teeth; when the inflammation of the pulp is more widespread local pain is seldom absent (see p. 1671). Pain of a neuralgic type may also, but less commonly, be produced by other causes such as exostosis of the roots of teeth, while inflammatory affections of the roots of teeth generally cause a distinctly local pain. Paroxysmal neuralgia of excessive severity, the 'tic' of older writers, is rarely, if ever, due to diseases of the teeth.

Besides pain other reflex disturbances may sometimes be traced to teeth. Lachrymation on the affected side, blepharospasm, and even amaurosis have been observed, and such severe nutritional disturbance as glaucoma has been attributed to the same cause. Muscular spasm in the form of trismus has been alluded to in connection with the eruption of wisdom-teeth, and the writer has seen strong and very painful spasm of the muscles which open the jaw induced by closure of the mouth making contact with an exceedingly tender spot; the spasms continued for some time afterwards.

Nerves may become involved by direct extension of inflammation from the teeth; thus the facial nerve has been partially paralysed by inflammation extending from an upper wisdom-tooth; the inferior dental nerve has been similarly involved in its bony canal, and the nerves passing through the upper jaw have been affected: these cases are rare.

16. Periosteum, Alveolar Dental, Diseases of (Periostitis).—SYNON.: Periodontitis; Pericementitis.—Mechanical injury, such as blows upon the teeth, and in rare cases general conditions probably of rheumatic character, may induce periostitis, in this latter case affecting many or all of the teeth simultaneously. Mercury also will cause it if pushed too far, and it is sometimes observed in

tertiary syphilis independently of the administration of mercury.

In the vast majority of cases, however, dental periostitis is septic and is due to infection through the apical foramen by which the vessels and nerves enter the tooth-pulp. It is associated with a dead or nearly dead tooth-pulp, which is always crammed with organisms of a highly virulent character. The periosteum has some little power of resistance, so that when infected it by no means always runs on to suppuration, if early treatment is undertaken. If the septic material is not afforded free exit and antagonised by antiseptics, the inflammation spreads widely through the tooth-socket, while suppuration occurs at the apex of the root which becomes detached and lies in a small abscess; if the tooth is extracted at this stage the abscess-sac comes away with the root. If the root-canal is not sufficiently patent to give exit to the pus, the overlying bone becomes perforated and the pus finds an outlet between the alveolus and the lip or the cheek, or sometimes makes its way to the outer surface and points on the face.

In the earlier stages the tooth is elongated and tender, though gentle continued pressure often affords relief, and the margin of the gum is marked by a red line. In the later stages the pain is severe, especially at night and in the recumbent position, and does not abate until the pus has found an exit from the bone. Then external swelling appears, and with its appearance the pain usually moderates, unless the case is of exceptional severity. A chronic gumboil which provides free exit for any pus that may form is not necessarily painful nor is the tooth always tender. In a few rare instances the infection has been so intense that diffuse osteitis is set up with consequent necrosis; and even fatal cases occur. These fatal complications take the form of septicæmia, pyæmia, erysipelatous inflammations of the face and neck, or extension of inflammation through the foramina at the base of the skull to the meninges.

TREATMENT.—Cases of simple periostitis, whether due to injury or to constitutional conditions, do not run on to suppuration. Rest to the affected teeth, slight counter-irritation such as the application to the gums of equal parts of Tincture of Iodine and Fleming's Tincture of Aconite, warm lotions and the like, are generally sufficient to give relief. When constitutional conditions exist they should be appropriately treated. Iodide of Potassium in a few full doses is often of great value in general dental periostitis, although it itself is capable of actually causing a similar condition when its use is prolonged. In septic periostitis the first thing to be done is thoroughly to open up and disinfect the offending tooth, taking especial care that the root-canals are cleansed and pervious to their very ends; and if there is reason to suppose that any pus has already been formed the tooth should be closed but very lightly, so that there may be drainage. For this disinfection peroxide of hydrogen is one of the best agents, or perchloride of mercury may be used. So soon as it is found that the inflammation has subsided and the interior of the tooth is clean and aseptic, the root-canals and the cavity may be filled. The tooth is then harmless, and although the pulp is gone and the dentine dead, the cementum remains alive and has healthy periosteum attached to it. Such a tooth must not be filled (unless there be a fistula on the gum) till

all suppuration has ceased, and the success of the operation depends on the completeness with which the roots can be disinfected and filled; with teeth with large and straight roots the percentage of success is very high. If inflammation has extended far beyond the immediate surroundings of the tooth, and does not yield to treatment promptly, it may be advisable to extract it.

A chronic abscess-sac on the root of a tooth sometimes becomes apparently cystic and contains cholesterolin. Although the cementum of a 'dead' tooth, i.e. a tooth of which the pulp is dead, usually remains alive, it also may die, and the tooth is then described as 'necrosed'; if not extracted it will speedily be expelled by suppuration. This result has been known to follow an arsenical dressing if too large a dose be used, or if it be left too long in the tooth after the destruction of the nerve has been accomplished. The periosteum may become detached from a portion only of the cementum, the rest remaining alive and healthy; such teeth may be long retained.

17. Exostosis of the Cementum.—The normal cementum on a human tooth is quite thin, but it is subject to subsequent deposits which may thicken it. This may occur on sound teeth as well as upon those which are diseased, and may take the form of nodular excrescences, or may be generally distributed. The bony socket is absorbed to make room for it, and it may lead to the fusion of the several roots which were originally distinct or may even unite the roots of two contiguous teeth. A peculiarity of the process is that it is generally intermittent, periods of absorption alternating with those of deposition, the latter preponderating. In slight degree it gives rise to no inconvenience; but when considerable, the tooth may become tender to percussion, and may give rise to pain not very distinctly located, and even to considerable neuralgia. Sometimes the enlargement can be felt through the gums, but it is often impossible to diagnose it with certainty except by the help of a skiagraph (which, however, is by no means always conclusive), until one or more teeth have been extracted and seen. A good many of the teeth are usually affected, often successively, and nothing can be done in the way of remedy save extraction. But a dead tooth which has repeatedly been the subject of slight degrees of inflammation is usually the site of more or less exostosis, and this would be no indication that others are likely to be affected.

18. Tooth-pulp, Inflammation of.—When the pulp is actually exposed, or sufficiently nearly so to be infected by organisms, inflammation speedily ensues. This may be limited to a small area, in which case pain may be absent, slight or severe, intermittent or neuralgic in type; or it may involve the whole pulp, in which case pain is always severe, throbbing, aggravated by changes of temperature, or by anything which increases the blood-pressure, such as dependent position of the head. When cold water held in the mouth gives relief, and the pain returns as soon as the tooth warms up again, severe inflammation which will soon result in the death of the pulp *en masse* may be diagnosed. The tooth-pulp is singularly devoid of recuperative power: when once it has ached severely there is no chance of its ultimate recovery to health, and the sooner it is killed the better for the patient's comfort. The death of the pulp is generally sudden; a violently aching pulp ceases to ache

almost abruptly, and this cessation is coincident with thrombosis of its nutrient vessels. A period of freedom from pain then ensues during which decomposition of the pulp takes place, toxic products and organisms escape from the apical foramen, and periosteal inflammation and ultimately gumboil follow. These sequelæ may not take place if the opening into the pulp-cavity is sufficiently free to allow of the escape of gas and other liquid products by that route.

Acute general inflammation of the pulp may also be caused by changes in temperature conducted through metallic fillings which are too close to it without any actual exposure having ever existed.

TREATMENT.—Pure carbolic acid or creosote applied on a pledget of wool to the exposed spot will often give temporary relief, if the inflammation be not of the most violent character, but the nerve should as soon as possible be destroyed with arsenious acid, of which about a sixteenth of a grain is sufficient; if the nerve be left to die of itself there is much more risk of septic infection of the periosteum, but the application of arsenic requires skill and care. It should be very exactly applied to the point of exposure, as if it gets to the pulp imperfectly it causes unnecessary pain by further irritating it without speedily killing it. If any of it escapes on to the gum it causes sloughing and even exfoliation of portions of the edge of the socket. It should not be left in more than two days, when the dead pulp can usually be removed.

When the inflammation is localised it sometimes happens that the congested pulp swells through the opening and, new-growth taking place in it, a polypus of the pulp, which may fill up the whole of the carious cavity, is formed. This appears not to contain nervous tissue in any quantity, as it is usually not tender to the touch, unless pressure be indirectly made thereby on the pulp within the walls of the pulp-chamber. Such a pulp may still be destroyed with arsenic, but the ultimate results are not very satisfactory; no pain is attendant on this condition. A special bacillus, *B. gangrenæ pulpæ*, has been described as infesting dead pulps; the reaction is always alkaline, so that softening of the walls of the pulp-cavity in the root does not usually occur.

19. Tooth-pulp, Degenerations of the.—In old age and in teeth which are loosening the pulp loses to a considerable extent its nervous and cellular elements, which are replaced by fibrous tissue. When subject to slight but prolonged irritation, such as is produced, for instance, by gradual wearing down of the tooth until the pulp is approached, it may partially or wholly calcify, so that it does not become exposed on further wear. Irregular calcifications in the form of hard nodules also occur in its substance even in sound teeth; these are often unsuspected as they cause no inconvenience, but occasionally, perhaps, because they have involved nerve-filaments, they cause neuralgic pains and hyperæsthesia of the tooth. They never, however, cause ordinary toothache of any severity.

20. Pyorrhœa Alveolaris.—This disease is of much importance on account of its frequency, and because in it the patient is swallowing in the twenty-four hours larger quantities of pus than in any other dental disorder. The first indication seen is that the margin of the gum, which ought to adhere closely to the necks of the teeth, is in places detached from them and is thickened. Even at

this stage, though more markedly later, if firm pressure be made with the finger, a trace of pus or blood-stained fluid can be squeezed out of the intervening space. As it progresses, the detachment proceeds to greater depth, so that an instrument or a piece of silk can be passed down for some distance between the tooth and its socket, the pouch ultimately often extending the whole length of the root, and leading to the complete detachment and loss of the tooth. Several teeth are affected, and it may extend round the whole mouth. From these pouches there is a continual secretion of pus, which is swallowed during the day, but at night sometimes runs out and stains the pillow. This pus is full of organisms, but no specific organism of the disease has been discovered. As it progresses, the edges of the sockets are absorbed, the absorption being deepest next to the tooth, so that the edge is cupped and the appearance readily recognisable in a macerated skull. It thus progresses from the surface inwards; but it is not certain whether it originates in the gum, in the edge of the alveolar periosteum, or in the edge of the bone itself. It was formerly supposed to be set up by the irritation of deposits of tartar; but there are many reasons for rejecting this idea: the tartar, when present at all, is secondary, being deposited in the vacant pouches. There is neither tenderness nor pain in its earlier stages, so that it is often overlooked. It is rare before middle life; but although it has much in common with the processes by which teeth are lost in advanced age, it appears to be distinct from these, especially in the abundance of the secretion. It appears to spread from tooth to tooth, but it is not clear that this is by virtue of an infection, as it is apt to be more or less symmetrical on the two sides of the mouth. Its ætiology remains obscure, and it is not certain that it is connected with any recognised constitutional condition, though a somewhat similar disease is found in stall-fed animals and in some wild animals kept in confinement, notably the lemurs. Perfectly sound teeth are attacked at least as frequently as those which are or have been carious.

TREATMENT.—This is unsatisfactory; for although great temporary improvement can easily be attained, the disease almost always recurs. The margins of the gum should be painted with cocaine, all tartar carefully removed, and the pouches syringed, any especially deep ones being slit up. Into the larger pouches a strong antiseptic is passed by means of filaments of wool, or into the smaller pouches by means of a thin slip of wood. Powdered sulphate of copper, with or without carbolic acid, gives good results, and is not harmful to the teeth. Mercuric chloride (1 : 500) is sometimes used, and this treatment is repeated every three or four days till improvement is seen in the diminution or absence of secretion. The patient can be instructed to carry it out for himself in accessible positions, and in addition the teeth should be brushed with a soft brush and an antiseptic mouth-wash several times a day. Shampooing the gums with the finger-tip tends to empty the pouches, and at the same time to remove the congestion which is always present.

21. Syphilitic Teeth.—Hutchinson first pointed out that children who inherit syphilis are liable to characteristic deformity of certain teeth, and that this is not infrequently associated with specific interstitial inflammation of the cornea. Syphilitic

teeth are small, narrow, more or less pointed, and usually of a dirty-grey colour. Both the temporary and permanent sets may be affected; but it is the front teeth of the latter, and often the first permanent molars, that exhibit the characteristic and most marked deformity. The lower incisors are peggy and pointed; those of the upper jaw are narrowed, instead of expanded towards the cutting edge; and the central incisors frequently have a crescentic notch. This is due to the tooth having been subjected to a stunting influence at the period when its calcification commenced. Later on this is more or less surmounted, so that the parts first formed are the smallest. The other irregularities of shape in the teeth may arise, or be closely imitated, where there is no specific taint, but the crescentic notch in the contracted cutting edge of the superior permanent central incisor is believed to be diagnostic of inherited syphilis. Hutchinson considers that these malformations of teeth are occasioned by specific stomatitis. But perverted form and nutrition need not be inflammatory in origin; and it may be doubted whether such action arises in these cases. The teeth are dermal organs, and upon the skin syphilis inflicts some of its chief injuries.

22. Tartar.—The teeth at or near the margins of the gums are liable to become coated with a more or less hard deposit of lime-salts derived from the saliva. This consists mainly of calcium phosphate, with a varying proportion of calcium carbonate and a certain proportion of organic matter; a large variety of bacteria thrive in it. It is of importance that it should be removed; for it is uncleanly, is a nidus for bacteria, and causes an unhealthy condition of the subjacent gum. Its accumulation may lead to a progressive recession of the gum, with waste of the alveolus and the loss of the tooth. It is more than doubtful, however, whether it can actually set up the condition described as *Pyorrhœa alveolaris*. When it is present in that disease it is probably secondary to it. A form of tartar is found deep in the alveolus where pouches exist which is darker in colour and harder; all sorts of hypotheses, quite unsupported by any reliable evidence, have been propounded as to its real nature, one being that it is a gouty deposit containing uric acid or urates. See p. 334.

23. Toothache, Diagnosis of.—It may be convenient to enumerate the ordinary causes of toothache and their diagnosis, although this involves some recapitulation.

Pain tolerably constant: (1) *Teeth tender to pressure.*—Dental periostitis, septic or general; advanced stage of *Pyorrhœa alveolaris*; pressure exercised by un-erupted tooth on its neighbours.

(2) *Teeth not tender to pressure.*—Inflamed pulp, locally or generally; irregular calcification of pulp (rarely).

Pain intermittent.—Localised inflammation of pulp; exostosis; mild periostitis; calcifications in pulp.

Great sensitiveness to change of temperature.—Exposed pulp; inflamed pulp, the latter more aggravated by heat than by cold, which often relieves it.

Moderate sensitiveness to change of temperature. Pulp nearly exposed; slight inflammation of pulp; periostitis; exostosis. See also PAIN IN VISCERAL DISEASE, p. 1144.

The examination of the teeth should be made systematically. They should first be inspected with

a dental or laryngeal mirror, and cavities searched for with a fine instrument. Then the teeth should be tapped in succession, to find if any be tender, and finally they should be individually tested with heat and cold. The former can best be applied by touching them with a heated instrument, the latter by a pledget of wool dipped repeatedly in cold water. Finally the patient should be asked to take a mouthful of warm water, followed by one of cold water. See also RÖNTGEN RAYS, p. 1437.

With regard to teeth already filled, it must not be forgotten that a tooth-pulp may be dying under a filling which has in no way failed.

S. J. SALTER.
C. S. TOMES.

TEETH, Grinding of.—Automatic movements of the mouth are common to many diseases, especially in young subjects. The movements may be vertical, as if the patient were chewing, or lateral, the teeth being ground together, so as to give rise to a hard unpleasant grating sound. This symptom is not necessarily dependent upon disease, as it may occur in excitable children during sleep, and is often an indication that too much excitement or fatigue has been permitted. Grinding of the teeth may be observed at all ages, and in many different complaints. It is commonly present in cases of cerebral disease and of intestinal disturbance, being often, and probably erroneously, attributed to the presence of worms.

Sometimes children will grind their teeth voluntarily, and apparently with full consciousness of what they are doing. Such cases are, however, rare.

The treatment of teeth-grinding consists in the correction or removal, if possible, of the condition upon which it depends.

TEETHING, Disorders of.—See DENTITION.

TEICHOPSIA (τεῖχος, a wall; ὄψις, vision).—A visual sensation occurring in megrim, and consisting of a dark zigzag line suggestive of the ground-plan of fortifications (p. 972).

TELANGEIECTASIS (τῆλε, far; ἀγγεῖον, a blood-vessel; and ἐκτασις, a dilatation).—Dilatation of capillaries. See TUMOURS.

TELEGRAPHIST'S CRAMP.—See OCCUPATIONAL-DISEASES.

TELESE, in Italy (Benevento).—Sulphur-waters. See MINERAL WATERS.

TEMPERAMENT.—SYNON.: Fr. *Tempérament*; Ger. *Körperanlage*.—In its earliest significance this term was used to denote a relation between the physical characteristics of each individual and his mental attitude to external stimuli of various kinds. Subsequently its significance was narrowed until at the present time it is used in a loose way to indicate the mental characteristics alone.

It was early recognised that no two individuals are exactly alike, either in conformation of body or in attributes of mind. An endeavour was therefore made to group men in definite classes according to their salient characteristics. This endeavour took shape in the recognition by Galen of temperaments which depended upon variations in the amounts of 'fire' and 'water' that entered into their

composition, these being the two of the four 'elements' that were supposed to take part in the process. Galen, therefore, described nine different kinds of temperament. First there came the *ideal* or *balanced* temperament, which was neither hot nor cold, moist nor dry, and in which all qualities of body and mind were therefore present, but no single one present either in excess or deficiency. Then followed four temperaments of simple excess or deficiency, forming the *hot*, *cold*, *moist*, and *dry* types. Lastly came four types in which the two elements were mixed, with the formation of the *hot and dry*, *hot and moist*, *cold and dry*, and *cold and moist* temperaments. Of this classification we still see remnants in the expressions 'hot-tempered,' 'cold-blooded,' and probably also in that of 'dry humour.'

As time went on, the doctrine of 'spirits' arose and exerted its influence upon the doctrine of 'temperaments,' as witness the expressions 'high-spirited,' 'mean-spirited,' 'volatile,' &c.

With the re-entry of the humoral theory into physic an alteration took place in the nomenclature of temperaments, while at the same time an effort was made to correlate the mental characteristics with physical peculiarities determined in some degree by anatomical factors. Here were introduced many of the uncertainties of anatomy. These uncertainties were least in the case of the heart, the connection of which with the blood was about the most certain point of ancient knowledge in anatomy. Of the three types of temperament, therefore, that were recognised at this period, viz. the *sanguine*, the *melancholic*, and the *choleric*, the *sanguine* was regarded as being bound up with a special development of the heart, but the seats of dominion over the other temperaments were more uncertain. Thus there is the greatest difficulty in arriving at an opinion as to the organ that was supposed to be concerned with the choleric temperament. Etymologically the liver with its formation of bile would seem to have been so regarded, but the bile was supposed to be concerned especially with the production of melancholy, and one can hardly credit physicians at this early date with a conception of the multiple functions of the liver, especially when so important a mass of tissue as the spleen remained unappropriated to a temperament. The confusion is still further increased by the fact that by some of the old writers the spleen is definitely stated to be associated with the production of the choleric temperament. The word 'testy' indicates that at a later date the head was substituted for both liver and spleen in this connection. Use of the expression 'lily-livered' by Shakespeare shows that at even his comparatively late date the influence of the liver upon the production of terror was regarded as certain.

Still later the theory of temperaments underwent further compression and modification, with the result that only three varieties—the *sanguine*, the *nervous*, and the *lymphatic*—were recognised. It is unnecessary to discuss the features of these temperaments in detail, but it may be said that the compression took place chiefly in the physical direction, so that although certain broad features were held to characterise the three temperaments so far as the anatomical conformation of their possessors was concerned, the principal force of the distinctions lay in the different classes of character that they described.

With the foregoing brief sketch the theory of temperaments has been brought up to the present day. But it must be confessed that our greatest difficulty has now only begun. For the question is treated both by physicians and by psychologists, and except, to some degree, in the matter of terminology, no two authors agree; while the divergences between the physicians and the psychologists as classes of writers are remarkable. Speaking generally, however, it may be said that modern writers recognise four different kinds of temperament—the *sanguine*, the *choleric*, the *melancholic*, and the *phlegmatic*. These expressions at the present day have entirely lost any significance that they formerly had with reference to the anatomical characteristics of the individual, so that the term 'temperament' has come to possess an entirely psychological significance.

The greatest difficulty with which we have to contend in reference to consideration of the subject of temperaments is that we are face to face with a number of terms that have obtained a firm root in the language. It therefore becomes a question not merely whether we ought or ought not to break loose from all old traditions and build up a fresh doctrine of temperament upon the basis of scientific experiment; but the question also arises whether we can do so, even if we consider that such an iconoclastic course is advisable. The very fact that it has long been customary to speak of four kinds of temperament is even regarded by one writer (Wundt) as a reason why such a division should be fundamental.

The present position in which the matter finds itself is due to the fact that the subject has not been approached from the point of view of experiment. Modern medicine is so strongly bound up with experimental methods that all forms of knowledge that are not founded upon experiment are regarded with disfavour, if not with suspicion. But though such a course is intelligible it is not justifiable. For there is no doubt that persons differ considerably in their mental and physical reactions to external stimuli, so that among men we meet with the pessimist or melancholic person and the optimist or sanguine, to mention two of the most striking contrasts. It must be conceded that the reactions of individuals to external stimuli are largely influenced by education and surroundings. But since we see that the temperaments of parents are reproduced in their children, no less than are their physical characteristics, we shall probably not err if we hold that temperament may be inherited, however much its main characteristics may be subsequently intensified or modified by other factors. Further, even if we put on one side the general impression that the mental characteristics of a child are liable to resemble those of the parent to which it bears the greatest physical resemblance, we are still forced to recognise the fact that the mental processes must result from chemical and physical processes taking place in cells. That is to say, there must be a physical foundation for the mental aspect of temperament. Without presuming, therefore, to assert what must be the way in which temperaments are to be divided in the future, it may be pointed out that inquiry will have to take place in two directions—the physical and the psychological. Physical research will have to be partly ethnological and partly individual, and the same is true of the psychological side of the question.

Upon the physical side a certain, though very small, amount of work has been done already. We know that the specific gravity of the blood is lower in persons with light, than it is in persons with dark hair, eyes, and complexions (Lloyd Jones). Moreover, we know that the specific gravity of the blood-plasma which is normal for one class of individuals is not normal for another class; that some persons in perfect health breathe more slowly than others who are quite comparable with them; and that rates of heart-beat vary in healthy adult individuals of the same sex under conditions that are identical so far as we can determine. And a few other facts of a like nature are known.

Upon the psychological side it is only within the last few years that the subject has been approached from the experimental side at all. Such work as has been done we owe to Kraepelin and his pupils, and they have certainly added a number of points of the greatest importance from the individual side. From the ethnological point of view little or nothing has been done upon this aspect of temperament. Nevertheless the predominating minor character of Anglo-Saxon and Slavonic music is a well-established example of the kind of subject that might be investigated with advantage.

A hopeful branch in which investigation might be carried on is medicine generally. We are already acquainted with certain points which have a bearing upon the subject. Thus the whole class of conditions that are summed up under the name of 'diatheses' are important in this respect. It is well established that rheumatism and gout, to mention only two examples, are diseases that show a great tendency to affect persons of one family. It is not impossible that a series of investigations into a number of points in connection with the physiological characters of persons possessing these diatheses would show that they have certain common peculiarities.

Using the term 'temperament' more from its psychological aspect, we have evidence, too, that it may become altered in the course of disease. This is markedly the case in the different varieties of insanity, in the altered mental attitude that characterises hysteria, in the hopefulness of persons afflicted with thoracic disease as contrasted with the melancholy of those suffering from abdominal disease, in the mental changes that accompany pregnancy and the onset of the climacteric in women, and so on. In the case of all of these, such investigation as has been done, has been done on the psychological side alone. And yet if we allow that the mental processes are but the manifestations of chemical and physical changes occurring in nerve-cells, it is clear that the physical side must be considered also. The matter is, it must be confessed, a very difficult one to approach. For it is quite possible that the processes going on in the nerve-cells are themselves modified by the processes going on in other parts of the body, perhaps, even, by the chemical substances formed during the functional activity of these non-mental parts.

From a practical point of view the subject of temperaments is one of considerable importance. We already know that in the case of hysteria the only treatment that is of any real value is that which is directed to the mental side, when once the physical conditions of the patient have been placed on a satisfactory basis. And in the case of the wounded in warfare it is said that those who have belonged

to the victorious army make better recoveries, *ceteris paribus*, than those who have belonged to the defeated army. The facts upon which this statement is made are difficult to arrive at, but it is not improbable that the statement itself contains a large element of truth. To what extent questions of treatment would be modified by full investigation of the subject of temperament it is impossible to say. But that it is one worthy of research there can be no doubt. It has sufficient in common with the subjects of immunity and predisposition to make us hope that its investigation would be accompanied by recognition of facts of the greatest practical importance. Just as no one could have predicted that researches directed to the explanation of immunity would have given us the treatment of certain diseases by specific sera, so no one can at the present time prophesy as to what benefits investigation into the subject of temperament shall, or shall not, confer upon mankind.

W. S. LAZARUS-BARLOW.

TEMPERATURE.—SYNON.: FR. *Température*; Ger. *Körperwärme*; *Eigenwärme*.

TEMPERATURE IN HEALTH.—The heat of the blood is at every moment of life the result of different forces balancing each other, namely, the heat-producing and the heat-destroying processes and influences. So, also, the temperature of a single part of the body results from the heat of the blood circulating, and heat-production going on, within it, and its exposure to cooling influences, and is chiefly dependent upon its blood-supply. The heat of the body is, therefore, most variable on the surface, and is lowest in its uncovered parts, especially in the most projecting ones; almost uniform, on the contrary, in the interior, where only slight differences, amounting to a few tenths of a degree, exist. In the lower animals Claude Bernard found the temperature highest in the hepatic veins and the right auricle. The heat of an organ increases when its functional activity is heightened, as, for instance, when the brain, a muscle, or a gland is stimulated to increased function.

It is important for practical purposes to consider chiefly the temperature in the interior, or the blood-heat. The blood-heat is measured, as nearly as possible, by means of the clinical thermometer. See THERMOMETER, CLINICAL.

In a healthy man the temperature of the body, as measured in the axilla, is about 98·6° F. (37·0° C.). Inside the mouth, underneath the tongue, it is almost the same; whereas in the vagina or rectum it is 0·3° to 0·6° higher. Under special circumstances—for instance, when a considerable cooling of the surface takes place, or when the skin freely perspires—the difference may be somewhat greater, and there may be a difference of 20° between the temperature of exposed parts of the skin and the interior; on the other hand, all parts may be pretty equally warm in the morning in bed, or in a warm room, or when the circulation has been influenced by slight exercise, or by a good meal and a moderate amount of alcohol. Of considerable influence upon the temperature of the surface of the body is the amount of fat in the subcutaneous tissue. In plump children and in very obese adults the surface may be considerably colder than the interior, and in the latter case there generally is yet another and even more effective cause for this difference, namely, weakness of the heart's action.

The temperature of the body is not the same all through the day. Numerous careful observations, of which those of Jürgensen, Liebermeister, and V. W. Ogle may be specially mentioned, have shown that the temperature of a healthy person, even when kept entirely at rest in bed, will fluctuate from about $1^{\circ}8'$ to $2^{\circ}3'$ F. in the course of the twenty-four hours; the mercury standing lowest between 2 A.M. and 6 A.M., and then gradually rising until it reaches the highest point between 5 P.M. and 8 P.M. This rise is mostly not continuous, but becomes somewhat slower, or even interrupted by a slight decrease, in the middle of the day, the afternoon hours showing a more rapid elevation.

This daily fluctuation of the body-heat is a fact of fundamental importance, for it not only takes place in health, but also when, in disease, the whole range of the temperature is either depressed or abnormally elevated. The causes of this daily fluctuation of temperature are not yet fully made out; but this much is certain, that rest and movement, as well as the taking of food, have some share in producing it. Another cause which must not be overlooked, and which was pointed out by Liebermeister, is the force of habit and inheritance.

Race and sex have no influence, to speak of, upon the range of the temperature. Age, on the contrary, has by different observers been found to influence the range as well as the daily fluctuation. In the infant, immediately after its birth, the temperature is slightly higher than later on, its temperature in the rectum having even been found higher than that of the vagina of its mother. A higher range is maintained in the first weeks of life, and there has also been found wanting in infants that steady course of the daily fluctuation which is observed in adults. In children, even somewhat more advanced in age, the temperature is still easily influenced by external causes, and the range of the daily fluctuation is greater. In old age, again, the range is a little greater than in adult life, and here, also, a greater mobility of the temperature under various external circumstances is observed. The menstrual process, as shown by Goodman, Mrs. Jacobi, and Reinl, causes a slight elevation of temperature, amounting, however, to only a few tenths of a degree in the pre-menstrual period, the temperature going gradually down again during the flow and after it is over. Pregnancy has no appreciable influence in healthy women. Parturition slightly increases the temperature, evidently by the increased muscular action, an increase which is compensated by a corresponding fall after the birth of the child. If no complications occur, the temperature in the puerperal state generally does not deviate from the normal.

Such, in fact, is the constancy of the body-heat in health, that the general conditions of life, occupation, &c., hardly show any influence upon it, and whenever, by muscular exertion, or by the effect of external heat or cold—as, for instance, by baths of various temperatures—a more considerable deviation from the normal range has for a time been caused, there is a strong tendency in the system to compensate for the increase or the loss of heat by a corresponding fall or rise afterwards. This faculty is somewhat altered in disease; and even in those states which are on the borderland of disease, as well as under the influence of fatigue or exhaustion, we frequently find a less perfect action of the regulation of the local or general temperature of the body.

LOCAL CHANGES OF TEMPERATURE.—Local changes of temperature are brought about by external thermic influences acting locally, or by disease. Thus the normal symmetry of the two sides of the body, as regards their temperature, may be disturbed. Local stoppage of the blood-supply or local death lowers the temperature of the part; inflammation, in its first stage, raises it. Considerable local changes of temperature may arise simply from vaso-motor disturbances. Thus, in a paralysed limb the temperature may either be lower or higher than in the corresponding limb of the other side; in hemiplegia the temperature of the paralysed side is frequently found 0.5° – 1.5° higher than on the normal side. Neuralgia is sometimes accompanied by dilatation of the blood-vessels, and a considerable rise of the local temperature; and, as a purely vaso-motor disturbance, local heat and redness of the skin, due to a passing dilatation of blood-vessels, sometimes occur in hysteria.

CHANGES OF THE GENERAL TEMPERATURE.—Of much greater practical importance than local disturbances of the body-heat are changes of the general temperature, such as occur in many diseases, whether of the nature of *depression* or of *elevation*.

1. Depression.—Depression of the general temperature is observed as a consequence of considerable loss of blood; in starvation from any cause; and in the wasting of some chronic diseases, such as cancer of various organs; or in diseases of the brain and spinal cord. In brain-disease, with the symptoms of melancholia, extreme coldness of the surface and lowering of the general temperature occasionally occur. In a case of hæmorrhage into the medulla oblongata, Lemcke observed a temperature as low as 73.4° F. (23° C.) in the rectum twenty-seven hours before death; and extreme loss of heat, though hardly to such a degree, by vaso-motor paralysis and dilatation of the blood-vessels, may be caused by severe injuries to the upper part of the spine. A considerable fall of temperature may take place in a very rapid manner in the collapse sometimes occurring in the course of typhoid fever, but especially in that of acute peritonitis, and of poisoning by various substances. In the collapse of cholera the lowering of the temperature of the axilla may be considerable, a temperature as low as 89.6° F. (32° C.) in the axilla, and even less under the tongue, having been observed; at the same time the temperature of the interior of the body is generally very high, reaching 104° F. (40° C.), and sometimes much more. In peritonitis a low general temperature may be present for days, even if the peritonitis supervene in the course of typhoid fever. With the collapse caused by alcoholic intoxication great depression of the general temperature occurs when the patient is exposed to cold and wet; and in a case of carbolic-acid poisoning, which came under the observation of the writer, the vaginal temperature fell as low as 93.92° F. (34.4° C.). A temperature of 71.6° F. (22° C.) has been observed in sclerema neonatorum.

In chronic diseases of the respiratory organs, not of an inflammatory or tubercular nature, as well as in chronic heart- or kidney-disease, the temperature is generally found somewhat below normal; and the same is the case in chronic nephritis, more especially in those cases which are accompanied by general dropsy. In cases of the latter kind we sometimes see even a febrile temperature, caused, for instance,

by tubercular disease of the lungs, become considerably abated, if not entirely reversed, when chronic kidney-disease supervenes; as also when intestinal ulceration becomes more prominent, or leads to peritonitis. From some observations of the writer of this article, it would seem as if intracranial disease, such as softening or tumour, arising during the course of a febrile disorder, e.g. pulmonary phthisis, may not only disturb the regularity of the febrile temperature-changes, but, by a kind of inhibitory action, entirely suppress the febrile elevation of temperature.

2. Elevation.—Elevation of the general temperature, as part of the febrile process, is the most prominent symptom in most diseases of an infectious origin, with or without inflammation. An increased production of heat, no less than a disturbance of the regulation of the temperature, is the effect of the presence in the blood of some foreign substance, acting injuriously on the nervous system, and causing altered chemical processes. Modern research gives the most prominent part in these actions to micro-organisms, which by chemical substances contained in their own bodies, or by chemical products of their own life-changes, or by changes which they cause in the cells of the body, are assumed to be the cause of the febrile process, and thus of the increased temperature.

Some such substances, belonging chemically to the albuminoids and acting as ferments, have recently been extracted from pure cultures of the yeast-fungus by Roussy, and of various bacteria by Koch (tuberculin), Buchner, and others; and their action on the temperature of the body has been studied by Krehl and Matthis. *See FEVER.*

The proper balance of the heat-forming and heat-destroying processes may also be disturbed by other influences acting upon, and by primary diseases of, the nervous system. When the body is subjected to external cold after it has been fatigued by exercise and already cooled by perspiration—if, for instance, a cold bath were taken under such circumstances—a rigor, with rapid rising of the temperature, may follow; but, no local disease becoming developed, the temperature quickly goes down again amid profuse perspiration, and the whole attack may be over. Or a disturbance of the heat-regulating functions of the nervous system may be caused by the irritation of some nerve-filaments, as by a gall-stone passing the biliary duct, or a stone passing through the ureter or the urethra, and a febrile attack will follow. The rigor, leading to a high fever of an evanescent character, which may follow the introduction of a catheter (urethral fever), sometimes belongs to the same group of cases. But generally, in cases of this kind, the nervous system is already in an abnormal state through the previous disease, which, besides, may be of an infectious nature and thereby give rise to pyrexia. The functions of the nervous system may further be deranged by injury; and a rise of temperature has not only been observed in injuries to the brain, but, in a most excessive degree, sometimes after injury of the cervical part of the spinal cord, when temperatures of 110° to 111° F. (43.3° to 44° C.) have been observed (B. Brodie, H. Weber, Teale, and others). In tetanus a very high temperature may occur, rising still higher a little after death; as much as 112.55° F. (44.75° C.) was reached in a case observed by Wunderlich. An alteration of the heat-regulating functions of the nervous system may be brought about by a con-

siderable external heat acting upon the body, especially when combined with moisture of the air and fatigue. In such cases of sunstroke or heat-stroke, it is quite common to see the temperature of the body rise to 108° F. (42.2° C.) and more; and it would seem probable that a febrile elevation of temperature, if going on unchecked for a considerable time, by causing exhaustion of the nervous system, may lead to hyperpyrexia. Thus it is not very uncommon to see the temperature rise excessively in infectious diseases, especially scarlatina, towards the close of life (*proagonic hyperpyrexia*); and the temperature may, in such cases, even rise a little more immediately after death. This is due to the loss of heat being greatly reduced after the stoppage of the circulation, the heat-production going on in the interior for a time; and the gradual failure of the circulation probably also takes a great share among the causes of a proagonic hyperpyrexia.

Hyperpyrexia sometimes comes on during convalescence from acute rheumatism, even after the fever has entirely subsided, and when the patient is apparently convalescent. An excessive rise has occurred and caused death in severe cases of hysteria; and in hysterical patients hyperpyrexia has occasionally been observed without any of the symptoms which in other cases usually accompany so grave a phenomenon. Cases of this kind are extremely suspicious, and in some of them it was discovered how this hyperpyrexia was simulated. Thus a patient had driven up the mercury by rubbing the bulb of the thermometer between the folds of her night-dress; while in other cases the high elevation of the mercury had been brought about by means of a hot poultice, or by the patient having lowered the top of the instrument, so that the column of mercury began moving by its own weight. This, however, is not possible with a thermometer of the thin bore which English thermometers now generally have. A very high temperature, to which the pulse and respiration and the other symptoms do not correspond, must always arouse a suspicion that the rise of the mercury has been artificially produced, and the verification will be easy if the physician carefully watch the mercury as it rises, or take the temperature in the rectum or vagina.

The very important part which the nervous system plays in regulating the blood-heat is also seen in the great liability of the temperature easily to deviate from the normal range during convalescence from acute disease, when the weakness of the nervous system, brought on by the previous illness, will show itself in this no less than in other alterations of function. This can frequently be observed in convalescence, not only from the eruptive fevers, but also from pneumonia and other acute febrile diseases, when trifling external influences may cause a considerable rise of the temperature, which, however, is generally of short duration only, but which, in the case of specific fevers, may cause apprehension lest a relapse or a complication be coming on. In a somewhat different manner, and more lasting, a slight sub-febrile elevation of temperature may be observed in the convalescence from acute rheumatism, in which it may persist for weeks without any joint- or heart-symptoms being present.

SIGNIFICANCE OF ABNORMAL TEMPERATURE FOR DIAGNOSIS AND PROGNOSIS.—The maintenance of the heat of the body within a certain range being so insured, any deviation of the general

temperature from the normal standard, however slight in degree—unless of a very transient nature, or brought on by evident external causes—is to be taken as a sign of disease. Such deviation may be of a variable degree, along with symptoms which, in part, are the consequence of the abnormal temperature, such as an abnormal rate of pulse and respiration, and in part due to the nervous system. The whole range of deviation within which life can be maintained is comprised between 90°F . (32°C .) and 110°F . (43.4°C .). A temperature approaching either end of this range indicates a condition of extreme danger, which is already great with a temperature of 95°F . (35°C .), or beyond 106.5°F . (41.5°C .). With reference to the general condition of a patient who presents an abnormal temperature, a few distinctions may be conveniently tabulated.

(1) *Temperature below the normal*:—

(a) Temperature of collapse, below 97°F . (36.2°C .).

(b) Subnormal temperature, 97 – 98°F . (36.2 – 36.7°C .).

(2) *Normal temperature*: 98.0 – 99.5°F . (36.7 – 37.5°C .).

(3) *Temperature above the normal*:—

(a) Sub-febrile temperature, 99.5 – 100.5°F . (37.5 – 38.05°C .).

(b) Febrile temperature of moderate degree, 100.5 – 102°F . (38.05 – 38.88°C .), morning; 102.2 – 103°F . (39 – 39.44°C .), evening.

(c) Febrile temperature of high degree, 102.5°F . (39.2°C .) and more in the morning; 105 – 106°F . (40.6 – 41.1°C .) in the evening.

(d) Hyperpyrexia, 105.8 – 107.5°F . (41 – 42°C .) and more. Extremely dangerous.

Single Observations.—Near the extreme points of this scale a single observation of the temperature of a patient may at once decide the prognosis. Thus a temperature below 93°F . (33.88°C .) or above 108°F . (42.22°C .) is almost always fatal, although cases have recovered by active treatment, in which the latter point has been exceeded by several degrees. No less valuable may single observations be for diagnosis, chiefly in a general way, in showing that there is disease when, perhaps, no other symptom points to it, but also for the diagnosis of a special disease in some instances. Where there are other symptoms of disease, the discovery of an abnormally high or a febrile temperature may at once give quite a different aspect to a case, as, for instance, when a patient who has been suffering for some time from a troublesome cough without expectoration, but in whom the most careful examination of the chest could not detect any lung-disease, is found to have pyrexia. The suspicion that there is commencing phthisis may thereby be at once confirmed, or aroused for the first time. Or, again, in a case where the patient simply complains of dyspepsia and lassitude, the thermometer may give a degree of heat which would not have been expected either from the looks of the patient or from the temperature of his hands or chest, and the attention may thereby at once be directed to the possibility of the case being one of typhoid or some other specific fever. One reservation must be made with regard to single observations in febrile patients who have not been kept at rest for some time before, for example, in patients who have walked to the physician's house, or who had

to undergo a journey to the hospital. In such cases the temperature may become somewhat altered by the fatigue; and it is quite common to find the first temperature in a patient, immediately after his admission into the hospital, considerably higher than after a few hours' rest, or, if he have been exposed to cold, much lower than what would otherwise correspond to his condition.

Systematic Series of Observations.—But of much greater value than isolated observations of temperature is the regular and continued watching of the course which the temperature takes in a disease. Many diseases present a deviation from the normal temperature, showing a typical course as regards the duration, as well as the daily fluctuations, of the abnormal temperature. The course of its temperature being part of the natural history of a disease, the study of this is of great importance for diagnosis. See FEVER.

TYPES OF PYREXIA.—First, it is the *mode of rising* of the temperature which varies, and by which some diseases may be distinguished. In some diseases a contraction of the peripheral arteries takes place at the onset, which, by diminishing the peripheral circulation and the giving-off of heat, leads to a rapid rise of the internal temperature, and is accompanied by a sensation of cold. In pneumonia, therefore, and other diseases commencing with a rigor, the temperature rises rapidly and continuously to a height of 104°F . (40°C .) or more; whereas diseases with a more gradual beginning show simply a slow elevation of the normal range, both morning and evening temperatures becoming gradually higher, the usual daily fluctuation being maintained. Thus, in the first few days of typhoid fever the temperature rises every day about 2°F .; but the temperature going down again in the morning by about 1°F ., the maximum of about 105°F . is only attained on the fifth or sixth day.

At the *height* of a disease the temperature may fluctuate round an average temperature of about 103°F . (39.5°C .) or more, while it shows the same daily course as in health, that is, is lowest in the morning and highest in the evening. The range of this daily fluctuation may, however, differ considerably in different diseases; and according to the extent of the daily fluctuation three types may be distinguished. When the daily fluctuation of an elevated temperature shows only the normal difference, or even a smaller difference, between the morning and evening temperatures, we speak of *continuous*, or, more correctly, *sub-continuous* pyrexia; when the difference is greater than the normal, the remission having a tendency to a low temperature, and the exacerbation, on the contrary, to a considerable rise, the pyrexia is called *remittent*; and, thirdly, when the remissions reach the normal, or recede even below it, we have the *intermittent* type of pyrexia.

A *continuous* elevation of temperature is observed soon after the commencement of a disease, and during its height.

Considerable *remissions*, or even *intermissions*, of the febrile temperature are chiefly observed in the decline of some acute diseases, and in chronic inflammatory diseases, especially of a tubercular nature, or in chronic syphilitic affections, in pernicious anæmia and leucæmia, as well as in some cases of lymphadenoma (Hodgkin's disease), the remissions generally becoming more marked as the exhaustion of the patient increases.

The *intermittent* type of pyrexia is most typically shown in malarial diseases, in which the elevation of temperature may follow a quotidian, tertian, or quartan type. The same also sometimes occurs in chronic tubercular disease of the lungs and in pyæmia. Pyrexia of a remittent type may present a peculiarity which is worthy of note, as being of some diagnostic value. Whereas in the great majority of cases the daily fluctuation follows the rule of health, the exacerbation taking place in the evening, we sometimes meet with cases where this order is reversed, the rise taking place in the morning, and the remission occurring in the evening. This 'inverse type,' as Traube has called it, of the daily fluctuation of a febrile temperature has been observed in some rare instances in typhoid fever; more frequently in cases of chronic lung-disease. In doubtful cases of inflammation of the lungs it has some significance as to the disease being tubercular.

Slight deviations in the maximum daily rise of a febrile temperature occur sometimes in such a way, that the height is reached in the middle of the day, or that the exacerbation takes place in the night, or that two or more considerable elevations, instead of one only, take place in the twenty-four hours. Such occurrences, which have been observed in typhoid fever and in phthisis, can, of course, only be found out by the observations of the temperature being repeated with sufficient frequency. A more frequent application of the thermometer will also be necessary in some cases of ague, where the attacks are not well marked, or occur in the night, in order correctly to judge of the case.

The *decline* of the elevation of temperature, at the termination of a disease, may be gradual, the daily fluctuation, however, taking place as usual; or it may be rapid, by a continuous sinking of the temperature to, or somewhat below, the normal, in the course of from twelve to thirty-six hours, or even in six to eight hours, as in relapsing fever. The latter mode of termination of a fever is called *crisis*, whereas the former is designated *lysis*. A crisis may sometimes be accompanied by symptoms of collapse, and, in some rare instances, by acute delirium, which, however, generally passes off within a day or two, and is not of bad omen provided the general condition of the patient remain good. Symptoms of this kind, as well as a more considerable elevation of the temperature just previously to its fall, or a great irregularity in the course of the temperature preceding it, may be called *perturbatio critica*. It would appear that diseases caused by the action in the system of some foreign substance—as, for instance, some infective agent, its action being of a limited duration—have a tendency to a critical defervescence. Diseases, on the contrary, in which an organ has become materially altered, as by an injury, or by some infection either primarily or, in the course of a chronic disease, by a longer duration of the morbid action, or by some supervening secondary infection, show a slow decline of the pyrexia, with a tendency to a remittent type. The repair of the damaged structures taking some time, the decline of the pyrexia is slow, and the defervescence by lysis. Examples of the former mode of defervescence are furnished by acute pneumonia, erysipelas, typhus, relapsing fever, and measles when not complicated by more serious inflammation; the latter type is shown by typhoid fever, in which the specific process produces deep

ulcerations in the glandular structures of the intestine, which persist for some time after the specific process has terminated. The ancient physicians believed that a crisis took place on certain days in particular, as, for instance, the seventh day of an illness; but more extended experience, gained by means of the thermometer, has shown that, although a change or a termination of a disease may take place at a certain definite period, the latter is not bound to one particular day. See *CRISIS*.

Any *irregularity of the course* of the temperature in a disease in which, as a rule, it runs a very regular and definite course, is indicative of some disturbance or complication, and its early detection is therefore important for diagnosis, no less than for prognosis and treatment.

On the *approach of death* the temperature in many cases gradually sinks; but instances are not of rare occurrence in which, on the contrary, especially in diseases with high fever, a continuous rise takes place towards the fatal termination, reaching sometimes hyperpyrexial degrees.

In *convalescence* the temperature is more easily influenced by external causes, as well as by internal changes, and the approach of a relapse or complication being at once indicated by a rise of temperature, the continuance of regular thermometrical observations in the first period of convalescence is of very great importance; the more so, as convalescents are sometimes not sensible to changes, which at first only show themselves in an alteration of the temperature.

TREATMENT.—Abnormal states of temperature ought not, as a rule, to be considered as objects of treatment by themselves, all the concomitant symptoms, in fact the whole state of the patient, having to be taken into consideration, in order properly to treat a case of febrile disease. But there are exceptional cases in which the state of the temperature at once urgently requires a symptomatic treatment. Such are, for instance, cases of *hyperpyrexia* in sunstroke or heat-stroke, in which the most energetic means ought at once to be applied to reduce the temperature. As the experience of Levick and other American physicians has shown, life may in such cases sometimes be saved by perseveringly rubbing the surface of the body with large pieces of ice, using at the same time stimulants by the rectum or subcutaneously. A rapid abstraction of heat by rubbing with ice, or cold bathing with affusions, may also be the only means of saving a patient in whom, in the course of acute rheumatism, hyperpyrexia has set in; and a case published by Wilson Fox, in which the temperature reached 110° F. in the rectum, showed that external cooling may be successful, when even very large doses of quinine (120 grains had been given in six hours) had been administered without effect. The same plan must be followed in hyperpyrexia occurring in the course of other diseases. Complications, such as pneumonia, or even pericarditis, do not contra-indicate this treatment, the success of which is, however, dependent upon the possibility of rousing the nervous system, and upon the circulation remaining sufficiently active.

An *abnormally low temperature* requires the external application of heat, which will be materially assisted by warm stimulating drinks or injections, using eventually subcutaneous injections of ether or of tincture of musk, or intravenous or subcutaneous injections of a 0·6 per cent. solution of

chloride of sodium in water, to stimulate the action of the heart, and to increase the blood-pressure. See SHOCK.

Apart from such exceptional cases, the treatment of the abnormal states of the temperature must be subordinated to the general treatment of the case. In many cases the abnormal temperature being dependent upon some local cause, the removal of the latter will make the abnormal temperature also disappear, or at least reduce it—an experience with which surgeons are quite familiar.

Rise of temperature being, however, the most appreciable and a most important symptom of *pyrexia*, which, by weakening the heart's action, by lowering blood-pressure, and in other ways, may of itself lead to serious consequences, it would appear advisable in many cases of protracted febrile disease, besides the general or special treatment which the case requires, to treat the febrile temperature symptomatically. An overwhelming experience has actually shown that the course of the specific fevers, such as typhus, typhoid and scarlatina, although it cannot be cut short, can yet be materially influenced, by measures the primary object of which originally was to keep the febrile temperature artificially down, by means of cold baths or wet packing, or by antipyretic medicines. In rehabilitating the cold-water treatment of fevers, which already in the hands of J. Currie had been so successful, E. Brand, Jürgensen, Liebermeister, and their followers started from the idea that the increased blood-heat ought to be combated; and Liebermeister, than whom few physicians have more practical experience in these matters, laid down as the principle to be followed in the antipyretic treatment of fevers, to increase the remissions that normally take place in the daily fluctuation of temperature, and to prolong them as much as possible. Comparative experiments having shown that external cooling by baths, as well as antipyretic medicines, are of greater effect on the temperature at those times of the day and night when it spontaneously has a tendency to decline, these periods were declared the most favourable for the employment of antipyretic measures, necessitating their least frequent repetition. Others have not laid so much weight on the normal daily fluctuations of febrile heat, but have used the bath whenever the temperature rose to a certain point, say 102.2° F. (39.0° C.) or 103° F. (39.5° C.), obtaining in this way equally favourable results, though, perhaps, with more inconvenience to the patients. More extensive experience has, however, shown that lowering the febrile temperature in itself—which at present, by using one or the other of the antipyretic medicines which modern chemistry supplies in such variety and profusion, can be accomplished to a very high degree—does not produce the same good effect on the whole condition of the patient, or so favourably influence mortality as cold bathing or other methods of external cooling. It therefore appears very probable that the beneficial action of the cooling treatment by these external means is due not so much to the reduction of the temperature, as to their powerful influence on the circulation and on the tone of the nervous system. So there may, perhaps, after all, be no reason to feel disappointed at the very transient effect which even a very cold bath has in a case of high fever, and which, as far as mere reduction of temperature is concerned, makes its action appear much inferior to that of antipyretic

medicines. For, troublesome as it may be for the patient, as well as for his attendants, to repeat the external cooling over and over again in the course of a day, it may yet be this very repetition of the bath, with all its effects, which is of essential importance.

The theory from which antipyretic treatment originally started—that pyrexial elevation of temperature is an unmixed evil—is becoming more and more modified as the conviction is gaining ground that a process like the febrile reaction of the system following upon various external influences, which was, no doubt, gradually acquired through evolution, must be of some advantage to its possessor, if it be only this—that by the increased chemical action which goes on at a higher temperature, abnormal and noxious products of tissue-change and of the life-process of infectious germs will be more rapidly destroyed and cast out of the body. But it would certainly be a step in the wrong direction if such considerations were to lead to giving up all antipyretic measures. On the contrary, experience teaches that it is very important not to wait in a case with continuous high temperature until symptoms of failure of the heart's action—a weak pulse, cold extremities, cyanosis and congestion of the lungs, and muttering delirium—show themselves, but to try to prevent these symptoms by at once resorting to external cooling. Patients treated early on this principle will be found much less frequently to pass into that state, to sleep more soundly, and to retain their appetite, bedsores and other serious complications being of much rarer occurrence; and it has been established that the mortality in specific fevers has by the cold-water treatment been very considerably diminished, and that convalescence also is quicker than in cases treated on a purely expectant plan. If consistently carried through, the good effects of such treatment mostly show themselves in a few days, not only in the whole condition of the patient, but also in the effect of successive baths on the temperature becoming greater and more lasting, so that the number of baths, as required by a certain height of temperature, becomes less every day.

As regards the methods of external cooling, by far the most effective means are cold baths from 60° to 70° F. (15° to 20° C.), of about ten minutes' duration. More agreeable to the patient are baths of about 95° F. (35° C.), gradually cooled down by the addition of cold water to 70° F. (20° C.), or less, as recommended by von Ziemssen, but their duration must be longer to have the same effect as the former. Riess tried prolonged immersions in warm water of 90° F. (32° C.), but, although acting very powerfully on the temperature, the general effect of such permanent baths is inferior to that of repeated short cold baths. Cold wet-packing is less effectual, but may replace baths in special cases, and when they cannot be given. The same holds good as regards cold sponging. See HYDROTHERAPEUTICS; and COLD, Therapeutics of.

Antipyretic medicines may be used sparingly in order to prolong the effect of a bath on the temperature in cases of very high and persistent fever, but principally with a view to allay some of the troublesome symptoms accompanying pyrexia, especially the headache, the feeling of heat, and uneasiness. For a long time sulphate of quinine had been the only reliable antipyretic drug, but now we possess a great number of chemical preparations, which are

much more powerful in reducing a febrile temperature and subduing some of the other symptoms of fever than anything before known. But it ought never to be lost sight of that these preparations, foremost among which stands phenazone, although in individual cases they may be of considerable service, are substances whose effects on the tissues of the body, and especially on the nervous system, are as yet but very imperfectly known, and that a routine treatment of elevated temperature with their aid is much to be deprecated, and cannot compare in innocuity and results with even a routine treatment with cold water, which, it need hardly be said, must also be carefully adapted to the requirements of the case and the individuality of the patient.

TENDERNESS.—*See* PAIN IN VISCERAL DISEASE.

TENDON-REFLEX.—*See* NERVOUS SYSTEM, Examination of; and SPINAL CORD, Diseases of.

TENESMUS (τέλινω, I stretch).—**SYNON.** : Fr. *Ténésie*; Ger. *Stuhlzwang*.—Tenesmus is a comprehensive term applied to certain morbid sensations referred to the anus and its vicinity. There is a feeling of fulness and weight, an uncontrollable desire to go to stool, and straining during the act of defecation, little or nothing being passed, and that often of the nature of slimy mucus or blood, while little or no sense of relief is experienced afterwards. Tenesmus is a common symptom in cases of dysentery. It may also be associated with local diseases about the lower part of the rectum or anus, such as piles, fistula, or malignant disease. Other morbid sensations are often present at the same time.

TREATMENT.—Any local cause of tenesmus must be removed or cured, if practicable. The sensations are best relieved by local applications of heat or cold, wet pads, or the use of small enemata containing laudanum, or of suppositories of morphine, belladonna, or cocaine.

TESTES, Diseases of.—The diseases of the testes will be discussed in the following order:—

1. Abnormalities, p. 1681.
2. Atrophy, p. 1682.
3. Chondroma, p. 1682.
4. Cystic Disease, p. 1683.
5. Fibroma, p. 1683.

6. Hernia Testis, p. 1683.
7. Hypertrophy, p. 1683.
8. Inflammation, p. 1683.
9. Injuries, p. 1685.
10. Carcinoma and Sarcoma, p. 1685.
11. Neuralgia, p. 1686.
12. Teratoma, p. 1686.

See also HEMATOCELE; HYDROCELE; and PAIN IN VISCERAL DISEASE.

1. **Abnormalities.**—(a) *Absence.*—There may be complete absence of the testicles. The subjects of this imperfection, if they attain the age of puberty, present the ordinary characteristics of eunuchs. As the complete gland is formed from two distinct parts, the failure or arrest of development may be limited to either part, separately from the other. Thus cases are described where a well-developed vesicula seminalis and vas deferens have been found, without any trace of a testicle; and others, where a testicle existed with complete or partial absence of the vas deferens.

(b) *Excess.*—Supernumerary testicles have been described, and men not infrequently believe themselves to be so gifted. The mistake has arisen from the presence of encysted hydroceles, or of fatty or fibrous tumours of the cord, or of an old epiplocele. There is no perfectly authenticated case recorded of the presence of more than two testicles.

(c) *Malposition.*—The testicles are developed in the abdomen, and at birth, or shortly after, are lodged in the scrotum. A pouch of peritoneum, the processus vaginalis, precedes the testis into the scrotum. This change of position is frequently described as ‘descent of the testicle,’ an obvious misuse of words, if regard be paid to the usual position of the foetus in the uterus.

The testicle may be retained in the *abdomen*, or in the *inguinal canal*; or may pass through the inguinal canal into the *perineum*, and be lodged between the bulb of the urethra and the anterior part of the tuber ischii; or over the external pillar of the ring into the subcutaneous tissue of the *upper part of the thigh*; or through the crural canal to the *upper and inner part of the thigh*; or, if it has passed into the scrotum, may be *rotated*, so that the epididymis is in front and the testicle behind. More rarely it has the long axis transverse instead of oblique; or it may be completely inverted, so that the globus major is below, the globus minor above.

Retention in the abdomen or inguinal canal may be the result of non-attachment of the gubernaculum to the testis, of adhesions from intra-uterine inflammation, or of disproportion between the gland and the orifices through which it has to pass, or of some constricting band. The passing through the crural canal to the thigh, or through the inguinal canal to the perineum or thigh, is explained by the wide and extensive attachments of the lower end of the gubernaculum. Malposition in the scrotum may be caused by some abnormality in the development of the cord.

The consequences will vary with the position. If the testicle is retained in the *abdomen*, the corresponding half of the scrotum remains undeveloped, and the gland is always much smaller than normal. Sometimes there is an arrest of development, or it undergoes fatty or fibrous degeneration, or, if otherwise normal, does not secrete a fertilising fluid. This seems fairly established by numerous observations, both in men and the lower animals, where the testicle has been abnormally retained in

the abdomen. One case, however, has been recorded by Hutchinson, where the observer, to whom the retained testicle was submitted for microscopical examination, stated that he found numerous spermatozoa.

When the testicle lies at the internal inguinal ring, the epididymis is frequently found partly in the badly developed scrotum, into which also extends the processus vaginalis. As the communication between this and the peritoneal cavity is usually maintained under such conditions, in case of peritonitis with effusion there may be distension of this process, so as closely to simulate a hernia, and render an exploratory examination necessary. In most instances testicles which are retained in the inguinal canal do not produce spermatozoa.

Retention of the testicle in the *inguinal canal* is more liable to produce complications than retention in the abdomen. It is often accompanied by inguinal hernia; the organ is more exposed to injury; and when enlarged at puberty, or by inflammation, may cause severe pain from constriction by the surrounding parts. The retained testis may also undergo axial rotation causing torsion of its pedicle. This usually follows sudden descent into the scrotum. The writer has known the descent occur at the ages of six months, ten years, and sixty-eight years. The sudden change in position is usually followed by a sharp attack of orchitis. But, owing to the length of the mesorchium, the spermatic cord may become twisted, and obstruct the return of the venous blood. The whole testicle and epididymis then become infiltrated with blood, and subsequently inflamed. The tumour in the inguinal canal and scrotum closely simulates a strangulated hernia, and the accompanying pain and vomiting heighten the resemblance. The bowels, however, continue to act together with the passage of flatus and fæces. The treatment of torsion of the cord is by open incision so as to allow of the twist being undone, or the testicle removed if obviously gangrenous.

Inflammation of a testicle retained in the inguinal canal has been mistaken for strangulated bubonocoele, or for a bubo. Careful examination of the scrotum should, therefore, be made in doubtful cases.

Retraction can usually be distinguished from retention of the testicle by the state of development of the corresponding half of the scrotum.

The *perineal* or *femoral* position of the gland is not of necessity attended by any bad results. A testicle, however, so situated is usually smaller than normal and is more exposed to injury. This is especially the case in the perineal position. In addition it is important to remember before undertaking operative proceedings that the processus vaginalis accompanies the testis into the perineum and usually communicates with the abdomen.

TREATMENT.—If retention of the gland in the inguinal canal be attended by any inconvenience, operative interference may succeed in placing it in the scrotum. But if this should fail from shortness of the cord, and in spite of separation of the cord and inversion of the testis, then extirpation might be necessary. It is undesirable to thrust the gland back into the abdomen. When in infants retention of the testicle is complicated by an inguinal hernia, the use of a truss is not to be recommended, as it will prevent the possible descent of the testicle, and the hernia not infrequently spontaneously sub-

sides. But if a truss with a horseshoe-pad can be adjusted above the testicle, the hernia is prevented and the descent of the testicle assisted. If the retention of the gland be permanent and cause inconvenience, it is better to operate at once. If the gland has passed through the crural canal, little can be done to remedy the malposition; but when it has passed through the inguinal canal into the perineum or the thigh, an attempt may be made to place it in the normal position. In an adult such a proceeding might be difficult owing to the non-development of the scrotum.

John Wood successfully transplanted in an infant a testicle from the perineum to the scrotum subcutaneously. When a band of tissue in the perineum, probably the gubernaculum, had been divided with a tenotomy knife, the gland could be pushed up to the inguinal canal, and from thence into the scrotum, where it was retained by a hairlip pin passed above it as in acupressure. This method is now replaced by the open operation. As sometimes the unaided efforts of nature draw the gland from the perineum up to the inguinal ring, where it is comparatively safe from injury, and more favourably situated for any attempt at removal to the scrotum, it is advisable always in infants to allow time for such a possible modification. Should an operation be deemed advisable, an open incision should be practised, and each step guided by vision.

Of malpositions in the scrotum, that in which the epididymis is in front, and the testicle proper behind, is alone of any practical importance. In any operation for hydrocele or hæmatocele of the tunica vaginalis, the position of the testicle ought first to be ascertained.

(d) *Arrest of development.*—This sometimes occurs after the testicles have passed into the scrotum, so that these glands remain permanently in their infantile condition. No general cause has been discovered for this abnormality.

2. **Atrophy.**—Wasting of the testicle may result from inflammation, from lesions of the spinal cord caused by injury or disease or secondary to injuries of the head. It may also be produced by early and excessive venereal excitement; or by deficient blood-supply, due to aneurysm or other causes. It is frequently found associated with varicocele, and is also caused by the pressure of the fluid of a long-standing hydrocele. It follows division of the spermatic arteries and veins, or of the vas deferens.

3. **Chondroma.**—Cartilage, either cellular or hyaline, but sometimes of the fibrous variety, is found in association with many new-growths in the testicle. Pure chondroma is comparatively rare; and the cartilage is usually associated with sarcoma, which is composed of spindle-cells. It has been seen in association with carcinoma.

DESCRIPTION.—This form of tumour of the testis occurs as disseminated nodules, connected by fibrous tissue; or as elongated masses with branching processes. By compression of the seminal tubules, it leads to dilatation of other parts of the tubules; and by invagination of the walls of such dilatations the growth often seems to be in the interior of a tubule. Careful examination, however, will always prove it to be of extra-tubular origin. It also invades the lymphatics, and through them has a great tendency to infect other parts of the system. It is often associated with myxoma; and sometimes, though

rarely, it develops into bone. It can only be diagnosed with any certainty when the tumour has attained a large size, and is then characterised by the hardness and slow growth of the mass.

TREATMENT.—Castration is the only treatment; and in consequence of the tendency of this disease to invade other organs, it is usual to recommend an operation without unnecessary delay, in all cases of large sarcocele which do not give any indication of yielding to treatment.

4. **Cystic Disease.**—Cysts are frequently found in the testicle, either separately or associated with other growths.

DESCRIPTION.—In true cystic disease or simple cystoma, the whole or part of the body of the testicle is replaced by a closely aggregated mass of cysts, of very variable size. Some are so minute as only to be visible on microscopical examination, while others may attain a diameter of from one to three centimetres. When only part of the gland is so affected, healthy glandular substance is found at the periphery, enveloping the cystic growth. The cysts have no thick fibrous wall, and are lined with shallow cylindrical epithelium, which is sometimes ciliated. They are filled with either clear watery, or sometimes very viscid, fluid; or with atheromatous matter, resembling the contents of a sebaceous cyst. These latter are usually dermoid cysts and owe their origin to developmental causes. Dermoid cysts containing teeth and hair are also met with. Very frequently nodules of cartilage are found interposed between the cysts. The disease usually occurs in adults, but one case has been recorded where the enlargement was first observed at the age of three months.

There is another form of cystic disease, where the cysts are separated by a considerable quantity of gelatinous connective tissue, and often contain polypoid ingrowths, which sometimes completely fill their cavities. This form is regarded as cystic adenoma of the gland, and may exhibit a varying degree of malignancy. A true malignant cystic sarcoma of the testis is also met with.

Cysts of the epididymis are described in the article on HYDROCELE. The origin of many of the cysts of the hilum of the testis and epididymis from the remains of the Wolffian body needs to be further elucidated.

SYMPTOMS.—Cystic disease of the testicle is usually attended by very little pain. The tumour is of an oval form, either with a smooth surface, or with irregular elevations; and does not attain a very considerable size, being generally from five to ten centimetres in diameter. There is an indistinct sense of fluctuation, unequal at different parts.

DIAGNOSIS.—Cystic disease of the testis has sometimes been mistaken for hydrocele or hæmatocele. The form of the tumour, its relatively greater weight, the absence of transparency, and the impossibility of detecting the body of the testicle at any part, distinguish it from hydrocele. The distinction from hæmatocele is in some cases more difficult. An exploratory incision will clear up the diagnosis.

TREATMENT.—Castration is the only remedy for this condition.

5. **Fibroma.**—Fibrous tissue is found in abnormal quantity in atrophy of the testis, in chronic orchitis, and associated with new-growths. By fibroma of the testicle, however, is meant a new-formation of fibrous tissue to a considerable extent,

without any other important change. In structure it resembles fibrous tumours of the uterus. It so rarely occurs, however, as to be practically devoid of clinical importance.

6. **Hernia Testis.**—This morbid condition will be referred to under the heading of tubercular orchitis (p. 1684). It also ensues in rare cases upon the softening of gummata. A third variety, fungus hæmatodes, is sometimes described. It is caused by the fungation of a malignant growth, and is now seldom seen. A fourth may be caused by traumatism, such as sloughing of the scrotum after injuries or operations for the radical cure of hernia, of varicocele, or of hydrocele—all accidents which are becoming increasingly rare.

DESCRIPTION.—It consists of a fungous protrusion from the scrotum, of a red or yellowish-red colour, and varies from one to five centimetres in diameter. There are two varieties, which may be distinguished as *superficial* and *deep*. The superficial form springs from the visceral layer of the tunica vaginalis, and is very comparable to the fungous granulations occasionally met with in cases of suppuration, or in wounds of the synovial sheaths of tendons. In this the tunica albuginea is intact, but probably altered in structure. In the deep form the tunica albuginea has been perforated, and the protruded mass consists largely of seminal tubules. It cannot be regarded as an evidence of any special disease of the gland, as it may occur, but by no means necessarily, after any form of orchitis in which there has been suppuration.

TREATMENT.—The treatment depends upon the cause. Tubercular and malignant disease of the testis will usually demand castration. Syphilitic orchitis is more amenable to treatment with mercury and iodide of potassium. Locally the protrusion may, in suitable cases, be treated with caustics, red oxide of mercury, or nitrate of silver, or with the galvanic cautery. Some anaesthesia with cocaine should be induced before any of these applications. Hernia of the testis has become excessively rare, and many of the palliative measures which used to be attempted are now forsaken.

7. **Hypertrophy.**—When only one testicle has been retained in the abdomen, the other sometimes attains an unusually large size. Such cases of, as it were, compensatory development are, however, the exception and not the rule.

8. **Inflammation.**—A. *Acute.*—When acute inflammation attacks the body of the gland solely or chiefly, it is called *orchitis*; when the epididymis, *epididymitis*. For the comparatively rare cases in which the vas deferens, or this duct along with the other structures of the spermatic cord, is affected, without the testicle being implicated, the barbarous hybrids *deferentitis* and *funiculitis* have been coined.

ÆTIOLOGY.—Acute inflammation may be caused by direct violence, or by the extension of inflammatory processes from the mucous membrane of the urethra. It may also occur, though rarely, as a sequela in typhoid fever or small-pox, or in pyæmia. Orchitis is not infrequently a concomitant of parotitis or mumps.

Of these varieties, the most frequent is gonorrhœal epididymitis. This was at one time regarded as an instance of 'sympathetic inflammation.' Careful examination will, however, always prove that the vas deferens is also affected, though sometimes in so slight a degree that its participation in

the inflammation might easily escape notice. This form is, therefore, due to direct extension of the inflammation from the urethral mucous membrane. Orchitis associated with mumps used to be attributed to such vague abstractions as 'sympathy' or 'metastasis.' Kocher, however, considers it to be the result of urethritis. According to this experienced observer, the disease commences as stomatitis, by which the parotid, or sometimes the sub-maxillary and neighbouring lymphatic glands become infected. The morbid material is carried by the blood to the kidneys, and in its course through the urinary passages sets up cystitis or urethritis, and thus the orchitis results. This explanation is not satisfactory, since in some epidemics of mumps orchitis has occurred prior to or without any affection of the parotid gland. We may, however, safely infer that an infective agency is concerned in its causation. Orchitis and epididymitis sometimes occur in rheumatic or gouty subjects. Occasionally cases are met with in which no exciting cause can be discovered. It sometimes occurs in very young children, and, in the absence of any constitutional taint or other discoverable cause, probably results from some accidental injury in these cases.

SYMPTOMS.—The symptoms of orchitis are local pain and swelling, with, in cases of orchitis sometimes, and in cases of gonorrhoeal epididymitis frequently, redness and tension of the corresponding part of the scrotum. Severe lumbar pain is in some cases felt, especially by labouring men, who apply for relief on account of some supposed sprain or injury, being ignorant of, or attaching no importance to, the affection of the testicle. This is probably due to inflammation of the lumbar lymphatic glands, with which the lymphatics of the testicle freely communicate; but it may possibly be an example of 'referred sensation.'

PROGNOSIS.—The prognosis is good. The inflammation usually subsides speedily, and leaves the gland in a healthy condition. Atrophy sometimes results after inflammation associated with mumps, or caused by severe contusion. Chronic induration of the epididymis may persist; but after some months it usually disappears. Stricture of the epididymis, or of the vas deferens, is very rare. Suppuration does not occur except in pyæmia, or after the eruptive fevers, or in tubercular orchitis.

TREATMENT.—Rest in the recumbent position, with the scrotum supported by a crutch-pad, and the application of ice locally, are in ordinary cases sufficient. Where rest is impossible, well-adjusted strapping of the part affords considerable relief, and promotes absorption of the products of inflammation so rapidly as not infrequently to necessitate the re-application of the strapping within twenty-four hours. Attention to diet, and avoidance of all violent exercise, will be requisite. The acute pain of the early stages is relieved by tartarated antimony and free purging. In more protracted cases mercury, taken in small doses internally, or applied locally by inunction or on strapping, will be found of benefit. Small and repeated doses of quinine and of iodide of potassium are a valuable adjunct. The practice, of late years recommended by some eminent surgeons, of puncture or incision of the ordinarily inflamed gland, is seldom necessary. If suppuration, however, occur, a free incision should be made as early as possible.

B. Chronic Inflammation.—Chronic orchitis may sometimes be the result of an acute attack, but is much more frequently induced by *syphilis*, *tuberculosis* or *gout*.

(a) *Syphilitic Orchitis.*—This variety may occur in young children who are the subjects of inherited syphilis, in the form of hard nodules in the testicle. In adults it belongs to the gummatous stage of the disease, and is very often symmetrical. It is usually painless, the patient being frequently ignorant of its existence. The gland is enlarged, very hard, insensitive to pressure, and often nodular in form. A gummatous testis has not infrequently been mistaken for malignant disease and excised. The diagnosis may be exceedingly difficult, but treatment with mercury and iodide of potassium usually sets the doubt at rest.

During the period of general eruption syphilitic orchitis sometimes commences in an acute form. The testicle is enlarged, very tender on pressure, with dull aching pain limited to the gland or radiating to the groin and back. There is usually effusion in the tunica vaginalis, varying in quantity in different cases, and the scrotum is congested and cedematous. Generally only one testicle is affected, but after some weeks the other gland may also present similar symptoms. The condition resembles gonorrhoeal epididymitis, but may be distinguished from it by the absence of any existing or precedent urethral discharge, by the body of the gland being solely or chiefly affected, and by the existence of concomitant syphilitic symptoms. It rapidly improves under mercurial treatment, but if left untreated generally passes into the ordinary chronic form.

TREATMENT.—This form of orchitis is usually very amenable to treatment, but has a tendency to recur. Iodide of potassium combined with mercury in small doses internally, when it can be tolerated, and strapping locally, will in most cases produce rapid disappearance of the disease, for a time at any rate. In obstinate cases intramuscular injections of mercury are of great value. Atrophy may sometimes result; and in some cases suppuration, with the formation of troublesome sinuses, may occur. In some cases the gland has, after very prolonged and unsuccessful treatment, to be removed.

(b) *Tubercular Orchitis.*—Tuberculosis nearly always begins in the epididymis, and may spread thence along the vas deferens to the vesicula seminalis. It ultimately attacks the rete and body of the testes. It is, however, unusual for tuberculosis to affect solely the genito-urinary organs, so that other foci may be found in the lungs, cervical lymphatic glands, or elsewhere. In children tubercular orchitis is not uncommon, and may begin in the body of the testis. It usually runs a rapid course, and is associated with tuberculosis elsewhere.

Tuberculosis runs the same course in the testicle as it does in other organs. After the deposition of tubercle-bacilli an inflammatory process takes place, and the inflammatory products tend to undergo fatty degeneration and caseation. The disease may continue at this stage for a long period, or the caseous nodule may become enveloped in a fibrous capsule, or calcification may in very rare instances occur. As a rule, however, the tuberculous mass softens and an abscess is the result. The pus may escape by extension of the inflammatory and degenerative processes through the back of the

epididymis to the scrotum. In the final stage the skin of the scrotum becomes inflamed and ulcerated, and the abscess empties itself, leaving, perhaps, a tubercular sinus. Or the inflammatory process may spread from the tunica vaginalis vera to the tunica vaginalis reflexa, causing an adhesion of those layers of serous membrane, and allowing the tubercular inflammation to reach the scrotum, with subsequent ulceration and escape of the pus. Not infrequently the escape of the pus is followed by a protrusion of granulation-tissue and testicular substance, constituting one of the commonest of the varieties of hernia of the testis.

CLINICAL PHENOMENA.—Tubercular disease of the testes is usually insidious in its onset. Pain is seldom a marked feature, and, perhaps by accident, an indolent, nodular swelling is felt in the epididymis or body of the testis. This nodule is hard to the touch, and can be handled without causing an excess of pain. After a while 'testicular sensation' is altered or lost—a point on which some lay great stress. In some cases tubercular disease of the testis runs a more acute and rapid course and quickly results in the formation of a tumour of considerable size, and with a decided tendency to soften, ulcerate, fungate, and become septic. In this class the general condition of the patient may be serious, owing to tuberculosis of the lungs, hectic fever, and the pain and discomfort of the scrotal tumour. Under such circumstances as these the removal of the testicle affords great relief, and is borne exceedingly well.

In most instances the vas deferens becomes inflamed and thickened, and tubercular nodules may form along its course. The vesiculæ seminales, bladder, prostate, ureters, and kidneys may become infected by extension along the vas deferens. A rectal examination is, therefore, always necessary, and an endoscopic examination of the urethra and bladder may be required.

DIAGNOSIS.—The diagnosis of tubercular orchitis is not, as a rule, difficult, but may present many difficulties. Gonorrhoeal epididymitis sometimes leaves indurations which have a close resemblance to those caused by tuberculosis. Furthermore, gonorrhoeal epididymitis may actually be followed by tuberculosis. Cysts of the epididymis, gummata, and malignant growths have also been mistaken for tubercle. In cases of doubt a test-dose of Koch's tuberculin may be administered.

Tubercular orchitis is sometimes a complication of general military tuberculosis. This variety does not require surgical intervention.

The tunica vaginalis may be full of inflammatory effusion, so as to obscure the tubercular nodules in the testicle. For purposes of diagnosis the fluid should be removed with a fine trochar and cannula.

TREATMENT.—When the tubercular nodule is small and localised, it may be explored under an anæsthetic, and thoroughly evacuated with a sharp spoon. The wound is rubbed with iodoform, and closed after the insertion of a temporary drain. If necessary this operation may be repeated. When the testicle contains several tubercular nodules, the operation which has just been described is unlikely to remove all the disease, or, if it did so, leave an organ of any size or utility. Under such circumstances as these castration is required. If the cord is healthy it may be divided at the external abdominal ring, but should doubt exist as to its healthiness, the inguinal canal should be opened so that as

much as possible of it can be excised. More extensive operations have been performed for the excision of the vas deferens and vesicula seminalis, but have not found favour in the eyes of British surgeons.

When an operation is contra-indicated the progress of the disease may be delayed by careful attention to the general health, cod-liver oil, malt-extract, carbonate of guaiacol, and abundance of fresh, dry air.

(c) *Gouty Orchitis.*—Chronic orchitis from gout can be diagnosed by the history of the patient, and yields readily to the ordinary treatment for gout, but is very apt to recur.

9. *Injuries.*—The testes are greatly protected from accidental violence by their mobility, and the laxity of the surrounding structures. Immediate death has resulted from severe contusions of the testicle, probably from reflex inhibition of the action of the heart. Contusions and wounds require appropriate surgical treatment.

10. *Carcinoma and Sarcoma.*—These are classed together, because, though histologically of very different origin, the distinction between them in any individual case is often impossible, except by microscopical examination of the tumour after removal. Even then the distinction is sometimes impossible, if we may judge from the description of recorded cases of mixed sarcoma and carcinoma.

Carcinoma originates in the epithelial structures of the gland, and is almost invariably of the encephaloid variety. Scirrhus occurs sometimes, but many specimens in museums classified under that heading are probably examples of fibrous sarcoma. Encephaloid cancer usually commences in the body of the testis, by the formation of one or more nodules. Sometimes the epididymis is first attacked. Very rarely is there general infiltration of the gland. In an early stage of the disease the testis is hard, from tension of the tunica albuginea, but when this has been destroyed in the progress of the growth, the mass is soft, and there is often distinct fluctuation. This may be unequal at different parts, from the presence of cysts. The growth is usually painless, but in some cases there is acute pain, either locally or in the lumbar region. The chief aids to diagnosis at this period are the rapidity of the growth, the enlargement of the blood-vessels of the cord, and the age of the patient. For while encephaloid cancer has been met with in young children and old people, still the vast majority of recorded cases have occurred between twenty and forty years of age. The writer has met with cases of malignant adenoma of the testis which closely resembled the Wolffian body in structure.

If the tumour attain a very large size, the scrotum may slough, and a bleeding fungus protrude. The disease has a great tendency to invade other parts of the system, and especially at an early period the lumbar lymphatic glands. This may lead to oedema of the lower extremities, from pressure on the abdominal veins. The inguinal glands generally escape infection, except in some cases where the scrotum has been involved in the disease. Secondary growths have been found in the mesenteric glands, liver, spleen, and lungs.

Sarcoma originates in the connective tissue of the testicle, and sometimes develops in both glands simultaneously. On microscopical examination two varieties can be distinguished, the round- and the spindle-celled. The latter grows more slowly, and

both are often associated with cystic and cartilaginous formations. The symptoms are very similar to those of cancer.

Sarcoma sometimes commences in the tunica vaginalis, and is then usually accompanied by extravasation of blood into the sac. Two such cases were met with in which the shape of the tumour, the complete absence of pain, the history of gradual enlargement, and the very distinct fluctuation were suggestive of hæmatocele. Exploratory examination, however, proved them to be cases of sarcoma. Castration was performed, and the testicles were found to be only slightly affected by the disease. Both cases died within a short period after the operations, from secondary affection of other organs, accompanied by similar hæmorrhages.

Melanoma of the testis was formerly regarded as a form of cancer, but is now considered to be sarcomatous. It is extremely rare, and in the few recorded cases of it similar growths were found in many other organs of the body.

DIAGNOSIS.—As a general rule it may be stated that sarcoma occurs most frequently under ten and over forty years of age; and that the epididymis is more frequently the primary seat of the disease, and, when secondarily involved, is attacked at an earlier period than in cancer. The distinction in any individual case must, however, be very uncertain, and is of little importance.

PROGNOSIS AND TREATMENT.—The prognosis is very unfavourable in both, as recurrence of the growth in other organs after the removal of the tumour is the rule to which there are but few exceptions. But hitherto an early exploration of doubtful tumour has hardly been practised by surgeons. The present writer (C. B. L.) has had much more favourable results by early intervention. It is now, with modern antiseptic precautions, much safer to explore doubtful tumours of the scrotum. Castration is the only possible treatment for both diseases.

II. Neuralgia and Irritability.—The testicle is sometimes the seat of very acute persistent or periodically recurring neuralgia. This must be distinguished from hyperæsthesia or irritability of the gland, which is occasionally associated with varicocele, or may be the result of self-abuse, excessive venery, or even of unsatisfied sexual excitement. Neuralgia may be due to some local cause, to varicocele, to a descending hernia, or to induration of some part of the glandular apparatus from precedent inflammation. It may be a transferred sensation, as in renal colic. Sometimes it occurs in cases of enlargement of the prostate, and more especially when prostatic calculi are present. The presence of a urethral stricture ought to be suspected and sought for. Occasionally no cause can be discovered, and we have to assume that it is due to some affection of the central nervous system. A family history of epilepsy or of lunacy would also have to be taken into consideration.

TREATMENT.—When of local origin, the treatment of neuralgia of the testis must be directed to the removal of the cause; and if all other methods fail, and the pain be severe enough to warrant it, castration may be required. When due to affections of other parts of the body, the treatment must be regulated accordingly.

Hyperæsthesia of the gland usually yields in time to tonics and attention to ordinary hygienic conditions.

12. Teratoma.—The testis, like the ovary, may be the seat of cysts containing hair, skin, bones, &c. The cysts are sometimes within, sometimes upon the gland. The more complex cases may be best explained as resulting from the inclusion of a second fertilised germ; while the simpler cases may be due possibly to the accidental inclusion of part of one of the proto-vertebræ within the rudimentary testicle. The history of a congenital tumour will suffice to direct attention to any such case. They are very rarely met with, and castration is the only suitable treatment. In this class we may include some of the cystic tumours originating near the hilum of the testis, which, in addition to the cysts, contain cartilage and muscle of both the smooth and striped varieties. The cysts in these cases originate, it is thought, in Wolffian remains.

J. MCCARTHY.
C. B. LOCKWOOD.

TETANUS.—SYNON. : Lock-jaw ; Fr. *Tétanos* ; Gr. *Starrkrampf*.

DEFINITION.—Tetanus is an acute infectious disease due to a specific micro-organism, and is characterised by painful tonic spasms, which at first affect certain groups of muscles, but tend to become generalised, and are accompanied by exacerbations of a paroxysmal character.

ÆTIOLOGY.—Though in many cases of tetanus no wound or focus of infection has been discovered, yet the modern conception of the nature of the disease compels us to the belief that in all alike the infective material must have gained admission through some breach of surface. The term 'idiopathic tetanus' is now used merely to indicate that the primary focus has not been found. In the majority of cases a wound or a recent cicatrix is present or a definite history of a wound can be obtained.

The primary lesion in tetanus may be of the most varied character, but the commonest forms are punctured, contused, or lacerated wounds, and the most frequent sites for these are the extremities. As the causal agent is a constant inhabitant of certain soils it is easily understood how these are the parts most commonly infected. Dirty wounds, especially those which have been contaminated with soil, and which have been neglected or which are difficult to cleanse, are the most fruitful source of the disease. Rarer cases have been described as following tooth-extraction, hypodermic injection, ligature of piles, frost-bite, and fractures. It has also occurred as a complication of typhoid fever (Rose); and such cases help us to understand how easily the focus of infection in 'idiopathic' tetanus may have been overlooked. Tetanus is commoner in hot than in temperate climates, and in the dark-skinned than in the Caucasian races.

Epidemics of tetanus have been described. Indeed their occurrence suggested the infective nature of the disease long before its actual demonstration. In certain wars tetanus has been a frequent complication of wounds, and there appears to be no doubt that excessive exertion, great fatigue, and exposure to cold are important predisposing causes. The fact that the wounded frequently lie on the ground for some time, and that their wounds are apt to be contaminated by dust and soil, are important factors to be noted in this connection. In emphasising a chill as a predisposing cause of tetanus Macnamara says 'it is a matter of common observation in Bengal that after sudden changes of

temperature cases of tetanus appear among surgical patients.' The introduction of *antisepsis* has almost abolished the disease as a result of surgical operations. In the Transvaal war (1899-1901) it appears to have been almost unknown. It is no doubt in most part due to the same cause that there has been great diminution in the number of puerperal cases, and of cases of the tetanus met with in new-born children (*tetanus neonatorum*) which occurred in epidemic form in certain West Indian islands and in St. Kilda. Of the domestic animals the horse is most susceptible to tetanus.

Isolation of the Bacillus.—The bacillus of tetanus was first successfully isolated and grown in pure culture by Kitasato in 1889. To isolate the bacillus, pus from the wound in a case of tetanus is inoculated on the surface of sloping agar-agar or solidified blood-serum. The tetanus-bacillus grows along with the other organisms present. After forty-eight hours' growth in the incubator the culture is subjected to a temperature of 80° C. in a water-bath for an hour. As a rule only the spores of the tetanus-bacillus survive this treatment. Plate-cultures on gelatine or agar-agar inoculated from the heated material and grown in an atmosphere of hydrogen give a growth of the tetanus-bacillus.

Morphology of the Bacillus.—The rods vary in size from 2-5 μ in length and from .5-.8 μ in breadth. The round or ovoid spores may reach a diameter of 2 μ . They are most frequently situated on the end of a rod, giving rise to a characteristic pin or drumstick form, which, however, is not strictly limited to the tetanus-bacillus. Filaments which may form spores, and have been described as sometimes branching, are often present. The bacillus is motile and possesses numerous cilia, which may be situated at the ends or round the rod. The bacillus is readily stained by any of the ordinary aniline dyes, and also by Gram's method.

Habit of Growth.—When newly isolated from the animal body the bacillus grows only in the absence of free oxygen, but after long cultivation on artificial media it tends to become less strictly anaërobic. With this change loss of virulence usually occurs. On the other hand, when grown under anaërobic conditions the organism retains its virulence well for years.

Races of the tetanus bacillus which grow best under aerobic conditions have been described by several observers, but these are exceptional. Aërobic bacilli growing in association with the tetanus bacillus may favour its growth by absorbing oxygen. It grows best at a temperature of 36°-38° C., the spores appearing at the end of thirty hours. Below 14° C. its growth ceases; between 20° and 25° C. it is very slow, and spores do not appear for seven or eight days. The spores show great resistance to heat, to drying, and to antiseptics. A moist heat of 80° C. for an hour does not kill them, and kept in a dry condition they retain their vitality for years. Water or steam at 100° C. kills them in five to fifteen minutes; steam at 115° C. in five minutes. They resist the action of carbolic acid (5 per cent.) for ten hours, and a solution of corrosive sublimate (1:1000) for several days.

Cultural Characters.—Only the most striking features can be described here. Grown on gelatine-plates in an atmosphere of hydrogen the colonies appear as minute grey specks with spike-like projections from their margins. Under a low magni-

fication these projections are seen in the form of columns of fine wavy threads running out from and forming a halo round the central mass of the colony. After a time the gelatine is liquefied. Deep puncture-cultures in agar show no growth at the surface of the medium, but in the depth along the needle-track a line of growth takes place, and from this radiate delicate processes, the whole resembling the outline of a fir-tree.

When sugar is present in the medium gas is evolved. Certain substances, such as glucose and sulphindigotate of sodium, when added to the media aid the growth by acting as reducing substances.

Distribution.—Not only is the tetanus-bacillus found in the wounds of men and the lower animals suffering from tetanus, but it has a wide distribution in nature. It is common in earth, especially the soil of cultivated land, and in the dust of cities and dwellings. It is constantly present in the dejecta of the herbivora, especially of the horse, and is not infrequent in the fæces of the healthy human subject.

Relation of the Bacillus to the Disease.—The tetanus-bacillus when introduced under favourable conditions into a wound multiplies in its depth, and here elaborates its toxin or poison, which, becoming diffused, attacks the central nervous system, for which it has a special affinity, and thus gives rise to the spasms which characterise the disease. The bacillus remains localised at the focus of infection; it is not distributed throughout the body in the blood or organs. Nicolaïer, arguing from this fact, formulated the correct hypothesis of its method of action even before the demonstration of a toxin. The fact that the tetanus-spore is so widely distributed in nature, and that, notwithstanding, tetanus is a rare complication of wounds, requires explanation. Vaillard and Rouget have thrown light on this by demonstrating experimentally that the spores of tetanus deprived by heat of all toxin do not develop in healthy tissues, and that certain conditions are necessary for their development. If there are introduced with the spores wood-splinters, other microbes, or substances such as lactic acid, or if the spores are surrounded by a collodion sac, then they grow and give rise to tetanus. The favouring influence of these substances is supposed to be due to an interference with the action of the phagocytes. In the case of wounds in the human subject the organisms carried in with the tetanus-bacillus probably play the most important part in aiding its growth.

Tetanus-toxin.—The fact that the tetanus-bacillus produces a toxin in artificial media was first demonstrated in 1890 by Knud Faber. He found on filtering a broth-culture of the bacillus through a porcelain filter that the filtrate, which was free from all formed elements, could even in minute doses produce all the symptoms of tetanus in experimental animals. These results were confirmed by Tizzoni and Cattani, who concluded that the toxin was of the nature of a soluble ferment or enzyme. Brieger, by using chemicals such as alcohol and ammonium sulphate, precipitated from cultures a substance which gave rise to tetanus, and which he regarded as a toxalbumin. It is probable that these precipitates only carry down albuminous substances in which the real toxin is entangled. Buchner showed that the precipitate obtained by saturating with ammonium sulphate, when kept in the dry state, was more stable than unprecipitated toxin. This

fact has been used by Knorr and Behring to obtain a stable test for the standardising of antitoxins. Such toxins may be so powerful that 0·000,000,04 grammes is sufficient to kill a mouse.

Kitasato stated that five minutes at 65° C. destroys the toxin, but Vaillard and Rouget have shown that an hour at 80° is necessary to remove the tetanising properties completely. The liquid toxin rapidly loses strength when exposed to sunlight and air, and even when kept in the dark *in vacuo* undergoes changes similar to those occurring in diphtheria-toxin, non-lethal toxoids being formed. In two months it may be reduced to one-fifth of its original strength. Tetanus-toxin has thus many points of resemblance to the soluble ferments: it is difficult to dialyse, is soluble in water, is precipitated by alcohol and tends to adhere to precipitates, is modified or destroyed by the action of air, sunlight, and comparatively low temperatures, and requires an incubation-period for its action on animals.

The injection of toxin produces in many animals the symptoms of tetanus as they occur spontaneously, or from the injection of cultures of the bacillus. Different species of animals have different degrees of susceptibility, which have been accurately worked out by Behring. The horse, probably next to man, is the most susceptible. Of experimental animals, the guinea-pig, mouse, and rabbit are most frequently used. The frog is more susceptible when kept at the temperature of warm-blooded animals than at lower temperatures. The tortoise is completely insusceptible and retains the toxin for several months unchanged, so that its blood is capable of producing tetanus in mice (Metchnikoff). Only one case of injection of tetanus-toxin into man has been recorded. M. Nicolas accidentally pricked his thenar eminence with the needle of a Pravaz syringe which was only moist with tetanus-toxin. After an incubation-period of four days a severe attack of tetanus supervened. The muscular spasms began in the hand but became generalised. Recovery took place after forty-one days. If one can judge from this single case man must be reckoned among the most susceptible of animals.

Between the injection of tetanic toxin into an animal and the development of the symptoms, there is always an incubation-period, which varies in length with the species of the animal and with the dose of toxin. In the mouse, rabbit, and guinea-pig it varies from 8 to 36 hours, in the fowl from 4 to 9 days, in the horse from 5 to 7 days. Even if one injects into a guinea-pig a dose of toxin many thousand times the minimal lethal dose, there is always an incubation-period of several hours. In such cases the disease, when it appears, runs a very rapid course, and it may be stated that as a rule the shorter the incubation the more severe and rapidly fatal is the disease. Tetanus-toxin, in requiring a latent period, differs markedly from such poisons as strychnine.

In the guinea-pig, rabbit, and mouse, after subcutaneous injection of toxin, spasms of the muscles first occur near the site of inoculation. With small doses of toxin the condition may remain localised and recovery may take place. With larger doses the muscular spasms become generalised and death usually occurs. Intravenous injection causes generalised spasms.

Roux and Borrel, by injecting tetanus-toxin into the cerebral cortex of animals, have succeeded in producing a distinctive form of tetanus, 'cerebral

tetanus,' which is chiefly characterised by psychical phenomena. The animal appears to labour under hallucinations, has periods of excitement, during which it runs wildly about, and epileptiform crises, alternating with periods of repose. Animals actively or passively immunised are not protected against this cerebral tetanus, even though their blood-serum is strongly antitoxic. Ehrlich has shown that, besides the tetanising substance in tetanus-toxin, another body, tetano-lysin, is present, which has the property of destroying or laking the red blood-corpuscles, and that an antilysin which neutralises this hæmolytic action is present in tetanus-antitoxin.

The affinity long suspected by clinicians to exist between the tetanus-poison and the nervous centres has been demonstrated experimentally by Wassermann and Takaki in a tangible and striking manner. If the brain or spinal cord of a healthy animal is emulsified and added to tetanus-toxin, the mixture is found to be no longer toxic when injected into a susceptible animal. 1 c.c. of brain-emulsion completely neutralises ten minimal lethal doses for the mouse. The protective action may be exercised even when the brain-emulsion is injected before or at different points from the toxin. They regard the experiment as confirmatory of Ehrlich's theory of immunity and attribute the neutralisation to the presence of preformed antitoxin in the nerve-cells. Roux, Metchnikoff, and others interpret the observation in a different manner. According to them the toxin is unchanged, but adheres to the nerve-cell like a colouring matter, and the phagocytes can deal more readily with the poison when thus fixed. The toxin reaches the nervous centres by two paths. One of these is along the course of the nerves, and hence probably the local muscular spasms in experimental animals, and the affection of the facial nerve in cephalic tetanus. Marie has proved experimentally that resection of part of a nerve prevents the onset of tetanus, if the toxin is injected into the paralysed muscle. The other path is by the blood-stream.

MORBID ANATOMY.—Hæmorrhages into the anterior cornua of the spinal cord and chromatolysis of the nerve-cells, as stained by Nissl's method, have been described by Marinesco as the essential changes in the disease. Goldscheider, Flatau, and others have found these same changes in strychnine-poisoning, and have failed to find them in tetanus in certain species, such as the dog. They therefore maintain that they cannot be held to be characteristic of tetanus only.

EXPERIMENTAL BASIS OF THE ANTITOXIC TREATMENT.—Behring and Kitasato were the first to show that susceptible animals could be rendered immune to tetanus-infection and that the blood-serum of such immunised animals possesses protective and curative properties when injected into other animals. Their first experiments were conducted on rabbits, and they succeeded in immunising a rabbit so that it could resist twenty times the lethal dose of toxin or of culture. They found that 0·2 c.c. of the serum of this immune animal injected into a mouse conferred immunity on it, and that tetanus-toxin, when mixed with this serum, was deprived of its toxic action. They also stated that mice which had already developed symptoms of tetanus could be cured by injections of the serum.

These experiments first showed the possibility of conferring passive immunity and were the basis of

serum-treatment. With the view of obtaining serum in sufficient quantities for therapeutic purposes, the horse was selected. Though naturally extremely susceptible to tetanus it was found possible to obtain a very high degree of immunity. Various methods of immunising have been employed. Small and progressively increasing doses of filtered toxin may be injected, or toxin modified by heating or by the addition of iodine terchloride, or Lugol's solution. After several months of treatment the horse may attain such a high degree of resistance that many thousand lethal doses of toxin or culture are tolerated. The serum from such a highly immune animal attains wonderful *preventive powers*. 1 c.c. of a serum of moderate strength can protect 100,000,000 grammes weight of mice against a lethal dose, and much stronger sera than this have been obtained. Behring and Kitasato's statements as to the *curative action* of the serum in experimental animals have been much criticised, and the evidence goes to show that after the appearance of symptoms a very small proportion of animals can be saved by subcutaneous injection of even the most powerful serum.

In the treatment of experimental tetanus Roux and Borrel obtained very favourable results by injecting the antitoxin into the cerebral substance. Out of 45 guinea-pigs, already tetanic, treated in this way, 35 recovered; out of 17 by subcutaneous injections of much larger doses of antitoxin only 2 recovered; the 17 controls which received no serum all died. A few drops of antitoxin injected into the brain had much greater curative power than large quantities given subcutaneously or intravenously.

Tetanus in Man.—**INCUBATION.**—In tetanus the incubation-period varies from days to months. About one-third of the cases occur in the first week and nearly one-half in the second week after the injury (Rose).

SYMPTOMS.—The symptoms begin in man as a rule with the occurrence of tonic spasm of the muscles of expression. The eyebrows tend to be elevated and the angles of the mouth pulled outwards and downwards, thus giving rise to the risus sardonius, which may however be absent in well-marked cases of tetanus. Even before this the patient may complain of stiffness of the neck or jaws. The spasm of the muscles of mastication increases till the jaws may be completely locked. Deglutition is impeded by spasm of the muscles of the pharynx. The stiffness of the muscles of the neck may extend to those of the trunk, and in severe cases the muscles of the lower extremities are also involved, the knee- and ankle-joints being extended. The tonic spasm of the muscles involved is never quite relaxed, but in addition paroxysmal exacerbations occur during which the contractions are so violent that rupture of muscles may take place. These paroxysms are accompanied by agonising pain. There is great hyper-excitability to stimuli so that even a draught may excite a paroxysm.

The muscular spasm may be so great that the body and limbs may be perfectly rigid (*orthotonos*), or arched like a bow, the patient resting on his occiput and heels (*opisthotonos*). More rarely the body is bent to one side (*pleurothotonos*), or forwards (*emprosthotonos*). In the severest type the respiratory muscles are affected, the thorax being compressed as in a vice (Watson), and spasm of the glottis may give rise to asphyxia. Hunger, thirst,

and inability to speak are very painful features of the worst cases. The body is usually bathed in sweat.

The temperature may be normal or little elevated even in severe cases; on the other hand some cases have pyrexia throughout. After death the temperature rises and may reach 110° or even higher. The intellect generally remains clear to the last. The immediate cause of death is asphyxia, heart-failure, or exhaustion.

Head-tetanus or tetanus facialis.—This form is due to wounds on the head usually in the region of the facial nerve, and the symptoms of tetanus are associated with paralysis of that nerve on the injured side. The prognosis is better than in the ordinary form.

Tetanus or trismus neonatorum.—The focus of infection is at the umbilical cord. It is rare in this country, though not uncommon in the tropics. Difficulty in sucking is the most prominent symptom.

Puerperal tetanus most frequently occurs after abortion, abnormal labour, and the use of instruments. It differs from other forms only in the site of infection.

PROGNOSIS.—Most writers estimate the mortality as over 80 per cent. Rose from the statistics of 716 traumatic cases finds a mortality of 88 per cent. He also found from an examination of 73 cases that those with an incubation-period within one week had a mortality of 91 per cent., within two weeks of 81.3 per cent., within the three and four weeks of 52.9 per cent., and of very late cases 50 per cent.

The length of incubation is perhaps the most important indication in prognosis. If the spasm rapidly affects one group of muscles after another the prognosis is bad; if it affects only the jaws and neck the prognosis is more favourable.

Macnamara from a large experience relies largely on temperature: 'if it rises beyond 101° there is impending danger, and if it reaches 103° the case is one to cause the greatest anxiety.'

TREATMENT.—**Local.**—It is essential when possible to put an end to the further elaboration of toxin, and this may often be effected by removal of foreign bodies such as wood-splinters by excision, or thermo-cauterisation and subsequent antiseptic treatment of the wound.

Amputation is sometimes advisable, especially of fingers or toes, where these are seriously injured. For the local treatment of the wound, solutions of iodine have been recommended by Sahli in view of Behring's observations regarding the power this substance has to neutralise the poison. Tizzoni and Cattani have shown that nitrate of silver in 1-per-cent. solution is one of the most powerful of antiseptics against the tetanus-organism.

General.—The patient must be guarded against all disturbing influences, which tend to cause paroxysms, such as draughts, noises, and too minute clinical examinations. Where the feeding is difficult from locking of the jaws the food must be administered by the nose or rectum. With the view of alleviating the severity of the spasms the pharmacopœia has been ransacked, but the most experienced observers are doubtful whether the course of the disease is in any way influenced by the use of drugs. Opium, chloral hydrate, and bromide of potassium are most frequently employed, but curare, calabar bean, Indian hemp, belladonna and many

others have been used. The administration of chloroform is indicated where the paroxysms are very violent and exhausting. Baccelli claims to have obtained excellent results by subcutaneous injection of carbolic acid in 2-per-cent. solution. About 5 grains of carbolic acid are given per day divided into several doses to which $\frac{1}{2}$ grain of morphine may be added.

The antitoxin-treatment of tetanus has hardly fulfilled the high expectations that were originally formed of it. As a prophylactic it has been proved, especially in veterinary practice where it has been used under test-conditions, to be almost infallible. Thus Nocard has collected the results obtained during twenty-two months by sixty-three veterinary surgeons who used preventive injections before operations such as castration, &c., in 2,300 animals, or after wounds in 400 animals. The cases both operative and traumatic they selected from those in which from their experience they knew that tetanus was liable to occur. Not one of these 2,700 animals died of tetanus, whereas the same observers recorded during the same period 259 cases of tetanus in untreated animals.

In the treatment of declared cases, however, both in man and in the lower animals, the bulk of opinion can hardly be said to be so favourable. The reason for the failure in many cases is due to the fact that the disease can be recognised only when the toxin has already seriously injured the nerve-cells. Though the antitoxin fails to remedy this injury, there is no doubt that it neutralises the toxin which is being elaborated and is entering the blood.

It ought to be administered in large doses on the very first symptoms appearing; and to give it, as has often been done, in small doses or as a last resort is to court failure. Neglect of these two requirements has been the cause of much of the discredit into which the treatment has fallen. One hundred c.cm. of the serum should be at once injected, and this repeated on the second and third days, and even if the case appears to be progressing favourably another injection ought to be given ten to fourteen days after the first. Even allowing that the results have fallen short of the original anticipation, the statistics tend to show that in cases treated with antitoxin the mortality is lower than in cases treated by the older methods. Hewlett in 1895 out of 50 cases found a mortality of 32 per cent. More recently Koehler dealing with statistics of 96 cases treated by antitoxin found the death-rate to be only 34.4 per cent.; of the cases with an incubation under ten days the mortality was 43.8 per cent.; when the incubation was longer than that the mortality was only 18.5 per cent. The favourable results obtained by Roux and Borrel from intracerebral injection of antitoxin in animals in which tetanic symptoms had already appeared has led to the treatment by this method of a number of cases of tetanus in the human subject. A small hole is drilled with an Archimedean drill through the skull just in front of the motor areas, and the needle of the syringe, which is 2 inches in length and blunt-pointed, is inserted through the trephine-hole and pushed its whole length into the brain-substance. $2\frac{1}{2}$ c.cm. are injected very slowly into each side. Under strict asepsis the operation is well tolerated.

The writer has before him the results in 27 cases treated by this method: 7 cases recovered, 20 died;

a mortality of 74.7 per cent. The results, therefore, have not been encouraging.

SUMMARY.—The most hopeful line of treatment consists in (1) the subcutaneous injection of large doses of antitoxin as described; (2) excision and antiseptic treatment of the focus of infection; (3) the use of chloral hydrate in large doses, or chloroform to restrain the violence of the paroxysms. See SERUM-THERAPEUTICS.

GEORGE DEAN.

TETANY.—SYNON.: *Tetanilla*; Idiopathic Muscular Spasm; Fr. *Tétanos Intermittent*; Ger. *Tetanie*.

Tetany is a neurosis described originally by Dance in 1831, and more or less fully since under many names, especially in France. It is probably much more common in that country than in England, where it is very rarely met with. It is mostly a comparatively trivial and temporary malady.

ÆTIOLOGY.—Tetany is associated with no recognised organic changes in any part of the nervous system; and much uncertainty prevails in regard to its causation. Apart from rickets it occurs mostly between the ages of fifteen and thirty years, though it may show itself in older people, as well as in children and in infants. It occurs in either sex, but is more common among females. Persons of a neurotic temperament, or those whose constitutions have been disturbed or weakened from many causes, are specially liable. Rickets, teething, the establishment of menstruation, chronic diarrhoea, lactation, and the state of convalescence from many acute diseases, are all conditions which predispose to this affection; while exposure to cold and emotional disturbance seem to act as the most common exciting causes.

SYMPTOMS.—The morbid manifestations of tetany consist, in the main, of tonic spasms, frequently recurring for brief periods in one or other part of the body, painful in character, and unaccompanied by loss of consciousness. The attacks in different individuals vary widely, the spasms being sometimes quite local, sometimes involving many different regions of the body.

In the *slighter kinds* of attack, a numbness and tingling is felt in the fingers and toes, which speedily become fixed in tonic spasm. As the spasms strengthen, they may extend to higher parts of the limb and become painful. The fingers are drawn together and slightly flexed, the thumb is bent into the palm, and the wrist slightly flexed. The toes also are drawn together and towards the sole, the big toe being drawn under them. The dorsum of the foot is arched, and the heel pulled up, while the leg and thigh are more or less rigidly extended. One or more of the limbs may be affected in this way; or if all are implicated, it may be simultaneously or successively. This condition of things lasts for a few minutes, or even for an hour or two, accompanied often by severe pain along the nerve-trunks, and by some diminution of sensibility in the parts affected. When the attack is about to terminate formication sets in, as at the commencement of the spasm. After variable intervals the attacks are renewed, it may be in an hour or two, or only after several days. Such paroxysms may be frequent during several months; and, according to Trousseau, so long as a tendency to recurrence of the spasms exists, they may always be excited anew by simply tapping or 'compressing the affected parts, either in the course of their principal nerve-trunks, or over their

blood-vessels, so as to impede the venous or arterial circulation' (*facial irritability*). On the other hand, the application of cold to the parts affected frequently arrests the spasms for a time.

In the *more severe forms* of tetany, the attacks may begin in the manner above indicated in the upper extremities, next in the lower extremities, and then, while diminishing in the parts first affected, the spasms may extend more or less generally to the muscles of the trunk. The contractions are invariably more or less painful. The spasms may even spread to the facial muscles, so that the jaws may be firmly clenched, and speech greatly embarrassed. If the muscles of the larynx are involved, as well as those of the chest and abdomen, extreme dyspnoea may be induced. Still there is no loss of consciousness. These attacks may be of brief duration; or they may be extreme in degree, long-continued, and frequently repeated. In these latter severe cases there is slight elevation of temperature, with greatly quickened pulse, and a furred tongue. After some weeks or months the paroxysms usually become less severe and less frequent, and finally cease altogether.

DIAGNOSIS.—The diagnosis must be based upon the progressive character of the attacks; upon the fact that they begin in the upper and lower extremities, and after a time completely intermit; upon the absence of all loss of consciousness during the attack; and upon the fact of the possibility of re-inducing the paroxysms by pressure upon the nerves or vessels of the parts affected. These characters will suffice to distinguish the affection from tetanus, epilepsy, and hysteria.

PROGNOSIS.—The prognosis is usually favourable, the complaint gradually subsiding after a few months. Still, in very exceptional cases, the patient may die asphyxiated during one of the extremely severe attacks.

TREATMENT.—The treatment of tetany should in the main be directed to the improvement of the patient's general health, and the diminution of all debilitating conditions or causes of irritation. At the same time, we must endeavour to lessen the general mobility of the nervous system, by seeing that the patient obtains regular and sound sleep, as well as by the administration of one or other of the bromides in suitable doses, in combination with valerian, musk, conium, or other antispasmodic remedies.

H. CHARLTON BASTIAN.

THALAMUS OPTICUS, Lesions of. —
SYNON. : Fr. *Maladies des Couches Optiques*; Ger. *Krankheiten der Sehhügel*.

INTRODUCTION.—Diseases of the optic thalamus vary in their symptomatology, according as the lesion is strictly limited to the ganglion itself, or implicates also neighbouring structures.

In the former case it is apparently well established by numerous recorded cases that lesions, such as apoplectic cysts or areas of softening, may exist without producing any discoverable symptoms, in the domain of either motility or sensibility, general or special. This is more particularly the case when the lesions occupy the convexity or ventricular aspect of the optic thalamus.

But more frequently diseases affecting the optic thalamus implicate also, directly or indirectly, the corpus striatum, internal capsule, crus cerebri, or corpora quadrigemina. Owing to the community

of vascular supply between the corpus striatum and optic thalamus through the optico-striate arteries of Duret, embolism or rupture of these vessels leads to conjoint destruction, more or less extensive, of both ganglia, as well as rupture of, or pressure on, the fibres of the internal capsule. A hæmorrhage or embolism in this region produces hemiplegia of the opposite side of the body. But that the hemiplegia is not necessarily due to the lesion of the optic thalamus is clear from the fact that such lesions may exist without any motor paralysis whatever. It is, therefore, more logical to attribute motor paralysis, when it does occur in connection with lesions of the optic thalamus, to implication, direct or indirect, of the motor fibres of the internal capsule.

LOCALISING PHENOMENA.—It is a question whether, apart from considerations as to causation, there are any symptoms specially characteristic of hæmorrhages in the region of the optic thalamus.

It has been stated, and there is considerable clinical evidence to show, that lesions of the optic thalamus are characterised by paralysis of the emotional movements of the face, as in laughing and crying; while the voluntary movements, as in showing the teeth, are unaffected, or only to a slight extent. The evidence on this point is somewhat conflicting, so that the relation of the optic thalamus to the emotional movements has not yet been satisfactorily established.

The occurrence of anæsthesia on the paralysed side is more constant and more enduring when the lesion invades the optic thalamus and its neighbourhood than when it is confined to the ganglia of the corpus striatum. This is owing to the fact that the posterior fibres of the internal capsule are directly injured, and not merely pressed on, as in the latter case. The anæsthesia may involve the special senses as well as common sensibility, but more frequently the tactile sensibility only is distinctly impaired. The reflex cutaneous excitability is also greatly diminished, as has been shown by Crichton Browne. The paralysed limbs are frequently also affected with unsteadiness, tremors, or chorea-like spasms, intensified on volitional efforts. This affection, termed *post-hemiplegic chorea*, is generally, if not invariably, associated with a greater or less degree of impairment of sensibility in the affected limbs. It is doubtful how much, if anything, can be assigned to the lesion of the optic thalamus itself in the causation of these symptoms. But for regional diagnostic purposes they may be regarded as significant of lesion of the optic thalamus and its immediate neighbourhood. When the lesion involves only the posterior fibres of the internal capsule, lying external to the optic thalamus, the result is hemianæsthesia, general and special, of the opposite side of the body. The power of movement may not be apparently affected. If it be, the leg is, in general, relatively more affected than the arm. But, though the motility is retained, the muscular sense is lost, so that the patient is unaware of the state of contraction of the muscles or the position of the limb, and requires the aid of vision in guiding its movements.

Cases have been recorded which render it in the highest degree probable that lesions of the posterior aspect of the optic thalamus, and region of the corpora geniculata, cause hemianopsia towards the side opposite the lesion, from paralysis of both retinæ on the corresponding side. In an experimental destruction of the pulvinar thalami in a monkey,

there was found temporary total blindness of the opposite eye and hemianopsia in that on the same side. This observation taken in association with the fact that there is an obvious anatomical relation between the fibres of the optic tract and thalamus on the one hand, and of the occipital lobe and the pulvinar on the other, would point to a close connection between the optic thalamus and the sense of sight. The facts of secondary degenerations also show that a large number of ascending bulbar and pontine tracts, including probably those of common sensation, enter the optic thalamus before being transmitted to the cerebral cortex. Hence the symptoms which have been found to follow destruction of the optic thalamus by disease may be due to direct interference with the functions of this ganglion. On the other hand, it is clearly difficult to exclude some implication, direct or indirect, of the adjacent internal capsule. Therefore hemianopsia alone, without other symptoms, cannot be taken as absolutely diagnostic of lesion of the posterior aspect of the optic thalamus. Conjoined with affection of the other forms of sensibility, however, it points to lesion in this region.

Tumours of the optic thalamus, in addition to the general symptoms of intracranial growths (though sometimes these even seem to have been wanting), produce either no special symptoms, or such a variety as to render the regional diagnosis very uncertain or altogether impossible. The symptoms may be those indicative of lesion of the internal capsule, both its motor and sensory strands; or they may be such as have been observed in connection with lesions of the corpora quadrigemina.

A direct relation between lesion of the optic thalamus and the production of pyrexia has been maintained by some observers (Hale White, Ott.). Many experimental facts and numerous recorded cases, however, show that there is no constant relation between changes in temperature and lesions of the optic thalamus.

THERMOMETER, Clinical (θερμῆν, heat; and μέτρον, a measure).—SYNON.: Fr. *Thermomètre*; Ger. *Thermometer*.

DEFINITION.—An instrument for measuring different degrees of heat or cold of the human body.

DESCRIPTION.—Clinical thermometers used in Great Britain and in the United States are graduated with *Fahrenheit's* scale, whereas on the Continent of Europe the *Centigrade* or *Celsius* scale is now everywhere used for medical and scientific purposes, the *Réaumur* scale falling more and more out of use. The difference between these three scales is this, that in the Centigrade and Réaumur scales the melting-point of ice is marked zero, and the boiling-point of water (or rather the heat of the steam of water boiling at an atmospheric pressure equal to 29·92 inches of mercury) marked 100° and 80° respectively; while Fahrenheit marked the former 32° and the latter 212°. Therefore 180 degrees of the Fahrenheit scale are equal to 100 degrees Centigrade and 80 degrees

Réaumur; and the relation of the three scales to each other is as follows:—

F.	C.	R.
9	:	5
	:	4

One degree of F. = $\frac{5}{9}$ C. or $\frac{4}{9}$ R.; one degree C. = $\frac{9}{5}$ F.

In converting degrees of the Fahrenheit scale into Centigrade degrees, it must, however, be borne in mind that zero of the C. scale corresponds to 32 of the F. scale; 32 must therefore be deducted in converting a certain degree of the F. scale into the corresponding degree of the C. scale, and 32 must be added when C. degrees are to be expressed by the corresponding degrees of F. The formulæ for these conversions are, therefore:—

$$x \text{ deg. F.} = (x - 32) \times \frac{5}{9} \text{ deg. C.}$$

$$x \text{ deg. C.} = (x \times \frac{9}{5}) + 32 \text{ deg. F.}$$

For instance:—

$$99\cdot5 \text{ F.} = (99\cdot5 - 32) \times \frac{5}{9} = 67\cdot5 \times \frac{5}{9} = 37\cdot5 \text{ C.}$$

$$39 \text{ C.} = (39 \times \frac{9}{5}) + 32 = 70\cdot2 + 32 = 102\cdot2 \text{ F.}$$

It will be convenient, for quick reference, to give the corresponding degrees of the Fahrenheit and Centigrade scales within the range with which human physiology and pathology are concerned, side by side:—

F.	C.	F.	C.
95·0	35·0	104·0	40·0
96·0	35·55	104·9	40·5
96·8	36·0	105·0	40·55
97·0	36·11	105·8	41·0
98·0	36·66	106·0	41·11
98·6	37·0	106·7	41·5
99·0	37·22	107·0	41·66
99·5	37·5	107·6	42·0
100·0	37·77	108·0	42·22
100·4	38·0	108·5	42·5
101·0	38·33	109·0	42·77
101·3	38·5	109·4	43·0
102·0	38·88	110·0	43·33
102·2	39·0	111·2	44·0
103·0	39·44	112·1	44·5
103·1	39·5	113·0	45·0

In thermometers for clinical use the degrees on the scale ought to be divided into fifths. Thermometers ought to be carefully compared from time to time with a standard instrument, as they are liable, after a certain time, to give abnormally high indications owing to the bulb gradually contracting a little. In England thermometers may be sent for comparison with a standard instrument to the Kew Observatory; in Germany to the Imperial Physico-Technical Institute, Sect. II., at Charlottenburg, near Berlin.

Of great convenience for clinical use has been the introduction of self-registering mercurial maximum thermometers. Casella was the first maker who constructed a registering clinical thermometer, by introducing a small quantity of air into the tube, and thereby separating a small part of the mercurial column from the rest. Instruments are now made in which the index—that is, the small separated part of the mercurial column—is prevented from falling back into the bulb, or in which an index is only formed each time the mercury rises out of the bulb. In using an instrument of this kind, the index, it need hardly be said, must be carefully shaken down below 95° or 90° before the thermometer is applied to the patient.

Another principle has been followed in the construction of very sensitive instruments for special researches on temperature, namely, that of the thermo-electric apparatus. The electric current that is produced in a circuit composed of two different metals when their point of contact assumes a different temperature from that of the other ends, or again, as first observed by Svanberg, the changes that a galvanic current shows when the resistance of a part of the circuit is altered by a change of temperature acting on it, can be measured by a galvanometer enclosed in the circuit. Gavaret, Heidenhain, and other physiologists have used the thermo-electric pile in physiological investigations in animals. J. S. Lombard, Hankel, Kunkel, and others, have applied it to observations in man. More recently a convenient form of thermo-electric apparatus for clinical purposes has been devised by Redard. The apparatus, constructed on the last-mentioned principle by O. W. Siemens, for measuring deep-sea temperatures, might also easily be adapted for clinical purposes.

A self-registering apparatus for continuous observations, on the principle of an air-thermometer, has been constructed by Marey; and an instrument automatically registering the changes of temperature on the surface of the body during a certain time was devised by W. D. Bowkett. A very neat little metal thermometer in the shape of a small watch, showing the movements of a 'Bourdon tube,' which are caused by variations of temperature, by the hand moving on the watch-face, has been constructed by Immisch. This can be placed in the axilla or between any folds of the skin, on the surface of the body or inside the mouth, and will correctly indicate the temperature. By a special arrangement the hand can be fixed before removing the instrument, which then acts as a maximum thermometer. But, although convenient for isolated observations and under special circumstances, it is less cleanly, and cannot for general clinical purposes compare with the ordinary glass thermometer, which, it need hardly be said, it surpasses in solidity.

For measuring surface-temperatures, mercurial thermometers of special shape, namely, a long cylindrical bulb coiled up in one plane at a right angle to the stem, have also been constructed. A thermo-electrical apparatus, or Bowkett's or Immisch's instruments, are, however, more sensitive and more convenient for that purpose.

Applications of the Thermometer. — The object we generally have in view with clinical thermometry being to examine as nearly as possible the temperature in the interior of the body, or the blood-heat, which is less variable than that of the surface (*see* TEMPERATURE), the localities most suitable for applying the thermometer would be the natural cavities, or the openings by which a thermometer might be introduced to a certain depth into the interior of the body. In the rectum, vagina, or bladder, the temperature is not subject to the ordinary changes acting from without, and the time required for taking an observation with the thermometer in any of these localities would be only such as is necessary for raising the temperature of the mercury to that of the surrounding mucous membrane. This time might be materially shortened by previously heating the thermometer to a degree a little below or above that to be expected in the body. With this preliminary measure an observa-

tion of the temperature in the rectum or vagina will not take more than half a minute.

The case is very different if we take the temperature in a cavity of the body which is not always closed, such as the mouth; or in the axilla, which can be formed into a closed cavity only by placing the arm closely against the chest. Here, quite independently of the sensitiveness of the thermometer, the time required for an observation is much longer, because the temperature of the mucous membrane of the mouth, or of the skin of the axilla, begins itself slowly to rise after the closing of these cavities, until it is raised to that of the deeper tissues which are not exposed to the loss of heat from without. Whereas nine to eleven minutes on an average are required for an observation of the temperature in the mouth, ten to twenty-four may be necessary for the mercury to become stationary in the axilla. The time varies also according to the state of the general circulation. It will be found much longer in persons with a weak circulation, for instance in a case of heart-disease, than in the case of a vigorous patient with a good circulation and with febrile heat. It is evident that, as was first pointed out by Liebermeister, the time for an observation in the mouth or axilla can be materially shortened, not so much by previously heating the thermometer, as by, previously to the introduction of the latter, keeping the mouth or axilla closed for ten to fifteen minutes. These cavities will then have assumed a steady temperature, and the time required for the observation will only be that necessary for raising the temperature of the mercury and the glass to the temperature of the surrounding parts. It is, therefore, a good plan, if the patient had been lying on one side, to turn him over to the other, or to make him lie on one side for a time before the thermometer is introduced, and then to place the thermometer in that axilla which had been closed by the position of the patient. If the skin of the axilla be very wet with perspiration, it ought to be wiped dry before applying the thermometer.

For practical purposes the rule generally recommended in observations being taken in the axilla, to leave the thermometer until the mercury has remained stationary for five minutes—a rule which naturally applies to self-registering no less than to ordinary thermometers—secures sufficient accuracy; and this rule should be given to nurses and attendants to whom the observations are left. Especially in obscure cases, in which much depends upon the discovery of even a trifling elevation of the temperature above the normal standard, which may be of great importance for diagnosis, this precaution ought never to be omitted; and for observations requiring scientific accuracy, as, for instance, when the effect of some drug on the temperature of the body is being studied, the observations ought to be made by the physician himself.

For various reasons the axilla is the locality most suitable, and therefore generally used, for thermometrical observations. In very young or restless children, however, as well as in very emaciated adults, axillary observations would become untrustworthy. In such cases, or where patients are in an insensible state, or under special circumstances—for instance, when a great divergence exists between the axillary and the internal temperature, or when doubts arise as to the

correctness of an axillary observation—the rectum, or the vagina, may be used for applying the thermometer, and with a self-registering thermometer this can be done without unnecessarily uncovering the patient. In using the rectum, great care must be taken not to let a small instrument slip into it, and in restless children to prevent the instrument from being broken. This is best prevented by placing the patient on his side, and while the thermometer is kept *in situ* with one hand, letting the other one rest on the hip of the patient, in order to be able at once to arrest any turning movement which he might happen to make. The thermometer ought to be introduced about two inches deep into the rectum; and may, before being taken out, be gently pushed forward a little more, in order to bring the bulb in contact with a fresh part of the mucous membrane, which has not been cooled by the thermometer. When large masses of feces fill the rectum, the thermometer passing into them may indicate a somewhat lower temperature than when in contact with the mucous membrane.

Other places of application, such as the inguinal fold, or the fold of skin between the thumb and the second metacarpus, may be used for special, but are quite unsuitable for general, clinical purposes. The clinical thermometer ought always to be carefully washed after being used.

Thermometrical Records.—It is extremely useful to register on a chart the thermometrical observations in a case of disease, and to connect the marks by lines; the curves which are thus formed being quite typical in many diseases. On the same chart may be entered, also by marks and lines, or otherwise, the numbers of the pulse and respirations, as well as remarks concerning other symptoms, or the treatment. For observations made with the thermometer, see TEMPERATURE.

The use of the thermometer for estimating the temperature of rooms and especially of wards, is fully described in other appropriate articles. See NURSING THE SICK; and PERSONAL HEALTH.

C. G. H. BÄUMLER.

THIRD NERVE, Diseases of.—INTRODUCTION.—The third nerve is purely motor in function. It supplies the levator palpebræ superioris; the superior, inferior, and internal recti; the inferior oblique; and the ciliary muscle with the sphincter of the iris. It arises from the surface of the crus cerebri by a series of fasciculi, proceeding from a prolonged nucleus of grey matter which lies beneath the hinder part of the floor of the third ventricle and the aqueduct of Sylvius, and is continuous behind with the nucleus for the fourth nerve. From the experiments of Hensen and Voelcker, and some limited facts observed in man, there seems to be a serial representation of the several functions of the nerves in this tract of grey matter. The anterior portion innervates the ciliary muscle subserving accommodation; next is the centre for the sphincter of the iris, through which contraction of the pupil is produced. Behind these centres for the internal muscles are, successively, those for the levator palpebræ and the rectus superior; while that for the internal rectus is probably by the side of the latter; farther back are centres for the inferior rectus and inferior oblique, while behind the former is the centre for the superior oblique (fourth nerve), associated in function with the inferior

rectus. It is probable that the series of separate roots of the third nerve corresponds to this series of centres and of functions. We do not yet know whether the associated actions in convergence, and those of the lateral movements of the two eyeballs, are arranged in this nucleus or in adjacent centres. The fibres for the internal rectus seem to pass up to the nucleus of the third nerve from that of the sixth—at least those fibres for the internal rectus that are concerned in the conjoined lateral movement.

SYMPTOMS.—Morbid states of the third nerve are revealed by (1) Spasm, or (2) Paralysis in the muscles supplied by it, that is, those of the eyeball and the upper eyelid; in the iris; and in the ciliary muscle.

1. **Spasm.**—The functions of the fibres of the third nerve vary much, so as to render it equivalent to several nerves. Spasm is never met with at the same time in all the muscles supplied by it. Isolated muscles may be involved, especially the internal rectus, in conditions of irritation of the trunk and nucleus of the nerve, as in meningitis, and hysteria; also in hypermetropia, and in paralysis of the antagonist-muscle. When extreme, the eyeball is turned inwards, and cannot be moved out. Clonic spasm of the muscles occurs in ‘nystagmus,’ which may be present only during voluntary effort, or may be spontaneous. The elevator of the upper eyelid is occasionally spasmodically contracted, so that the eye cannot be shut, but remains widely or partly open (*lagophthalmos*). Some degree of this elevation is common in exophthalmic goitre, and may occur alone, as a partial manifestation of a similar state. Slight contraction of this muscle occurs also in cases of long-continued paralysis of the orbicularis palpebrarum. Spasm of the levator may also be due, in rare cases, to peripheral irritation in the region of the fifth nerve; it has been observed for several hours after the extraction of a tooth.

Contraction of the sphincter of the iris produces diminution of the pupil (*myosis*), sometimes to very small dimensions. It may result from irritation of the trunk of the third nerve; or from stimulation, central or reflex, of the nucleus; or it may be secondary to paralysis of the dilator fibres supplied by the sympathetic. It may result from excessive (associated) efforts at accommodation. It is, however, most frequently met with in locomotor ataxy, and is associated with loss of reflex action to light. The condition is described more fully in the next section. Spasm of the ciliary muscle may result from the other causes of irritation of the nerve-trunk, or from excessive efforts at accommodation in hypermetropia. Its effect is to produce a fixed accommodation for near objects.

TREATMENT.—The treatment of the central causes of overaction of the third nerve commonly resolves itself into that of the primary condition. Rest is important, and attempts to converge and accommodate should be, as far as possible, avoided. If no exciting cause can be discovered, the over-action should be reduced by sedatives, of which bromide of potassium is the safest. Sometimes belladonna may be added with advantage, but its effect should be watched. It is needless to say that distinct errors of refraction should be corrected by glasses. When a peripheral source of reflex excitation can be ascertained its influence may be lessened by injections of morphine or cocaine. Functional over-action is often the expression of weakness, and needs nervine tonics in addition to

the other measures. Counter-irritation, in the region of the related sensory nerve, is frequently of great service in this as in most other forms of functional spasm. Persistent convergence in hysteria can generally be removed by a small blister to each temple. Atropine will overcome spasm of the sphincter pupillæ or of the ciliary muscle. The cold douche to the eyeball is useful in spasmodic lagophthalmos, but many cases of this affection are extremely obstinate. The treatment of the retarded descent of the lid occurring in exophthalmic goitre, and now and then met with as an isolated symptom (or combined only with a quick pulse), is that of this disease as a whole.

2. Paralysis.—**ÆTIOLOGY.**—The commonest cause of paralysis of the third nerve is some affection of its trunk as it passes through the membranes at the base of the brain, through the orbital fissure, or along the orbit; due either to rheumatic inflammation of the nerve-sheath, to syphilitic inflammation of the nerve or membranes, or to injuries of various kinds. Less frequent causes are acute lesions—hæmorrhage, softening, inflammation—in the nucleus of the nerve, or at the inner part of the crus cerebri through which the fibres pass and from which they emerge; compression of this part by an aneurysm or a growth in the interpeduncular space; basal meningitis; and aneurysm of the termination of the internal carotid. A syphilitic growth, on the nerve or near it, may compress the fibres. Paralysis is also met with as a result of diphtheria and in association with disease of the spinal cord, especially locomotor ataxy. It occurs also, in rare cases, as part of multiple neuritis, after diphtheria and other acute specific diseases, and from some toxic influences. Sudden palsy of a branch, occurring during effort or cough, is probably due to an extravasation into the sheath of the nerve.

Two peculiar causal varieties deserve mention. In *relapsing palsy* the nerve on one side becomes paralysed subacutely, the whole, or more commonly some, of its branches suffering; it recovers imperfectly; and then the other nerve becomes similarly affected. Afterwards the palsy of the first returns, and some permanent affection of both nerves remains. This form is met with in the subjects of old syphilis. *Periodical or recurring palsy* is a peculiar variety, perhaps allied to megrim, in which transient palsy of the third nerve occurs at intervals during many years, sometimes even from childhood up to adult life; each attack being completely recovered from.

Occasionally all the muscles supplied by the third nerve become paralysed, together with the other orbital muscles—‘*ophthalmoplegia externa*’—from degeneration of the nuclei of these nerves; and hence it is also termed ‘*chronic nuclear palsy*.’ This is due to alterations in the grey matter similar to those which, in the spinal cord, give rise to progressive muscular atrophy. It is met with in association with tabes, and also alone; and in both cases is most common in the subjects of syphilis, being met with in both the acquired and inherited forms.

SYMPTOMS.—Paralysis may affect some or all of the fibres of the third nerve. When complete, the upper eyelid is dropped and cannot be raised, and the eye can be moved only outwards, or also a little downwards; after a short time it constantly deviates outwards. The pupil is in a mid-state between contraction and dilatation, and cannot be made to con-

tract by light; power of accommodation in the eye is lost, owing to paralysis of the ciliary muscle.

Each muscle supplied by the nerve may be paralysed separately, by an affection of its special branch of the nerve after it leaves the main trunk.

When the levator palpebræ superioris is affected, *ptosis*, or drooping of the eyelid, alone results. It is seldom an isolated symptom of disease of the third nerve, since the branch to the levator is seldom alone affected; but it occurs, with palsy of the associated superior rectus, from limited disease of the nucleus, and may then be bilateral. It is met with in partial disease of the nerve, whatever be its cause. It is also congenital. A form of ‘*morning ptosis*’ sometimes occurs, owing to a difficulty in raising the lids on first waking. In hysteria, ptosis may be simulated by slight contraction of the orbicularis, a mechanism which becomes distinct if contraction of the occipito-frontalis is induced by making the patient look up.

Paralysis of one of the three straight muscles supplied by the third nerve is indicated by symptoms which occur chiefly during movements in which the paralysed muscle is needed; they are the series of symptoms that result from paralysis of any ocular muscle, and which are elsewhere described in detail—limitation of movement, primary deviation, strabismus, secondary deviation of the unaffected eye, diplopia, erroneous projection of the field of vision, and often vertigo as the result of the last. See p. 1065.

In paralysis of the sphincter iridis, the elasticity of the structure maintains the pupil at middle size, and it can be further dilated by atropine, but all power of contraction beyond that degree is lost. When the ciliary muscle is paralysed, the power of accommodation is lost: the far point of vision remains the same, but the near point is rendered much more distant.

The remarkable loss of reflex action of the iris which occurs in association with locomotor ataxy is often accompanied by myosis. Then, the pupil does not dilate on stimulation of the skin (Erb). When the pupil is not small, this reflex dilatation is usually preserved. In loss of the light-reflex the contraction on accommodation and convergence is often preserved (Argyll-Robertson). Sometimes this is also lost, the ciliary muscle being completely paralysed—the ‘*ophthalmoplegia interna*’ of Hutchinson. Power of accommodation may be lost although the pupil still contracts on an effort at accommodation. These symptoms also occur in cases of old syphilis, apart from spinal disease. They probably then depend on limited degeneration in the nuclei of the third nerve, the result of the more limited action of a post-syphilitic toxin.

DIAGNOSIS.—Paralysis of the third nerve is generally obvious; only the slighter palsy of separate branches supplying the ocular muscles is sometimes not easy to recognise; and for this purpose, a careful examination of the double images is often necessary. The diagnosis of the cause is less easy. Rheumatic paralysis succeeds exposure to cold, and is often attended by much pain, but it is rare; in syphilis other cranial nerves are often affected independently; in meningeal and spinal disease there are the respective distinctive symptoms; in organic disease of the crus there is hemiplegia of the opposite side, coincident in onset with the affection of the third nerve; in interpeduncular disease the affection of the third nerve may precede the hemiplegia, but

both third nerves commonly suffer. After diphtheria the ciliary muscle is usually alone affected. In the pseudo-ptosis of hysteria, the contraction of the orbicularis can be rendered evident by making the patient try to look up; the contraction of the levator has to be counteracted by conspicuous contraction of the orbicularis.

PROGNOSIS.—When due to cold or to recent syphilitic mischief, or occurring after diphtheria, the prognosis of paralysis of the third nerve is good if proper treatment can be secured. In cases of organic cerebral disease it is subordinated to that of its cause. In association with spinal disease the ultimate prognosis is unfavourable, for, although the early attacks are usually recovered from, the affection often recurs, and each recurrence leaves some residue. As a general rule, however, the prognosis must be guided by the nature of the morbid process on which the palsy depends, the extent to which this can be influenced by treatment, and the duration of the changes in the nerve-elements on which the symptoms directly depend.

TREATMENT.—In rheumatic paralysis of the third nerve from cold, hot fomentations in the early stages and afterwards counter-irritation by blisters to the temple, with an alkaline diuretic or salicylates, should be employed. In all forms of acute or subacute inflammation it is wise to give small repeated doses of mercury. Subsequently tonics are the most useful. When the palsy is of syphilitic origin, iodide of potassium usually suffices to effect a cure. If associated with spinal mischief, strychnine, iron, and arsenic are occasionally of some service. In intracranial disease—tumour, aneurysm, or meningitis—the treatment is that of its cause. After diphtheria tonics are alone necessary; it is indeed a merely subordinate symptom in most cases. In paralysis of the sphincter pupillæ and ciliary muscle, occasional instillation of a small quantity of solution of eserine is said to do good, by stimulating locally the paralysed fibres, and also to be beneficial in affections of other branches of the nerve. In the paralysis of the ocular muscles electricity has been recommended, but is practically useless, whether an attempt is made to apply it directly or whether applied indirectly as to the temple or forehead. The only 'satisfactory' results of electrical treatment have been in syphilitic cases in which iodide of potassium was also given.

W. R. GOWERS.

THIRST.—**SYNON.** : Fr. *Soif*; Ger. *Durst*.—Thirst is a sensation indicating a necessity on the part of the system for an increased supply of water, as appetite shows there is a need for the introduction of food. Although the sensation is referred to the back of the throat, it is not a purely local feeling, as is proved by the fact, well known to physiologists, that it cannot be allayed by the swallowing of water, unless the fluid reach the stomach and be absorbed. It is always present in febrile disorders, an increased supply of liquid being required both to reduce the heat, by promoting the evaporation of moisture from the skin and lungs, and also to wash away the products of the increased tissue-changes that accompany these complaints. In like manner it is always present when much fluid has been abstracted from the system; thus, it shows itself after all surgical operations attended by hæmorrhage. It is a prominent symptom in cholera and

diarrhoea, in which diseases large quantities of serum are rapidly removed from the gastro-intestinal circulation, and equally so in diabetes mellitus, where fluid is largely excreted along with sugar by the urinary organs. A craving for cold and acid drinks presents itself in acute gastritis, the intensity of the thirst being perhaps due to the incessant vomiting, which prevents fluids remaining long enough in the stomach to be absorbed. In chronic gastritis thirst is usually present, and is chiefly complained of towards evening. It forms a useful diagnostic sign between this disease and mere atonic dyspepsia.

TREATMENT.—Thirst is relieved by the agents usually recognised as refrigerants, such as water, barley-water, toast and water, and similar drinks; sucking small pieces of ice; effervescing drinks; freely diluted acid drinks, especially those made with vegetable acids or phosphoric acid, alone or combined with a little aromatic bitter; the juices of fruits, or these made into drinks. Care has often to be exercised in the employment of these apparently harmless agents, and their consumption has to be checked, otherwise patients will take them to excess, and may thus do themselves considerable injury.

SAMUEL FENWICK.

THOMSEN'S DISEASE.—This is also known as Myotonia Congenita, an unsuitable name because it is not always congenital. The name of *transient myotonia* has been suggested, but it is unlikely to displace the more familiar name of Thomsen's disease—a name depending upon the fact that the most complete description of it, and one of the earliest, has been given by a physician of that name, who is also the subject of the disease. Its most striking symptom is a rigidity of muscles which is set up on first attempting to use them. With repeated efforts the spasm is gradually overcome, and when the muscles originally at fault are once brought under voluntary control, their normal activity can be maintained without difficulty.

The muscles most generally affected are those of the lower limbs. Sometimes, however, others suffer, e.g. those of the hands or jaws, and even the acts of mastication, swallowing, respiration, micturition, and defæcation have been interfered with by spasm occurring in the muscles concerned in those acts.

The disease usually manifests itself in childhood. It may do so in early infancy, while, on the other hand, its onset may be delayed until puberty or even later. As a rule it is a hereditary condition, and affects more than one member of the same family. Occasionally, however, isolated instances have been met with, without any indication of family affection. When it is slight in degree it may cause only slight inconvenience; when it is severe the disability occasioned may constitute a very serious drawback to an active life. Its cause is probably to be sought for in some inherited peculiarity in the muscular condition. The muscular fibres are found to be larger than usual and not so distinctly striated.

The response of the muscles to an interrupted current is peculiar, the muscles when stimulated remaining unduly long in a condition of contraction—the stimulus, as it were, setting up a condition of spasm. A special name has been applied to this—the myotonic reaction. A galvanic current applied to the muscles is said to set up a series of

wave-like contractions, passing from the cathode to the anode.

No treatment seems to be efficacious in overcoming the tendency to spasm, but Thomsen is of opinion that a life of activity tends to ameliorate the condition.

JAMES TAYLOR.

THORACIC ANEURYSM.—Under this head are included aneurysms of (A) the Intra-Thoracic Aorta; and (B) the Arteria Innominata. Aneurysms of the Pulmonary Artery are discussed on pp. 262 and 1357, and Aneurysms of the Heart and Cardiac Valves on pp. 632 and 663.

A. Aneurysm of the Intra-Thoracic Aorta.—This may be most conveniently discussed in its clinical aspects under two heads, namely (1) *aneurysm of the arch*, and (2) *aneurysm of the descending thoracic aorta*; while the former may be subdivided into aneurysm of (a) the *ascending*, (b) the *transverse*, and (c) the *descending* portion.

Relative frequency.—Of 76 cases analysed by Hayden, the seat of aneurysm, single or multiple, stated in the order of relative frequency, was as follows: *Single*: ascending portion of arch, 30; transverse portion, 17; descending thoracic aorta, 10; ascending and transverse portions of arch, 9; transverse and descending portions, 2; entire arch, 2; descending portion, 1; thoraco-abdominal aorta, 1. *Multiple*: ascending portion of arch and descending thoracic aorta, 2; ascending portion of arch and abdominal aorta, 2.

1. Aneurysm of the Arch.—The different parts of the arch of the aorta must be considered separately.

(a) *Ascending portion.*—**ANATOMICAL CHARACTERS.**—Aneurysms arising from one of the sinuses of Valsalva rarely attain a size larger than that of a billiard-ball. They are sacular and not infrequently pedunculated, communicating with the aorta by a small orifice. They further exhibit a remarkable tendency to *descend* in the progress of growth, involving in their course the heart or the root of the pulmonary artery. By their position they are sheltered from direct influx from the ventricle, while they are exposed to the maximum force of reflux from the aorta. When, however, the orifice is partially or entirely above the level of the valves, the main pressure sustained by the sac is that of efflux from the ventricle; hence the direction of growth is upwards. Aneurysm of the portion of the vessel immediately above the level of the valves is especially prone to advance towards the right side, forming a tumour visibly projecting, or detectable by palpation and percussion, in the vicinity of the right nipple. It may be fusiform or sacular, true or false; it usually attains a large size; and, when fusiform, not infrequently extends over a great portion or even the whole of the arch. The direction of growth may, however, be backwards or to either side; the aneurysm in its progress implicating the œsophagus, the pulmonary artery or one of its branches, the superior vena cava, or either auricle; it is in such cases usually sacular, and of comparatively small size. Aneurysms of the extrapericardial portion of the ascending aorta usually tend forwards and upwards in the line of main blood-pressure, projecting at the right margin of the sternum above the fourth costal cartilage, and occasionally likewise into the root of the neck, involving the arteria innominata. They may, however, grow backwards and to the right, implicating

the right bronchus or lung, or the superior cava; directly backwards, pressing upon the œsophagus or the bifurcation of the trachea; or, projecting mainly towards the left side, they may involve the left branch of the pulmonary artery, and the left bronchus or lung.

SYMPTOMS AND SIGNS.—Aneurysm of the sinuses is rarely attended by very definite symptoms; indeed, only when it presents at the anterior wall of the chest.

Owing to its position within the pericardium, and its close proximity to the heart, the symptoms produced by aneurysm in this situation may be readily confounded with structural or valvular disease of the heart itself. The acoustic signs are, for the purpose of diagnosis, no less indefinite; because, from the position of the aneurysm close to the orifice of the aorta, a murmur produced by it, whether of influx or of efflux, may be easily mistaken for one of the same rhythm caused by obstruction at the aortic orifice or inadequacy of the valves. The difficulty of diagnosis is further increased by the usual co-existence of atheroma with dilatation of the first portion of the aorta, relative incompetency of the valves, and eccentric hypertrophy of the left ventricle. The ordinary symptoms are those of palpitation and derangement of the rhythm of the heart, from affection of the cardiac plexus. But the diseases just mentioned may, in the absence of aneurysm, give rise to similar phenomena. The existence of venous stasis and congestion of the upper half of the body, viewed in conjunction with tumultuous and irregular action of the heart, and in the absence of discoverable cause of venous obstruction at a higher point in the chest, would, however, warrant the *presumptive* diagnosis of aneurysm at the root of the aorta, implicating the right auricle or the termination of the superior cava; and if with these symptoms were associated systolic murmur at the base, not transmitted in the course of the aorta, or a double murmur, a positive diagnosis to the above effect might be made. Were the diastolic murmur preceded by a distinct second sound, valvular inadequacy from dilatation of the aorta, without valvular disease, would be thereby indicated, and the diagnosis of aneurysm *pro tanto* sustained. Symptoms of obstruction of both cavæ, namely, general venous congestion and engorgement of the liver, would in the foregoing connection justify the special diagnosis of pressure upon the sinus of the right auricle. The symptoms of pressure upon the other chambers of the heart are those only of deranged rhythm and circulation, such as may be due to various causes inherent in the heart. Systolic murmur in the pulmonary artery may result from the pressure of an aneurysm on the root of that vessel. Communication of an aneurysm with one of the chambers of the heart is usually effected by an aperture not more than two to three lines in diameter. It is the result of progressive absorption, and the symptoms are scarcely to be distinguished from those of antecedent pressure. The physical signs are more characteristic; they consist in a loud murmur, systolic or diastolic, of a 'booming' or 'splashing' character, accompanied by thrill, traceable from the root of the aorta in the direction of abnormal influx, and not transmitted in any of the ordinary lines of valvular murmur. If two murmurs exist, they are fused or converted into a continuous rumble. Sudden transfer of the seat of greatest

intensity of such a murmur, from the aortic area to some other point of the præcordia, would be conclusive, not only as to the irruption of an aneurysm into one of the chambers of the heart, but likewise as to the date of its occurrence. The sac of an aneurysm in the situation of the aortic sinuses does not attain any considerable size, as it usually bursts into the pericardium, thus causing sudden death.

Aneurysm of the ascending aorta, external to the pericardium, is occasionally latent, but ordinarily it is characterised by very definite physical signs. A large fusiform aneurysm of this portion of the vessel, or one engaging the entire arch, equally expanded, not in contact with the anterior thoracic wall or pressing inconveniently upon any of the adjacent organs, may be virtually latent; exhibiting no symptoms of aneurysm except vague neuralgic pains darting over the chest, shoulders, arms, and back, and no sign but exaggerated double sound. Pointing externally, or in persistent contact with the chest-wall, an aneurysm may be readily identified by the circumstance that it presents a second centre of pulsation and intensified sounds. The ordinary pulsation is systolic, expansile, and diffused (though not always equally) over the entire surface; but a second and minor impulse of diastolic rhythm may likewise exist (*diastolic shock*). The former is in many cases accompanied by tactile thrill. The acoustic signs consist either in two sharply accentuated sounds, nearly alike in character, and corresponding in rhythm to those of the heart; or in a single or double murmur of blowing or 'booming' quality. There is likewise absolute dulness, with suppression of respiratory sounds and of vocal fremitus, to the extent of the tumour.

Pressure upon the superior cava is characterised by venous congestion, limited to the upper half of the body: while actual communication with that vessel is evinced by cyanosis to the same extent; extreme engorgement with pulsation of the jugular veins; a buzzing systolic murmur; and intense thrill, at the seat of communication and transmitted into the veins of the neck. According to Mahomed, in cases of arterio-venous aneurysm *inspiration* alters the characters of a sphygmogram, by diminishing the volume of blood in the artery. Pressure upon the main bronchus is indicated by diminished or suppressed respiration, with normal percussion-sound, in the corresponding lung; and occasionally by 'whiffing' or 'jerking' inspiratory sound. Diminished respiration throughout either lung, with inequality as between its upper and lower portions, would indicate pressure, but unequal in degree, upon the primary bronchus and its superior secondary branch; while partial or complete suppression confined to the upper lobe would show that the superior lobular branch was alone implicated. Pneumonia from occlusion of the pulmonary vessels, or from pressure upon the pneumogastric or pulmonary plexuses, is a frequent result of the presence of an aneurysm. The consolidation of lung-substance so produced is due to implication of the laryngeal and pharyngeal nerves. Bronchitis may likewise arise from mechanical irritation; and where present may, in greater or less degree, mask the physical signs of aneurysm. The sudden irruption of an aneurysm into one of the bronchi is indicated by copious discharge of florid blood from the mouth and nostrils, and is instantly fatal by syncope or asphyxia. An opening established into the pulmo-

nary substance is followed by 'leakage' of blood, or repeated but limited hæmoptysis. Pressure upon the pulmonary artery is necessarily attended by engorgement of the right chambers of the heart, and general venous congestion; and the establishment of an opening into that vessel, by sudden and urgent dyspnoea without spasm or stridor, extreme congestion of the lung, and hæmoptysis. Death is rapid in such cases; but should an opportunity for physical exploration be afforded, a 'buzzing' systolic hum might be detected in the second and third left intercostal spaces, close to the sternum. Pressure upon the œsophagus is less common than in the case of aneurysms arising from other parts of the aorta. It is indicated by dysphagia, referred by the patient to a corresponding point of the chest. Dysphagia due to the pressure of an aneurysm is remittent, and varies in some degree with posture—traits by which it is distinguished from that produced by cancer. Dysphagia from volvulus of the œsophagus may, however, exhibit similar variations.

'Clubbing' of the finger-ends has been observed in aneurysm of the aorta where there has been implication of the subclavian artery and its surroundings. The same effect has been noted in cases of aneurysm of the axillary artery. See p. 548.

(b) *Transverse portion.*—ANATOMICAL CHARACTERS.—Aneurysms of this portion of the aorta are usually fusiform: they involve mainly its anterior and superior wall, pushing forward the upper end of the sternum, projecting into the neck, compressing the left innominate vein, and modifying, in many cases, the circulation in the primary arteries and their branches. They likewise frequently press backwards upon the œsophagus and trachea, the pneumogastric or sympathetic of either side, or the left recurrent nerve. Owing to the backward course of the left extremity of the arch, aneurysms arising from this portion of the vessel rarely appear in front. They project above the left clavicle, involving the innominate vein, the pneumogastric, sympathetic, or recurrent nerve of the left side, and occasionally all three; or posteriorly in the left scapular region.

SYMPTOMS AND SIGNS.—Pressure upon the left innominate vein is accompanied by visible engorgement of the thyroid, left jugular, subclavian, brachial, and superficial thoracic veins and their tributaries, with œdema of the left arm. The circulation in the carotid or subclavian artery of one side is often diminished or suppressed by the lateral pressure of an aneurysm, or by clot-formation in the sac. Pressure upon the trachea is indicated by clanging or metallic cough, and stridor 'from below,' that is, loudest at the upper part of the sternum, and distinctly audible over the lower cervical and upper dorsal vertebrae. The symptoms of aneurysmal pressure upon the sympathetic, pneumogastric, and recurrent nerves are most frequently exhibited on the left side only. Those due to implication of the sympathetic or its cilio-spinal roots are manifested in the pupil of the affected side. They consist in dilatation or contraction of the pupil according to the degree of pressure; the former from irritation, and the latter, which is the more usual phenomenon, from paresis of the nerve. Laryngeal stridor, huskiness or loss of voice, and harsh metallic cough, in the absence of local disease of the larynx, are eminently diagnostic of pressure upon either recurrent nerve. All these symptoms are paroxysmal in character, a fact recognised as regards aneurysmal

disease since the time of Morgagni. By means of the laryngoscope the vocal cord on the side of disease, and in rare cases the cords on both sides, are seen to be fixed during breathing and vocalisation, from unilateral or bilateral paralysis of the abductor muscles of the larynx. In bilateral paralysis the cough, as was pointed out by Wyllie, assumes the character of a loud long grunt or wheeze, like the cough of a cow, hence the name given to it of *bovine cough*. The cough in such cases is deficient in the explosive element, which indicates the first act of a normal cough—the forcible closure of the vocal cords. The cow has no false vocal cords or ventricles of Morgagni, and its cough represents a long loud grunt or wheeze without the initiatory explosion. The condition of the glottis in man when both adductors are paralysed resembles the condition of the larynx in the cow; hence the peculiarity of the cough described becomes a valuable sign of aneurysm. George Johnson held that unilateral paralysis is distinguished by slight huskiness of voice, with stridor on full inspiration; and bilateral paralysis, by permanent dyspnoea and stridor. Paroxysmal dyspnoea or fatal asphyxia may result from collapse of the arytenoid cartilages in such cases. Pressure upon either pneumogastric is especially characterised by paroxysms of remittent spasm of the glottis, which may be suddenly fatal; but, where the recurrent nerve is not likewise implicated, persistent stridulous breathing, aphonia, and metallic cough are not exhibited. Wherever the laryngeal mucous membrane is found to be normal in appearance, symptoms simulating those of laryngeal disease are due to intra-thoracic pressure, the tumour pressing upon one or other of the laryngeal nerves, usually the left. The great majority of such tumours are found to be aneurysmal in their nature. A marked difference in the volume of the pulse at the wrists is frequently noted in aneurysm involving the innominate or subclavian arteries.

The physical signs are identical with those already described in connection with aneurysm of the ascending portion of the vessel. *Tracheal tugging* is met with in deep-seated aneurysms. The following directions in reference to it are given by Oliver: 'Place the patient in the erect position and direct him to close his mouth and elevate his chin to almost the full extent; then grasp the cricoid cartilage between the finger and thumb, and use steady and gentle upward pressure on it, when, if dilatation or aneurysm exists, the pulsation of the aorta will be distinctly felt transmitted through the trachea to the hand.'

(c) *Descending portion.*—ANATOMICAL CHARACTERS.—Aneurysm of the left curvature and descending portion of the arch involves the left recurrent nerve in nearly every instance. In the progress of growth it passes into the root of the neck; backwards towards the left scapula; or backwards and outwards into the substance of the lung.

SYMPTOMS AND SIGNS.—These include symptoms of pressure upon the recurrent or pneumogastric nerve, as well as upon the subclavian or internal jugular vein; a pulsating tumour in the left interscapular space, which may attain very large proportions; and signs of congestion and consolidation of the upper and back part of the left lung. In the last case the aneurysm, being involved in the pulmonary structure, may afford no specific evidence of its existence.

The physical signs differ in no respect from those which characterise aneurysm of the other portions of the arch.

2. *Descending Thoracic Aorta.*—ANATOMICAL CHARACTERS.—Aneurysms of the upper portion of this division of the vessel rarely attain a large size. They may pass upwards and to the right side, implicating and perforating the trachea or oesophagus; or directly to the right, stretching the oesophagus or thoracic duct, and ultimately opening into one of them or into the right pleura. The aneurysm may advance to the left, and ultimately prove fatal by rupture into the left pleural cavity; it may erode the vertebræ and ribs, opening into the spinal canal, causing paraplegia; it may point in the left infrascapular region; or it may advance towards the anterior wall of the chest, displacing the heart, and involving itself in the substance of the left lung. Aneurysm of the lower part of the vessel usually extends into the abdomen, constituting the thoraco-abdominal form of the disease. It may displace the heart forwards, and the liver downwards; it may likewise extend backwards, eroding the vertebræ, and pointing in the lower dorsal or the lumbar region on the left side. Finally, an aneurysm in this situation may prove fatal by simultaneous hæmorrhage into the left pleural cavity and left retro-peritoneal space, or into the vertebral canal.

SYMPTOMS AND SIGNS.—To what has been already stated on this subject it is only necessary to add, that progressive absorption of the vertebræ is indicated by fixed and boring pain referred to a particular point of the vertebral column, which is tender to pressure, or not infrequently radiating or 'nipping' pains extend round the chest from implication of the intercostal nerves. Forward displacement of the heart by an aneurysm would be characterised by violent impulse, simulating that of cardiac hypertrophy (the distinction would rest upon the presence of the special symptoms and signs of aneurysm); a remarkable derangement of cardiac impulse, constituting the 'double jog' of Hope; with absence of the positive signs of hypertrophy. Pressure upon the thoracic duct is very rare; it would be indicated by the symptoms of mal-assimilation, wasting, and inanition—symptoms which are foreign to aneurysm under its ordinary forms.

The physical signs of aneurysm of the descending thoracic aorta are ordinarily limited to a sharp sound, single or double, audible over the dorsal vertebræ and somewhat to the left; and, more rarely, perceptible impulse. The existence of murmur is exceptional; when present, murmur is all but invariably single and post-systolic, and is inaudible in the erect posture.

The application of the X Rays has been utilised in the diagnosis of internal aneurysms. See RÖNTGEN RAYS.

DURATION AND TERMINATIONS.—The duration of aneurysm of the intra-thoracic aorta may vary from a few days to several years. Death is most frequently caused by rupture of the sac into various parts; or by gradual exhaustion from insomnia and inanition. Of 71 cases of aneurysm in this situation tabulated by Hayden, 26 were fatal by rupture of the sac; namely, into the pericardium 10—all being aneurysms of the ascending aorta; into the left lung or pleura 5—4 being of the transverse, and one of the descending thoracic aorta; into the trachea 4—

3 of the transverse, and one of the ascending aorta ; into the right lung or pleura 3—2 of the ascending, and one of the descending thoracic aorta ; into the left bronchus or œsophagus 3—2 of the descending thoracic, and one of the transverse aorta (in one of these an opening existed both into the left bronchus and the œsophagus) ; externally one—the aneurysm having arisen from the transverse aorta. Death may also result from asphyxia, from intercurrent inflammation of the lungs or pleura, or from coma.

B. Aneurysm of the Arteria Innominata. Aneurysm involving the innominate artery may be mistaken for aneurysm of the aorta, at or near the first curve of the arch.

SYMPTOMS AND SIGNS.—Those which are most distinctive of innominate aneurysm are the early appearance of pulsating tumour above the right clavicle, accompanied by arterial obstruction on the right side ; displacement of the trachea and larynx to the left ; and pulsation with accentuated sound, localised at the right sternoclavicular joint and immediately above it. Diminished circulation in the right carotid and subclavian arteries at an early period of the disease, and the reduction or arrest of pulsation in the sac by digital pressure upon these vessels, afford the most constant and least equivocal evidence of innominate aneurysm. The early occurrence of neuralgic pains in the right side of the neck, the right shoulder, and ear, followed by œdema and partial paralysis of the right arm, is likewise suggestive of innominate, as distinguished from aortic aneurysm. The symptoms of nerve-pressure on the right side, as exhibited in the larynx and pupil, are usually well-pronounced in this disease. The physical signs are in no respect different from those of aneurysm of the arch. Concurrent implication of the aorta is ordinarily determined with the greatest difficulty, and occasionally a positive diagnosis in this respect cannot be made. If pulsation and sound of maximal intensity exist at the level of the second costal cartilage, or an inch and a half below the sternal end of the clavicle, while the pulse-tracing of the right radial artery exhibits imperfect aneurysmal characters, the aorta may be considered as involved in the disease.

DIAGNOSIS.—Aneurysm of the ascending portion of the arch of the aorta is in most cases easily recognisable, owing to the formation of a distinct tumour upon the chest-wall, in the region of the second and third right costal cartilages, which is dull upon percussion—the dullness merging into the cardiac area—and presents distinct pulsation synchronous with the heart-beat. A pulsating sarcoma in this region—a very rare affection—may give rise to difficulty, but the impulse lacks the heaving character generally found with aneurysms, and the boundaries of the tumour rarely correspond so distinctly with the line of the vessel. The presence of a diastolic shock, or on the other hand of an aortic regurgitant murmur, would indicate a vascular lesion.

Aneurysm of the transverse portion of the aorta presents very much greater difficulties, since the presence of a pulsating tumour is here the exception, and diagnosis must be made upon the existence of symptoms of pressure within the thorax. Mediastinal tumours may give rise to very similar effects. The principal points of difference are that in aneurysms the arterial and nervous structures are more frequently affected, so that irregularity of the radial pulses on the two sides of the body and laryngeal paralysis are more likely to be present :

irritation or paralysis of the sympathetic, as shown by affection of the pupil, is also more common with aneurysms, as is the existence of dysphagia, which last is uncommon with new-growths other than those originating in the œsophagus itself. The presence of well-marked tracheal tugging is commoner in aneurysm. The age and past occupation of the patient are of some assistance in arriving at a probable conclusion, aneurysm being much more common in males than in females, and originating generally in middle life and in those who have followed laborious occupations. Soldiers are specially frequent subjects of this condition. A history of syphilis is a point in favour of aneurysm (see *MEDIASTINUM, Diseases of*, p. 969).

Aneurysm of the descending part of the aorta is a rare affection, and the difficulty of diagnosis may at times be insuperable. The existence of a bruit, heard best at the back of the chest, along with pain radiating round the body or referred to the abdomen, may at times betray the presence of the condition : in other cases fatal rupture into the pleural cavity or other part may be the first and last clear manifestation of the disease. Aneurysm of the descending aorta which has eroded the vertebræ may simulate spinal caries so closely as to render distinction impossible ; and *vice versa* an abscess due to spinal caries and pressing backwards may form a pulsating tumour and be mistaken for aneurysm. The resemblance of a large aneurysm of the descending aorta to pulsating empyema must not be overlooked. The use of the X-rays gives prospect of being of the greatest use in the diagnosis of all intrathoracic aneurysms, since the shadow of a pulsating mass may be distinctly visible upon the fluorescent screen.

The signs present in cases of innominate aneurysm have already been mentioned.

PROGNOSIS.—In all cases of aneurysm within the thorax the outlook is most grave. The probable duration of life depends greatly upon the ability of the patient to lead a quiet life, and upon his willingness to undergo protracted treatment. Even in favourable cases in which apparent cure has been effected, there is often a tendency to fresh aneurysmal dilatation of neighbouring parts of the diseased vessel. When there are signs of implication of the skin over an aneurysmal tumour on the chest-wall, the patient's condition becomes alarming. Actual leakage of blood may occur and threaten a fatal issue by external hemorrhage ; but even in these circumstances the fatal rupture of the sac is usually internal, and in rare instances death may not take place for several weeks after hemorrhage first occurs. The occurrence of asphyxial attacks is a serious symptom, and points to a speedily fatal issue, but in individual attacks the patient may rally from an apparently moribund condition under energetic treatment (venesection, &c.). Hemorrhage occurring into the larger air-passages is generally the precursor of death within at most one or two days, but the presence of streaks of blood in the sputum is not infrequent in earlier stages, owing to compression of the lung and the strain of coughing.

TREATMENT.—The treatment of aneurysm will be found described in the article *ABDOMINAL ANEURYSM*. The *curative* treatment of aortic or innominate aneurysm should be directed to the single object of effecting consolidation of the contents of the sac. With this object in view, three methods have been pursued, either separately or conjointly, namely, the *postural* and *dietetic* ; the

medicinal; and the *operative*. As an assistance to the first plan of treatment of thoracic aneurysm, an occasional blood-letting by venesection, to the amount of eight to ten ounces, for the purpose of reducing arterial tension or venous engorgement, may be demanded. With a view to causing or promoting deposition of fibrin in the sac, several agents have been used, namely, acetate of lead, in doses of four to eight grains; iodide of potassium, ten to thirty grains; and aconite, five minims of the tincture thrice daily. Of these drugs by far the most satisfactory results have been obtained by the use of iodide of potassium given in doses ranging from ten to thirty grains three times a day, the administration of the drug being continued, having regard to the tolerance of the patient, for months. The explanation of the therapeutic value of iodide of potassium according to Balfour is to be found in the fact that under its use the lowering of the cardiac and vascular tension arrests or greatly modifies the dilatation of the sac at each stroke of the heart, and thus brings into operation again the natural elasticity of the arterial coats which contract the sac temporarily until ultimately this contraction is strengthened and made permanent by the hypertrophy of these coats—mainly of the *adventitia*. Ergotin has been used hypodermically by Langenbeck. The latest method of the treatment of aneurysm by medicinal means is that advocated by Lancereaux and Paulesco. It consists in the injection into the muscles of the buttock of 2-per-cent. sterilised solution of white gelatine (p. 707). Three ounces of the fluid are injected by means of a special apparatus devised for the purpose, the injection being made in rather less than fifteen minutes. The injection is repeated every six or eight days until consolidation of the sac has taken place. The results of the treatment are still *sub judice*. In some of the cases treated death followed symptoms resembling those of tetanus, the cause of which, having regard to the antiseptic precautions taken, is obscure. Each of the agents mentioned has been credited with success in the treatment of aneurysm, but, as spontaneous cure has been occasionally witnessed under favourable circumstances as to diet and rest, where no medicines had been given, a more than promotive influence, by retarding the circulation and reducing vascular pressure, can scarcely be assigned to the medicine used, where rest and restricted diet have been observed. Galvano-puncture of the sac has been practised with success. Macewen advocates the production of white thrombi in organic connection with the wall of the aneurysm by the introduction of sterilised needles, by which the inner surface of the sac is gently scratched. Deligation of the common carotid artery, or of that vessel and the subclavian, may be followed by the most favourable result, in cases where pressure upon these vessels has been found to control pulsation in the sac.

A few leeches applied from time to time in the vicinity of the sac, or a hypodermic injection of morphine or hydrochloride of cocaine, will relieve the pain and allay the inflammation caused by ex-centric pressure.

C. J. NIXON.

THORACIC DUCT, Diseases of.—**SYNON.** : *Fr. Maladies du Canal Thoracique*; *Ger. Krankheiten des Ductus Thoracicus*.

The diseases of the thoracic duct resemble in kind those of the absorbent vessels generally (*see*

LYMPHATIC VESSELS, Diseases of); and it will suffice to indicate here the following practical points : (1) The passage of fluid along the duct and its escape into the subclavian vein may be impeded by any condition which interferes seriously with the venous circulation, and distends the veins considerably, such as certain cardiac diseases. (2) Local obstruction of the thoracic duct may arise at any point, from direct pressure upon it, especially by an aortic aneurysm, and it may become thus permanently occluded; or from intrinsic tubercular disease, which is of special importance, inasmuch as it may involve the duct extensively, break down, and lead to acute general tuberculosis by infection. (3) As a consequence, dilatation of the portion of the tube behind the seat of obstruction will probably supervene in various degrees, and it may become considerably enlarged and thickened. The portion beyond tends to become contracted and atrophied. (4) Perforation of the thoracic duct occurs in exceptional instances, owing to the destructive effects of an aneurysm or other morbid condition, or as the result of injury.

It is, as a rule, quite impossible to determine during life that the thoracic duct is diseased. This might be suspected if, along with some known cause which might lead to obstruction of the tube, the patient became extremely emaciated, anæmic, and weak, without other obvious reasons to account for these symptoms. No treatment directed immediately to the thoracic duct can be practicable under any circumstances.

THROAT, Diseases of.—**SYNON.** : *Fr. Maladies de la Gorge*; *Ger. Rachenkrankheiten*.

The throat is a comprehensive term, its diseases including those of the pharynx, tonsils, palate, and uvula, and in popular language even those of the larynx and trachea. The affections of these different structures are described in their appropriate articles.

THROMBOSIS (θρόμβος, a clot).—**SYNON.** : *Fr. Thrombose*; *Ger. Thrombose*.

DEFINITION.—The formation of a solid clot or 'thrombus' in the heart or vessels during life. The earliest stage in the formation of at least some thrombi has been shown to consist in the agglutination of blood-platelets, or sometimes of leucocytes. Hence the term 'thrombosis' has a slightly wider significance than the formation of a fibrous coagulum, though for practical purposes the deposition of fibrin is its most essential feature. Clotting may occur anywhere in the cardio-vascular system, and rarely even in lymphatics. In many cases it serves a useful end. The coagulability of

the blood is a property of vast importance in the arrest of hæmorrhage: the deposit of clot upon the walls of an aneurysm tends to check its extension and may promote its cure. But more often thrombosis is harmful in its effects.

PATHOLOGY.—The following may be accepted as a working hypothesis as to the nature of blood-coagulation. Fibrin is derived from a globulin called 'fibrinogen,' present in the plasma. The immediate agent of its conversion is the 'fibrin-ferment' (thrombin), and this appears to be a combination of a nucleo-proteid substance with lime. The nucleo-proteid is derived from the breaking up of leucocytes and blood-platelets; the platelets themselves are probably derived from the disintegration of red corpuscles. Thus all the elements of the blood may have a share in the process. The one factor lacking to coagulation in normal circulating blood is the special nucleo-proteid which goes to form the fibrin-ferment.

This factor can be experimentally added in animals, thereby causing intra-vascular clotting. Wooldridge showed that emulsions or extracts of lymphatic gland or thymus rapidly injected in sufficient quantity into the vessels produce this effect. Preformed fibrin-ferment gives rise to a similar result, as in Köhler's experiment, in which serum, expressed from the blood-clot of a rabbit, and re-injected into the veins, causes death in a few minutes from intravascular coagulation. The injection of such chemical bodies as break up the corpuscles and liberate the requisite nucleo-proteid may produce the same effects: bile-salts, ether, and large doses of snake-venom have been found to do so. These experiments give rise to thrombosis in the presence of a perfectly intact vascular endothelium: there can be no doubt that the phenomena depend simply on the presence of free fibrin-ferment in the circulation. The clinical occurrence of such forms of thrombosis in man is very doubtful, though some writers have advocated the view that thrombi occurring in cachexias and in certain infections have this origin. The intra-vascular clotting that may follow transfusion of defibrinated blood is, however, evidently parallel to that above described. The presence of lesions of the vascular or cardiac endothelium is a factor of much importance in the production of thrombosis. An intact endothelium is commonly spoken of as exercising a restraining influence upon coagulation (Brücke); it would be a more natural way of putting the matter to say that the roughened surface caused by endothelial lesions, or presented by foreign bodies, affords opportunities for the adhesion and disintegration of the blood-corpuscles and the consequent liberation of fibrin-ferment. It is even possible that the ferment may be liberated from necrotic endothelial cells.

Since the discovery of the part played by the blood-platelets in coagulation, endeavours have been made to trace a connection between the absolute number of platelets present in the blood and the tendency to thrombosis. Although the method of estimating their number leaves something to be desired, some sort of connection seems traceable. In chlorosis the platelets are much increased in number and thrombosis is common; in pernicious anæmia their number is reduced, and thrombosis is extremely rare. In hæmorrhagic purpura there is extreme diminution in the platelets, and the condition is associated with marked indisposition to

coagulation. In post-hæmorrhagic anæmia the disposition to coagulation is increased, and here the platelets are increased too. This apparent relation between increase of platelets and tendency to thrombosis may, however, be an indirect rather than a direct one; both phenomena may depend upon an increased vulnerability of the red corpuscles.

There is yet another factor which plays an important part in the production of thrombosis, namely, retardation of the blood-stream—local or general. Local slowing may depend upon the production of eddies by obstruction, narrowing or dilatation of the blood-channels. General slowing depends upon feebleness of the heart's action in debility and cachexia arising from any cause. The efficacy of this condition in assisting thrombosis depends in part on the fact that fibrin is more readily deposited from stagnating blood, in part on the fact that slowing of the circulation interferes with the nutrition of the endothelium lining the vessels, and so promotes degenerative changes in the intima. It may be also that in conditions of marasmus chemical changes are present in the blood which predispose to coagulation, or that the vulnerability of the corpuscles is increased so that they more readily yield up the nucleo-proteid necessary for the formation of the fibrin-ferment. Also, with slowing of the stream, comes a broadening of the axial current of corpuscles and platelets, and a greater disposition of these to come into contact with the vascular walls. The thrombosis occurring in conditions of debility and marasmus is commonly spoken of as '*marantic*' thrombosis.

ÆTIOLOGY.—The general conditions leading to coagulation of the blood during life have been indicated above. It remains to enumerate the chief clinical conditions under which thrombosis is apt to occur.

1. Traumatic lesions in continuity of the vessel-wall.—Thrombosis is the natural method by which such lesions are remedied. When a surgeon ligatures a vessel in its continuity, he deliberately aims at the rupture of the inner coats in order that a thrombus may form which shall, when organised, permanently seal the artery.

2. Foreign bodies occasionally lodge in the blood-vessels and cause clotting of the blood around them.

3. Whenever a vessel is obstructed, even partially, by an embolus or a thrombus, such masses act as foreign bodies and induce further deposit of clot. In this way an embolus may form the nucleus for an extensive thrombosis, and by such means a thrombus is itself 'produced' or 'protracted.' In these cases the effect of stagnation or retardation of the current is added to that of the abnormal surface.

4. Any chronic lesion, inflammatory or degenerative, of the heart or vessel-wall, is apt to set up a local thrombosis in virtue of the surface-roughening which it implies. Thus it comes to pass that chronic endarteritis and atheroma are fertile causes of thrombosis, especially in the smaller vessels where the current is less rapid. Thrombosis of the cerebral arteries is usually secondary to such chronic changes in the intima, as, for example, in syphilis; and this is the way in which syphilis, tuberculosis, and gout act in producing thrombosis. The usual absence of thrombosis in the aorta and great vessels, even when highly atheromatous, is probably due to the great velocity of the blood-

stream in such situations, which must tend to prevent the adhesion of corpuscular elements, and to sweep away any commencing thrombus. When, however, any dilatation or *cul-de-sac* is present in addition, as in aneurysm, the conditions for the deposit of clot are very favourable. In endocarditis the diseased surface of the endocardium is commonly the seat of some thrombotic deposit; vegetations are usually capped by some recent fibrin, and in this way, by gradual organisation of the deposit, they increase in size.

5. Acute inflammatory changes in the walls of the heart and vessels may equally be attended by thrombosis, whether the affection be primary or due to extension from adjacent foci of inflammation. Phlebitis is thus usually accompanied by thrombosis, nor is it always easy to say which is the primary condition. In the majority of such acute inflammatory changes the process is septic in its nature, and thus bacterial invasion comes to be one of the most serious causes of thrombosis. Infective phlebitis is unfortunately a common affection. It is seen in the lateral sinus as a complication of middle-ear disease; and, starting from the uterine veins, it is one of the recognised dangers of childbirth. In fact, in all septic conditions it constitutes a serious risk. Bacterial invasion of the arteries is relatively rare, but in the heart it is by no means uncommon, and septic, malignant, or ulcerative endocarditis is usually associated with pronounced thrombotic deposit, with its attendant liability to embolism. It is possible that many of the cases of thrombosis occurring in the course of infective processes, such as the specific fevers, tuberculosis, &c., are in reality of bacterial origin.

6. Marasmus and debility of all kinds are liable to lead to thrombosis, for the reasons which have been already given. It is probable that slowing of the circulation cannot alone cause clotting, since blood will long remain fluid even when absolute stasis has been induced by the careful double ligaturing of a vein, provided always that the endothelium has not been damaged. Some additional cause is to be sought in most cases of marantic thrombosis, and it is likely that an infective element is often present; where this is not the case, malnutrition of the vessel-wall, with possible chemical changes in the blood, must be invoked as contributing causes. The clinical conditions under which stagnation-thrombi are formed comprise anæmias, especially chlorosis, and cachexias of all kinds, such as occur in phthisis, or after protracted fevers, e.g. typhoid. Thrombosis of the cerebral sinuses is occasionally seen in infancy as a result of extreme marasmus.

Structure.—There is experimental evidence that some thrombi consist, at least at their earliest commencement, not of coagulated fibrin, but of a dense agglutination of preformed morphological elements. Eberth and Schimmelbusch witnessed the agglutination of blood-platelets in the mesenteric vessels of warm-blooded animals. Others have demonstrated the occurrence of thrombi consisting of leucocytes alone, while Wlassow maintains the first origin of the white thrombus to lie in the sudden destruction and coagulation of the red corpuscles. Purely fibrinous thrombi are also described, especially in the capillaries in inflamed areas, e.g. in croupous pneumonia. They are often hyaline in appearance, and are then known as hyaline thrombi.

But in ordinary thrombosis the mass consists of a mixture of different elements. Weigert's method of staining fibrin is especially useful in demonstrating the structure of a thrombus. Whatever its primitive origin, it soon comes to consist of fibrin deposited from the blood, and entangling in its meshes leucocytes and red corpuscles in varying proportions. Speaking generally, the clot formed from blood at rest contains chiefly red corpuscles, and is known as a '*red thrombus*,' while that deposited from blood in motion contains a preponderance of leucocytes, and is called a '*white thrombus*.' The clot formed in a popliteal aneurysm after ligature of the femoral artery is a red thrombus; that deposited on the walls of an aortic aneurysm is a laminated white thrombus. A newly formed red thrombus is soft and not laminated; it shows a loose fibrin-network, entangling a multitude of red corpuscles, with a few leucocytes, perhaps proportionately more than in normal blood. The white thrombus is firmer and denser in its texture, and commonly presents a laminated structure. The fibrin is present in fibrillary form, or in broader and more irregular trabeculae. Leucocytes are the chief morphological elements present, though a varying proportion of red corpuscles may be seen; besides these recognisable elements there is present among the meshes of the fibrin-network much granular material believed to be derived from broken-down blood-platelets. A very common form is the '*mixed thrombus*' containing layers or areas of both the forms of clot just described. A white thrombus may become fissured, especially when laminated, and so fluid blood may penetrate and coagulate as red thrombus. Or the clot may originally form in alternate layers, according to the varying conditions under which it is deposited. A *primitive* thrombus is one occupying its original seat of deposition; when it extends along a vessel it is called a *produced* or *protracted* thrombus. A clot adhering to the vessel-wall but not completely filling the lumen is known as a *parietal* thrombus; if it absolutely obstructs the blood-channel the term *obliterating* thrombus is applied to it.

Growth and Extension.—When once thrombosis has commenced it tends to spread because the thrombus itself acts as a foreign body upon which new material is deposited from the blood in contact with it. Thus arises the propagated thrombus. In this manner the parietal may become an occluding thrombus. A clot may spread in this way along a vessel until, where it joins a larger trunk, the velocity of the current is sufficiently great to check its further growth, so that it projects by a free rounded extremity into the lumen of the obstructed channel.

Later changes.—Thrombi undergo a variety of secondary changes which are sometimes of great practical importance. They may be described under the following headings:—

1. *Hyaline transformation.*—The cellular elements break down, and such hæmoglobin as may be present is dissolved out. A granular mass thus arises which later becomes translucent and hyaline, shrinking in the process so that the lumen of the vessel may be partially reopened; nevertheless the thrombus commonly remains adherent at some points.

2. *Organisation.*—The thrombus itself is an inert mass: its organisation takes place from without, at its points of adhesion to the vessel-wall. The endothelium of the latter proliferates, and extends over

the clot; beneath the endothelial layer connective tissue is developed. Some hold that it takes its origin from the endothelial cells themselves, others that it is derived from the migration of wandering cells. It ultimately permeates the entire mass. Meanwhile the thrombus becomes vascularised; the new vessels arise in part from processes dipping down from its endothelial covering, in part by budding from the vasa vasorum of the vessel-wall; the two sets ultimately come into communication, and thus a complete circulation is established throughout the thrombus. The newly formed connective tissue undergoes contraction, and the whole mass may finally appear as a mere thickening of the vessel-wall, or as a fibrous strand crossing its lumen. The thrombotic obstruction may thus practically disappear in favourable cases; at other times a collateral circulation having been established permanent obliteration of the vascular channel may produce no harmful result.

3. *Calcification* is an occasional occurrence in a thrombus. Lime-salts may be deposited in it as in any other relatively dead tissue: thus arise *phleboliths*.

4. *Simple softening*.—In certain cases organisation does not take place, and softening and breaking down of the mass occur in its centre. This sometimes happens in venous clots, and commonly in large cardiac thrombi. It is probably due to the digestive action of ferments liberated from the disintegrating leucocytes, and seems undoubtedly to occur in truly aseptic cases.

5. *Septic softening*.—In clots which are due to bacterial action, or which have been secondarily infected, softening and liquefaction readily occur, as, for example, in lateral-sinus thrombosis secondary to middle-ear disease. To the naked eye the process may resemble simple softening; the clot breaks down into a creamy, puriform material which readily gives rise to septic embolism. Even simple softening may lead to a crumbling consistency and bland embolism.

Localisation of thrombosis.—There is no part of the cardio-vascular system in which clotting may not occur. Nevertheless, there are certain situations in which it is commoner than in others. It appears to commence more often in vessels of medium size than in the very large or the very small. When it arises from general conditions the veins are far more frequently affected than the arteries; among the reasons for this those which seem of most weight are the greater slowness of the blood-stream in veins, and the larger percentage of carbon dioxide in the blood. Where thrombosis arises from local conditions the proportions are more equal; the arteries are the more subject to chronic disease and embolism; the veins are more liable to be attacked by septic inflammation.

Arterial thrombosis is usually due either to embolism or to some form of chronic arteritis; in the latter case aneurysmal dilatation is an especially favourable condition. The lower extremities are more commonly affected than the upper, and the prevalence of chronic arteritis in the cerebral and coronary arteries renders these also common sites of thrombosis. In the veins, again, clotting occurs with especial frequency in the lower extremity; marantic thrombi are very commonly found in this situation. There are special causes which lead to a special incidence of the process on other veins; thus the slowness of the current in the cerebral

sinuses predisposes to the condition, while the proximity of the lateral sinus to the middle ear renders it liable to septic infection in otitis media. A similar septic condition after parturition is liable to spread from the uterine to the iliac veins, whence arises phlegmasia alba dolens. In the heart thrombosis is common. Endocarditis, especially in its malignant form, is frequently associated with thrombotic deposit upon the vegetations, and in addition to this, in cardiac feebleness and dilatation, it is common to find *ante-mortem* clotting in certain situations, notably in the auricular appendices and at the apices of the ventricles. As a pathological curiosity may be mentioned the free 'ball thrombi,' which in rare instances have been found in the left auricle in cases of mitral stenosis, and which probably result from the accretion of fibrin round a detached portion of clot.

True thrombosis in the heart and vessels must be carefully distinguished from *post-mortem* clotting. Coagulation of the blood after death leads to the formation of clots which are usually voluminous in proportion to the distension of the cavities at the moment of death, and are best marked in the right chambers of the heart. If the clotting has occurred quickly they are of uniform dark red colour; but if sufficient time has elapsed for the precipitation of the corpuscles they are yellow and gelatinous, except at their most dependent parts. They are soft and somewhat tenacious, never crumbling or breaking down centrally. They are never truly stratified, and their surfaces are not ragged or honeycombed. They are never truly adherent, though they may be closely entangled among the columnæ carneæ; when peeled off from the heart-wall the smooth intact endocardium is found beneath them. Attention to these points will prevent any errors in distinguishing between the two conditions. The term 'agony clot' is sometimes erroneously employed to designate these *post-mortem* clots. The fact that they are so frequently decolourised by subsidence of the corpuscles is sufficient to prove that they have been formed after death and not during the death-agony.

Capillary thrombosis is for the most part limited to areas of necrosis or of intense inflammatory change passing on to tissue-death. Hyaline capillary thrombi are described in various infective conditions. Thrombosis of the lymphatics is a condition of minor importance, but it has been described in connection with septic conditions in the uterine lymphatics. The lymph is only feebly coagulable, and lymphatic obstruction is rarely due to primary thrombosis.

Results of thrombosis.—In the left heart and in the larger systemic arteries the detachment of thrombi leads to embolism of the systemic vessels. In the veins and in the right heart such detachment leads to pulmonary embolism. But for the most part, the results and the symptoms of thrombosis are those of vascular obstruction, and so far as these concern the arterial system they have been described in the article on Embolism. Venous thrombosis leads to its own special train of symptoms (see article on VEINS, Diseases of). Anastomosis between veins is commonly more abundant than in the case of arteries, so that a collateral circulation is readily established when the obstruction is limited in extent and does not affect a main trunk. But often a main trunk, such as the femoral vein, is affected, and the degree of obstruction produced leads to marked oedema, i.e. the increase of pressure

in the capillaries behind the obstruction leads to a greater transudation of lymph than can be dealt with by the lymphatics. Even here the oedema is not due solely to the venous obstruction, for the femoral vein may be tied in man or animals without resultant dropsy. The accessory factor which probably contributes to the production of the oedema is an increased permeability of the capillary wall, which may depend partly on nutritional changes in the endothelium from impeded circulation, partly on the cachectic or other conditions which have led to the thrombosis. Thrombosis of the portal vein seems always to lead to ascites, and sometimes in this and in other veins (e.g. the renal) hæmorrhagic infarction may result. Cases have been reported in which moist gangrene of the extremities has apparently resulted from thrombosis of the main venous trunk, but this an extremely rare sequel of venous thrombosis, common as it is when the artery is the obstructed trunk. When a septic element is added to the mechanical obstruction of a vein, as is too commonly the case in uterine thrombosis after parturition, the dangers of septicæmia overshadow other considerations.

The SYMPTOMS of thrombosis are those of vascular obstruction, and naturally vary with the situation of the affected vessel and the character and degree of obstruction. In the heart and sometimes in the peripheral circulation embolism may be an important symptom. If the affected vessel be accessible to the touch, a firm and often tender cord may be felt.

The TREATMENT of thrombosis depends upon its cause and seat (see articles on HEART, Thrombosis of; PORTAL THROMBOSIS; VEINS, Diseases of, &c.). The general principles of treatment are directed (1) to the removal, where possible, of the primary cause. Anæmia, gout, and similar constitutional conditions are to be met by appropriate remedies; (2) to the obviating of the dangers and results which may arise. Perfect rest will, in venous thrombosis, limit the liability to pulmonary embolism, and assist in the development of a collateral circulation. In arterial thrombosis it will check the tendency to necrosis and gangrene.

FREDERICK W. ANDREWES.

THRUSH.—A popular name for parasitic stomatitis. See MOUTH, Diseases of.

THYMUS GLAND, Diseases of.—SYNON.: *Fr. Maladies du Thymus*; *Ger. Krankheiten der Thymusdrüse.*

The thymus has but a short period of full activity. At birth it weighs from 100 to 200 grains, and it reaches its full development by the end of the second year. It then remains in much the same condition till about the eighth year, after which it gradually diminishes in size, being converted into fat, till at puberty only a trace remains. Extracts of the thymus when injected either beneath the skin or directly into a vein have not been found to possess any special physiological action.

Persistence and Hypertrophy.—In some adults the thymus is found to persist as large as in the infant, while in others it is even larger and may weigh as much as 300 or even 400 grains. Cases have been reported of children dying suddenly from suffocation, with no other cause assigned for their death than pressure on the trachea of an enlarged thymus gland. Considering its position between the sternum and the windpipe, and the small power

of resistance possessed by the rings of the trachea during infancy, an enlarged thymus may be an occasional cause of asphyxia. Enlargement of the thymus may also occur as part of a condition known as lymphatism, in which death from cardiac failure may take place from some trivial cause such as a hypodermic injection. An enlarged thymus is frequently found in some diseases such as exophthalmic goitre, Addison's disease, acromegaly and lymphatic leucæmia.

Inflammation.—Acute inflammation of the thymus is rare and difficult to recognise. It may be followed by suppuration and the formation of an abscess. In one such instance the abscess burst into the trachea.

Tuberculosis.—Primary tuberculosis is very rare, but in general tuberculosis the thymus may be infected just as any other organ.

Syphilis.—Small gummata are sometimes found, or there may be a general syphilitic fibrosis.

Sarcoma.—Sarcoma of the thymus occurs more frequently than carcinoma. The sarcoma may be either round-celled or spindle-celled or of a mixed type. In some so large an amount of fibrous tissue is present as to warrant the name of fibro-sarcoma.

Carcinoma.—Carcinoma of the thymus may vary in type. The cells are generally rather large, and vacuolation has been found in them by H. D. Rolleston. In some cases 'epithelial pearls' occur which show that the growth is derived from the original diverticulum of the fore-gut from which the concentric corpuscles of Hassall are developed. Some malignant growths of the thymus show such different types of structure in the same tumour as to suggest that they are really combinations of carcinoma with sarcoma.

SYMPTOMS OF THYMUS TUMOURS.—The symptoms of a tumour of the thymus-gland are those of a growth in the anterior mediastinum. The tumour may extend upwards so as to be felt projecting above the upper end of the sternum, or it may grow downwards over the anterior surface of the pericardium. The superior vena cava and the innominate veins may be compressed; then the head and neck are cyanosed, the veins of the upper part of the body are distended and the subcutaneous tissues become oedematous. In addition there may be pleural effusion.

PUGIN THORNTON.
GEORGE MURRAY.

THYROID GLAND, Diseases of.—SYNON.: *Fr. Maladies de la Glande Thyroïde*; *Ger. Krankheiten der Schilddrüse.*

The thyroid gland produces, in the form of the colloid material which fills its alveoli, an internal secretion which enters the blood and plays an important part in the normal metabolism of the tissues. Diseases of the gland are accompanied, therefore, by general or local symptoms, according as the supply of secretion is or is not influenced by the morbid change in the gland. Thus associated with fibrosis and atrophy of the gland we have myxoedema and cretinism (see CRETINISM; and MYXŒDEMA). In exophthalmic goitre there is a special form of hypertrophy of the gland, while other forms of enlargement are included under the name of goitre (see EXOPHTHALMIC GOITRE; and GOITRE). As these conditions are described separately we shall here consider the remaining less common local diseases of the gland, which do not, as a rule, appreciably affect its functional activity.

1. **Acute Thyroiditis.**—Acute thyroiditis may be either primary, secondary, or traumatic in origin. The cause of the primary form is not known. Secondary thyroiditis has occurred as a complication or sequel of acute rheumatism, influenza, diphtheria, measles, and other acute infective diseases. In some of these the inflammation has been shown to be due to the bacteria of the primary disease. Traumatic thyroiditis has occurred as the result of a wound or burn in the thyroidal region.

SYMPTOMS.—The onset is generally acute and may be accompanied by a rigor, the temperature rising rapidly to 103° F. Pain and a sensation of fullness are commonly felt in the thyroidal region. One lobe or the whole gland then becomes tense and swollen. In severe cases there may even be dyspnoea and dysphagia from compression of the trachea and oesophagus. The attack may terminate by resolution, suppuration, or gangrene.

TREATMENT.—The patient should be kept in bed and fed on a light or liquid diet. Locally the application of ice or of leeches will give relief; if these fail, belladonna-fomentations may be employed instead. At the commencement 5 or 10 grains of calomel should be given at night, followed by a saline aperient in the morning. During the acute stage 10 or 15 grains of sodium salicylate should be given every three or four hours. If an abscess forms it should be emptied at once by aspiration or by incision and drainage.

2. **Hydatid Cysts.**—These have in a few cases produced an enlargement of the thyroid gland. A hydatid cyst closely resembles a cystic adenoma, but a microscopical examination of the fluid withdrawn from the cyst may, by the discovery of hooklets, enable a correct diagnosis to be made.

3. **Malignant Disease.**—(a) *Carcinoma.*—Primary cancer of the thyroid gland is a rare disease, which develops less frequently in a healthy gland than in one which is already goitrous. It occurs most frequently between 30 and 50 years of age. It may develop from the epithelium which lines the alveoli of the gland. It has, however, been shown by Horsley that some of the carcinomatous growths probably originate in the parathyroid gland, which they closely resemble in structure.

In carcinoma there is rapid enlargement of the thyroid gland, followed in an early stage by duskeness of the skin over the most prominent part of the swelling. Such signs are all the more important if the patient has passed middle-life. The enlarged gland feels hard and irregular, and is less movable than a non-malignant goitre. There may be radiating pain over the front of the neck. In some cases there is complete paralysis of one or even both vocal cords, owing to impaction of the recurrent laryngeal nerve in the growth which may involve the large blood-vessels in the neck as well. Dyspnoea and dysphagia are both common symptoms, especially in the later stages, the trachea and oesophagus being first compressed and then invaded by the growth. In advanced cases the skin may be destroyed, when superficial ulceration occurs with hæmorrhage. The lymphatic glands are not infected until the growth extends through the capsule of the gland. The total duration of life after the recognition of the disease rarely exceeds a year.

TREATMENT.—The only treatment which is of any avail is *total* excision at the earliest possible

date. It is most important, as Kocher has shown, that this should always be done even when the growth appears to be confined to one lobe. When the disease is too far advanced for this radical treatment, tracheotomy may be performed in some cases for the relief of dyspnoea.

(b) *Sarcoma.*—Sarcoma occurs much less frequently than carcinoma. It may develop in either a healthy thyroid gland or in one which is already goitrous. It grows rapidly, and may reach the size of an orange or even a coconut. The tumour is uniform and soft in consistence, and may contain cysts. The growth soon extends through the capsule and may involve the vessel and nerves in the neck, and the trachea and oesophagus as well. It is liable to involve the skin and cause ulceration with free hæmorrhage. Secondary growths may occur in the lymphatic glands in the neck and in the internal organs. The total duration of the disease is rarely more than a year. The growth may be either a round- or spindle-celled sarcoma. The entire gland should be removed as soon as the nature of the enlargement is determined.

(c) *Recurrent Thyroid Tumours.*—In this form of malignant disease the primary growth resembles a simple adenoma in structure. Secondary growths develop in the bones of the skull, long bones and vertebrae, and also in the lungs and lymphatic glands, the microscopical structure of which resembles that of the normal thyroid gland. They are, however, very malignant, as they rapidly extend and lead to a fatal termination. *See* TUMOURS.

4. **Tuberculosis, Syphilis, and Actinomycosis** of the thyroid gland are rare, but do not essentially differ from the same diseases in other organs except when the two latter, in very rare cases, so far interfere with the functions of the gland as to lead to the development of myxœdema.

Therapeutic Action and Uses of Thyroid Gland.—The thyroid gland and its preparations are now largely used as therapeutic agents. The two official preparations, *Liquor Thyroidei* and *Thyroideum Siccum*, are in general use, six minims of the former being equivalent to one grain of the latter. They are chiefly employed in the treatment of myxœdema and cretinism, for which purpose the *Liquor Thyroidei* was originally devised and introduced by one of the writers (G. M.). The usual dose is from five to fifteen minims of the *Liquor Thyroidei* or from one to three grains of the dry thyroid each day, under the influence of which the symptoms of myxœdema and cretinism rapidly disappear (*see* CRETINISM; and MYXŒDEMA). The same preparations are also useful in the treatment of simple goitre in young adults (*see* GOITRE), and of some diseases of the skin such as psoriasis and ichthyosis.

PUGIN THORNTON.

GEORGE MURRAY.

TIC-DOULOUREUX (Fr.).—**SYNON.** : Facial Neuralgia; Prosopalgia.

DEFINITION.—Neuralgia of the trigeminal, trifacial, or fifth nerve.

One alone, more often two, but rarely all three divisions of the fifth nerve of one side may be coincidentally the seat of neuralgia. It is less common for the third division to suffer than the first and second. Tic has often been preceded or followed by neuralgia in other districts, especially in that of the occipital nerve.

ÆTIOLOGY.—Trigeminal neuralgia is rare in young children, but may occasionally occur in them, associated, perhaps, with delayed or irregular eruption of the permanent teeth. But sex and occupation do not appear to influence its occurrence. In women utero-gestation, the exhaustion from hæmorrhage at parturition, menorrhagia, or over-suckling, as well as the sexual changes in middle-life, are especially prone to reproduce facial neuralgia, which has appeared in a slight form earlier in life. Exposure to cold and hardship apparently conduce to its production. It is, however, in the period of degeneration that the worst and most intractable instances occur.

The term 'brow ague' is still frequently applied to a neuralgia of the first division of the trigeminal, which cannot always be referred to a malarial origin. Formerly, when malarial fevers were rife in this country, such an affection was, doubtless, of common occurrence; but at the present day, owing to drainage and cultivation, it is rare for this cause to be in operation. Cases do, however, occur, and these may usually be recognised by regular periodicity in the attacks of pain, a semi-algid condition of the system, and the rapid and effectual influence of quinine. But a remarkable periodicity is often to be found in the recurrence of attacks, unconnected with ague. Cold wind, especially with a moist atmosphere, has an undoubted influence in starting neuralgia of the fifth nerve, the unprotected condition of the face explaining probably its peculiar liability to be so attacked. There appears reason to think, however, that when damp with cold excites an attack of neuralgia, there must be at the same time a peculiar condition of the system, or neuralgia of the fifth would be much more common in this climate than it is. Such a condition is probably of a rheumatic or gouty nature, and the cold seems to start a subacute inflammation in the sheath of the nerve. As regards other general conditions predisposing to the affection, they are those common to neuralgia. See NEURALGIA.

Injury of the nerve; foreign bodies, irritating either this or some other nerve; morbid growths of bone, especially such as cause contraction of bony canals traversed by branches of the nerve; and syphilitic periostitis, may act as exciting causes of tic-douloureux. Or the immediate cause may be in the floor of the cranium, in the form of tumours or disease of bone or of membranes, aneurysm, or abscess.

SYMPTOMS.—Some obscure feeling of discomfort may precede the outburst of actual pain, or this may occur suddenly and without warning in some part of the district supplied by the fifth nerve. There will be one or more foci from which the pain will seem to emanate in swift flashes, a dull aching remaining in the intervals, of a very wearying character. Generally short-lived at first, the paroxysms of darting, burning, boring pain gradually increase in severity and duration. The patient sometimes cringes under the violence of the agony. When fairly pronounced, there is a great tendency to the excitement of a paroxysm by the influence of such slight irritants as a current of air, a sudden noise, or the muscular movements concerned in speaking, laughing, chewing, blowing the nose, or coughing. The attack of tic may vary to any extent in degree and duration, from a short-lived paroxysm which never returns, to a disease of the most obstinate character, embittering, with more or less constantly

repeated attacks, the whole of a long life. In such cases it has a tendency to remit during the course of severe intercurrent diseases.

When the *ophthalmic division* of the nerve is affected, it sometimes happens that the first notice of the attack is an exceeding soreness of some spot on the scalp, recognised only on brushing the hair, and this is followed some hours afterwards by pains in the branch of nerve distributed to this point. The pains are most marked, and tenderness on pressure can generally be noted, in one or more of the following places: the supra-orbital notch, at a point a little above the parietal eminence, in the upper eyelid, at the junction of the nasal bone with its cartilage, within the eyeball, or at the inner angle of the orbit. There is often lachrymation, with redness of the conjunctiva, and sometimes intolerance of light. There is sometimes so much tenderness that the patient cannot wear a hat, or even wash his forehead. Or he may be unable to blow his nose. If one or two hairs be drawn over this hyperæsthetic surface, it will be found that the tactile discrimination is diminished, as compared with the corresponding region of the opposite side. The pain is sometimes described as shooting into the upper eyelid, or going between the eyeball and the cavity of the orbit, extending thence over the brow, as though the forehead were being slit open. Pressure upon the parietal eminence will send a sort of heavy dull shock into the eye. To neuralgia of this division, in consequence of the pain being limited to one-half of the anterior aspect of the head, the term *hemicrania* has been applied, whence the *migraine* of the French, and the vernacular 'megrim.' The neuralgic affection constitutes, however, only a portion of the complex group of phenomena to which the term 'migraine' is properly applicable, and which may include, besides, subjective sensations of dazzling lights or colours, often of a zigzag shape, transient hemiopia, vertigo, unilateral numbness and tingling of extremities, impairment of speech, nausea, and vomiting. See MEGRIM.

When the *superior maxillary division* is in fault, violent pain is experienced in the cheek-bone or jaw, or in both, points of tenderness being found at the site of emergence of the infra-orbital nerve, over the malar bone, or on the gum of the upper jaw. The pain may be so definitely localised in one or more teeth that these may be thought to be the cause of the suffering. In these circumstances extraction of teeth is often performed quite uselessly. The teeth are found to be healthy. The attacks of pain are sometimes accompanied by profuse watery secretion from the nasal and buccal mucous membranes. There may be swelling and acute sensitiveness of the lip and nostril, the slightest contact with which causes pain to shoot widely in various directions, sometimes appearing to affect distant parts of the body. Acute pain may also occur in the parotid gland, accompanied by a great flow of saliva.

When the *third division* is attacked, points of intensity may be found on the temple, a little in front of the ear, at the place of exit of the inferior dental nerve, at the side of the tip of the tongue, or more rarely in the lower lip. The writer has met with cases in which neuralgia of this division, attacking both sides of the lower jaw and the under-surface of both borders of the tongue, occurred in plunges of agony which caused the patient to utter a kind of shrieking groan, and the head was jerked

convulsively. Such attacks may be brought on by chewing, swallowing, and even by speaking. In other cases the pain may be entirely localised in one side of the tongue-tip, but here at times it is so intense that the patient rolls on the floor in agony. To cases of this kind, marked by lightning-like seizures of exquisite character, and accompanied by spasmodic movements of the facial muscles, the term *epileptiform neuralgia* is sometimes applied. Hereditary tendency to insanity sometimes accompanies this form. The lingual branch of the fifth is happily not so often affected as the other portions, for there is probably no form of neuralgia involving more exquisite suffering. When the auriculo-temporal division is affected, pain is situated in the outer auditory meatus and temple. Some cases of so-called *erache* are doubtless examples of neuralgia affecting this nerve.

There is a variety of trigeminal neuralgia which is known as *clavus hystericus*, and which occurs chiefly, but by no means solely, in females, and affects the period of bodily development. It is characterised by intense pain, limited to one or two small points (the parietal most often, or supra-orbital), and resembling the driving of a nail into the skull. It occurs most often in the anæmic, and has sometimes been mistaken, with unfortunate results, for some inflammatory affection demanding depletory measures.

In severe tic-douloureux the facial muscles, those of the tongue, and even sometimes those rotating the head, may be spasmodically contracted by reflex action (*see FIFTH NERVE, Diseases of*). With supra-orbital neuralgia there may be blepharospasm or strabismus. The writer once saw a patient liable to neuralgia of the supra-orbital division for a period of twenty years, in whom, one year before, the attack began to be attended by complete ptosis and external strabismus, from paralysis of the third nerve. A certain amount of weakness continued between the attacks, but it was as an immediate sequel of the pain that the loss of power was most strongly marked. Two days after the cessation of the pain the eyelid could be raised fairly well and the eyeball moved, though never quite freely. Some degree of vaso-motor paralysis was shown by the reddening and heightened temperature of the face and swelling of the veins, which occurred unilaterally during the paroxysms of pain, as well as by the soreness of skin, indicating probably a temporary congestion which remained behind. To the same cause must be referred the extreme redness of the conjunctiva and mucous membrane of the nostrils, with increased lachrymation and flow of nasal and buccal secretion, often observed in this form of neuralgia. The hair is liable to be changed in colour about the seat of pain. There may be a permanent blanching, as of the greater part of an eyebrow or a small tuft upon the head, or the change may be a fluctuating one, the colour returning during the intermissions of the disease. Individual hairs in the district of the affected nerve may be hypertrophied, or the converse may happen; and during the persistence of attacks the hair may become brittle and fall out, to return, however, when the neuralgia subsides. Anstie described a state of thickening, the result of subacute inflammation, in the periosteum of bone and in fibrous fasciæ in the neighbourhood of the painful points of neuralgic nerves. Pressure on these swellings may not merely excite pains in the

affected branches, but send a powerful reflex influence through the cord to distant organs, causing vomiting, or affecting the action of the heart. The skin is apt to grow coarse; and patches of pigment to occur in the painful situations. In neuralgia of the second and third divisions the corresponding half of the tongue is sometimes seen to be covered with fur from overgrowth of epithelium, and this even when the process of mastication has taken place equally on each side; or there may be salivation severe enough to cause a suspicion of mercurial action, but which may be distinguished by its being unilateral. Acute inflammation of the skin, in the form of herpes, sometimes attends neuralgia of the fifth, especially its first division; and the eyeball itself may become in similar circumstances the seat of serious inflammatory action in one or other of its tissues. There may be a profuse and extensive eruption of herpes, leaving cicatrices which suggest confluent small-pox. In such a case neuralgic pains may cease during the eruption, to recur with great violence while this is scabbing. Acute glaucoma is attended by symptoms which appear to refer it to trophic changes consequent on neuralgia of the ophthalmic division of the fifth. There appears reason to think that recurrent iritis may sometimes be related to neuralgia or some kindred affection of the same division. Common sensation is frequently blunted during and after paroxysms of tic; but occasionally there will be so much and such persistent hyperæsthesia of the skin, that the patient cannot bear the face to be washed. In epileptiform tic the sufferer will often be observed to rub violently with a handkerchief the part of the face affected; but, on the other hand, there are cases in which not even the touch of a light bonnet can be borne, so exquisitely sensitive is a portion of the scalp. A touch with the finger upon this locality will sometimes cause the patient to fall to the ground.

DIAGNOSIS.—The paroxysmal character of the pains, coupled with the tenderness on pressing various points, sufficiently indicates tic-douloureux. The only condition with which it is at all easily confounded is the painful anaesthesia which is apt to be an early symptom of the encroachment of a tumour upon, or some other destructive lesion of the trunk of the nerve within the cranium (*see FIFTH NERVE, Diseases of*). The presence of the pain will distinguish the spasmodic contractions of the facial muscles secondary to neuralgia from mimetic spasm proper. There is no doubt that neuralgia about the forehead has been often mistaken for some inflammatory intracranial mischief, and this is peculiarly liable to happen where either ptosis or strabismus forms part of the symptoms. Careful examination, bearing in mind the points of diagnosis described, ought to obviate error. Still more important is it to avoid the error of ascribing to this form of neuralgia the pain occasioned by the growth of intracranial tumour (*see BRAIN, Tumours and New-Growths of*). It must be remembered that pus in the antrum may occasion neuralgic symptoms; that a fruitful source of trigeminal neuralgia is caries of the teeth; and that careful examination should be made for any disease of the nares.

DURATION AND PROGNOSIS.—Tic-douloureux occurring in youth and apparently as an accident of exposure, or as a result of faulty teeth, may never recur. It is perhaps more common, however, for repetitions of the attack to take place, alternating, it

may be, with neuralgia in other quarters. Tic is not infrequently liable to recur, especially under circumstances of depression, through a whole lifetime, but it may never have the character of extreme severity. In certain few cases, however, it is not only obstinate, but of terrible violence, the patient being incapacitated through many years by the constantly recurring affection. As a rule the disease, however severe the agony entailed by it, does not seem of itself to shorten the duration of the life which it fills with suffering.

TREATMENT.—As in neuralgia generally, the treatment of tic is partly constitutional, and partly local and palliative of suffering (*see* NEURALGIA). The first care in a case should be to have the state of the teeth accurately investigated, and faulty teeth removed or otherwise treated. It may happen that a tooth betraying no outward signs of decay is carious internally, and may thus easily escape recognition. The state of the ear and the nares demands equally careful attention.

As a local means of palliation blisters are often of great service. A small one should be applied over the branches of the cervico-occipital nerve at the nape of the neck, and repeated if necessary. The constant voltaic current is sometimes useful. A sufficient number of cells (from four to eight or ten) should be employed to give such a current as causes the negative pole to impart a very distinct burning sensation. The circuit should never be abruptly opened by the removal of the rheophore; a gradual heightening and lowering of the strength, respectively, should take place, both on applying and when leaving off, to avoid a shock. The rheophores should be fitted with sponges well moistened with salt and water, or with carbons plunged for a minute or two in hot water. The application may be continued for five minutes at a time, and be repeated at very short intervals indeed, it may be for some hours. The medicinal treatment of tic embraces the employment of numerous drugs among which the synthetical compounds have acquired an important place not only on account of their efficacy in relieving pain, but also because they are to a considerable extent free from the objections attending the use of opium and its derivatives. In some cases of tic a combination of 20 or 30 grains of chloride of ammonium with 5 drops of liquid extract of opium, taken two or three times a day, is singularly efficacious. Butyl-chloral hydrate—2 to 4 grains in a pill taken every two hours for a few times—may be sometimes employed with advantage. So, also, the tincture of Gelsemium sempervirens, given in doses of 5 to 15 minims every two hours, till relief is obtained. This remedy requires close observation. Phenazone, in doses from 5 grains every half-hour, or from 10 to 20 grains every four or five hours for a few times, is sometimes particularly useful. So also phenacetin in doses of from 10 to 15 grains with 3 or 4 grains of caffeine will often give great palliation. Salicylate of sodium 10 grains, with 5 grains of iodide of sodium and 5-10 of phenazone 3 times a day, is often very useful. The hydrate of chloral in a dose of 20 grains will occasionally be of great service, if the pain is not very severe, in procuring sleep from which the patient wakes relieved. If, however, the pain be severe, chloral hydrate is useless. It is important not to confound the epithelial overgrowth of the tongue, which so commonly occurs in tic, with the ordinary furring from digestive difficulties

which is supposed to indicate a necessity for purgatives. It will be observed that it only affects a lateral half. The hypodermic injection of morphine should be avoided except in cases of extremely intractable character in which the employment of other drugs has proved useless.

It is in cases of this class that the aid of the surgeon may be invoked with advantage. Stretching and resection of the affected branch of nerve will often procure immunity from suffering for periods varying from a few months to a year or two. Where all three branches of the nerve are involved it is sometimes found necessary to remove the Gasserian ganglion, an operation which in recent years has found considerable favour.

T. BUZZARD.

TIN, Poisoning by.—**SYNON.**: Fr. *Em-poisonnement par l'Étain*; Ger. *Zinnvergiftung*.

The importance of tin as a toxic agent has only comparatively recently been recognised; for although attention was drawn nearly a century ago to the possible danger attending the use of tinned vessels for culinary purposes, the danger was supposed to be due simply to the contamination of the metal with arsenic. Subsequently alarm was excited in consequence of the employment of alloys of tin for the storage of preserved articles of food, such as meat, vegetables, and fruits; but here again the danger has been assigned to the lead with which the tin is alloyed, a lead-tin alloy being used for the construction of the capsules employed. Attention has also been directed to the tin with which tinned foods and fruits are almost invariably contaminated, as itself presenting a source of danger to the consumer. It is known that the soluble salts of tin, met with in commerce as *Dyer's salt*, *pink salt*, &c., are poisonous; and experiments on animals show that even the insoluble hydrated oxides of tin are fatally poisonous, the oxides being no doubt dissolved in the alimentary fluids, tin having been detected after death in such cases in the liver and other solid viscera. Certain kinds of sugar are prepared by a process which introduces tin to the extent of from one-fourth to one-third of a grain per lb. of sugar into the manufactured article; but it is not known that these sugars are deleterious.

ANATOMICAL CHARACTERS.—The *post-mortem* appearances in fatal poisoning by tin are those of the mineral irritants. The cases observed have been too rare to be spoken of otherwise than generally. *See* POISONS.

SYMPTOMS.—Of these but little is known. Concentrated solutions of stannous chloride and of stannic chloride—the lower and higher chlorides respectively of the metal—are known to act as irritant poisons. Neurotic symptoms are also manifested, so that tin-salts do not appear to act simply as irritants. In large doses the chlorides produce fatal results. Probably the toxic results are heightened by the free hydrochloric acid invariably present in the commercial solutions of stannous and stannic chlorides.

TREATMENT.—The treatment to be employed is that for mineral acids. *See* POISONS.

THOMAS STEVENSON.

TINEA (*tinea*, a moth-worm).—**SYNON.**: Ring-worm.

DEFINITION.—Contagious affections of the epidermic structures of man and some animals, caused

by the growth of various species of fungi, the *Microspora* and the *Trichophyta*. In addition to the various groups of bacteria (cocci, bacilli) recognised as pathogenic vegetable parasites of the human integument and its appendages, the hair and nails, there are certain cryptogamic organisms which contribute to make up the group of dermatophytes. The botanical place of some of these cryptogams is not definitely established, but we may mention in order the parasite causative of *Botryomycosis*; the *Streptothrix* or *Oospora actinomyces*, associated with the various forms of *Actinomycosis* and *Madura Foot*; the *Microsporon furfur* (Eichstedt) causing *Pityriasis (Tinea) versicolor*; the *Microsporon minutissimum* (Burkhardt) causing *Erythrasma*; the parasite associated with the hair-affection called *Piedra*; the *Achorions* of *Favus (Tinea favosa)*; and lastly the fungi, varieties of *Microsporon* and *Trichophyton*, causing respectively the *Tinea tonsurans* with little spores (Gruby-Sabouraud) and *Tinea trichophytina*, both of which are popularly known as *Ringworms*.

The term *Tinea* (Fr. *teigne*) was formerly in vogue to denominate a great variety of affections of the scalp, but is now used as a generic term to denote the various disorders excited by the *Achorion*, the *Microsporon Audouini*, and the *Trichophyton-fungi*. *Pityriasis versicolor* is frequently included under this generic term, and *Erythrasma* should be so likewise.

GENERAL REMARKS ON THE RINGWORMS.—A few years after Bassi and Audouin had discovered the *Muscardine* disease of the silkworm, and so prompted Schönlein's investigations, by which he recognised the *Achorion-fungus*, Malmsten found a chain-fungus in ringworm, and Gruby differentiated the three types of infection which we recognise to-day. The importance of Gruby's researches from one cause and another was not appreciated, and until recent years all the ringworms were believed to be caused by one kind of fungus (called *Trichophyton tonsurans*). Differences in the size of the spores and construction of the mycelium were attributed to differences of soil, &c. Chiefly owing to the brilliant researches of Sabouraud the whole subject has been elucidated and placed on a firm basis. We now distinguish, by the objective features of the ringworm-lesions and by the microscopical examination of the scales and hairs, by the special features of cultures on artificial media, and by microscopical examination of these cultures, one group of ringworms associated with the growth of different species of *Microsporon*, and another due to species of *Trichophyton*.

As to the source of these fungi, some appear to be exclusively human parasites. Others are inoculated directly or indirectly from animals, as the horse, cattle, dog, cat, birds, hedgehog, &c.; all these are liable to set up considerable inflammation. We may find a particular species constantly associated with some species of animal, perhaps because the animal in its life is frequently exposed to this special contagion, and passes it to its fellows. These animal ringworms are, however, often intercommunicable. There is also considerable evidence to support the view that these fungi pursue a saprophytic existence, and evidence has been adduced in favour of the theory that they are but larval forms of superior fungi.

The ringworms are *highly contagious*, directly or indirectly. The exclusively human forms (*Micro-*

sporon Audouini and the common school *Trichophyton megalosporon endothrix*), which comprise the bulk of the cases met with in London, are inoculated from person to person (chiefly children) by simple contact, or through the medium of infected caps, brushes, towels, pillow-cases, clothes, or hairdressers' appliances. Hence, institutions in which children are collected are fertile centres of contagion. Particular forms of ringworm may occur in single cases, or be endemic or epidemic.

Their *geographical distribution* is interesting, for the common microsporon of this country and France gets less frequent in Spain and Belgium, and disappears in Italy and Eastern Europe. A trichophyton giving a peculiar red-violet culture is rare in London and Paris, but forms the prevalent type in Parma, and so on.

Little is known of the *qualities of soil* favourable to the growth of the fungi in the human skin. The fungi differ. Some like children, some adults. The microsporon and common endothrix trichophyton especially attack children, and those with finer fair hair are perhaps preferred to those with coarser dark hair. There is no evidence, however, that any particular constitutional state predisposes to attack or favours the growth. In warm countries many forms of ringworm flourish under conditions of heat and moisture. Generally speaking, it may be said that these fungi occur mostly in the poorer classes or communities, where they are favoured by personal habits, and greater facilities for inoculation and persistence.

SYMPTOMS.—The ringworm-fungi give rise to characteristic lesions in the epidermic structures invaded, and when one fungus only was recognised it was customary to discuss the symptoms regionally. It will be seen, however, that all fungi do not affect all sites.

Ringworm of glabrous regions (commonly called *Tinea circinata*, from the character of the lesions) may be caused by all these fungi, and the latter grow excentrically and regularly, and set up an inflammatory reaction, which varies widely with different fungi. In the majority of cases, enlarging red perfectly rounded macules or slightly infiltrated areas are produced, either scaly or bearing superficial vesicles or pustules, with or without special implication of the follicles. The rate of extension varies, but is usually rapid, and the areas have a marked tendency to clear up in the centres, owing either to the lessened activity of the fungus or the tolerance of the tissues, so that the spreading margin (scaly, vesicular, or pustular) stands out prominently, and rings are formed, whence the name *ringworm*. Rarely concentric rings are formed. The follicles and lanugo-hairs may be involved. The *Microsporon Audouini* causes small and ephemeral macules, but some trichophyta form lesions of great extent, and may be persistent. The variations in aspect are mostly due to the qualities of the parasite and its products, and are to a great extent constant for each species of fungus. There may only be a single lesion, or by auto-inoculation many may arise and become confluent to form gyrate patterns. They usually occupy exposed regions, but may be more or less generalised. One or two lesions call for special remark. Some fungi, especially some trichophyta of animal origin, whether they are inoculated on the uncovered parts of the glabrous skin or in hairy regions, such as the scalp and beard, set up an *agminate pustular folliculitis*, which is

known as the *Kerion of Celsus*. The lesion commences by a firm cedematous lesion, simulating a furuncle, but less painful, situated around a pilosebaceous follicle, within which suppuration occurs. Pretty rapidly surrounding follicles become similarly involved, and a perfectly round, red, granuloma-like projecting swelling is evolved, which may attain 7-8 centimetres in diameter. The follicles exude pus freely, and a crust forms. The diseased hairs are detached from the papillæ and fall out, thus effecting a spontaneous cure of the lesions.

Again, there is a special phase affecting the inguinal regions primarily (*T. inguinalis*), and from the secondary complications brought about by scratching, &c., it has been included with erythrasma and some forms of superficial dermatitis under the generic term *Eczema marginatum*. This ringworm is apparently due to a special trichophyton-fungus, which does not infect the hairs, and it is notable that almost all the adult members of a household may be attacked at the same time. The ringworm begins as a small red itching spot, spreads downwards on the thigh by a marginal border, scaly or vesicular, and may also advance over the genitals, perineum, buttocks, and pubes. A similar state of things may be found in the axilla.

It will be convenient to refer here to the subject of *tropical ringworm*. The trichophyta are exceedingly common and flourish actively in damp warm atmospheres. In India there is a marked incidence in the rainy season, and the eruptions die down after a time, to reappear again in the following year. No doubt a number of different fungi are concerned, and possibly each country has its special flora; but the subject has not yet been worked out by modern methods of investigation. Though hairy regions may be affected, ringworm of glabrous skin seems to be far more common, and has monopolised attention. It occurs nearly always in adult life, and may attack any region; but in India and elsewhere it commences very frequently and has its headquarters in the inguinal region of the male, like the *T. inguinalis* of Europe, but in the hotter climates it is apt to spread far more widely and rapidly, to cover wide areas with confluent-margined patches from the knee upwards over the body. Sweating and scratching cause a secondary eczematoid dermatitis, and the intense irritation may be most distressing and sleep-destroying. Chronic patches may get much thickened and pigmented, and on the hands and feet may be intractable and present great difficulties in diagnosis. See p. 1717.

Ringworm of the Scalp, or *T. capitis*, usually has special objective features, because the circular or circinate rounded areas with excentric spread due to the growth of the fungi in the surface-epithelium, and comparable to *Tinea circinata* of glabrous skin, are ephemeral, and give place to the destruction of the hair which dominates the picture. We shall have occasion to describe in detail this hair-infection, which in this country is due in almost all cases to one of two kinds of fungus, the *Microsporon Audouini* or the common *endothrix trichophyton*. They affect children particularly, and very rarely the adult, but other forms of trichophyton may infect the adult scalp, and Surgeon-major Garden wrote in 1876 that ringworm of the scalp was very common in the native army in India. Fungi of

animal origin may set up vesiculo-pustular (cat) or pustular infiltrated patches (cattle), and the *kerion*, which we have already described, is occasionally met with. Sabouraud thinks that kerion is invariably due to ectothrix fungi of animal origin, but English observers hold it may be associated with the microsporon, and the writer finds the usual kerion of children's scalps in London is due to an endothrix fungus.

Ringworm of the Beard (*T. barbae*, *T. sycosis*) is fairly common in England, and, as in the scalp, may commence by circinate lesions, though the hair-infection or the folliculitis produced are the striking features. As in the scalp, also, most varied appearances are brought about by different species of fungi. The most common picture is produced by multiple areas of agminated or conglomerate pustular folliculitis analogous to that described as kerion, and due to a horse-fungus. From the horse also comes a fungus which sets up a less degree of inflammation, but vesiculo-pustular and encrusted, sometimes simulating eczema or sycosis. Highly inflammatory lesions may be set up again by cattle-ringworm. In striking contrast there are phases in which the inflammatory symptoms are practically absent, so that we only see very short stumps studding the beard-area and the follicle-mouths surrounded by a little redness, or only scalliness. A bird-ringworm, with rose-coloured culture, has been isolated from these lesions, and another with a violet culture. The eyelids may be involved in rare cases.

Ringworm of the Nails (*T. unguium* or *Onychomycosis*) is invariably due, according to Sabouraud, to the various species of animal trichophyta. It is rare in this country and in Paris. The clinical characters are similar in all cases, viz. thickening, discolouration and friability of the nail. Exceptionally a single finger-nail is affected, more often several, irregularly and on both hands, rarely all the nails. The toe-nails may also suffer. See p. 1054.

MYCOLOGY.—*Cultures* of the fungi can be obtained on suitable media from the epidermic lesions, and the same type of malady be reproduced by inoculation of the cultures. In culture each family has its formal and proper biological characters, and by culture each fixed botanical species can be differentiated, for 'a given fungus upon a given medium of culture takes a form personal, specific and invariable' (Sabouraud). The technique for the isolation and pure cultivation of these fungi, the composition of the media, and the methods of inoculation in animals, require detailed study, and the reader is referred to special works for information. As to *mycology*, the ringworms belong to the *Mucedines* or *moulds*, and hence are filamentous fungi, reproducing themselves by external spores. Each filament is composed of cylindrical cells placed end to end, and the cells are composed of a cellulose envelope containing protoplasm. The filaments may be composed of long cells, giving the appearance of a tube partitioned at comparatively long intervals (*plain filaments*), or of short cells, and then oval, round or square, forming a chain-like or necklace-like filament (*sporulated filaments*). A filament may break up into its constituent cells, which are then called *spores*, but they are *internal* or *mycelial spores*, and are not a part of true fructificative organs. The filaments of both sorts are commonly called *mycelia*, and the whole is the vegetative part of the fungus, which may be reproduced by any of its segments. Under favourable

conditions of culture the filamentous meshwork or *thallus* sends down root-like filaments (the mycelium proper of mycologists) into the substance on which the fungus grows, and emits to the free air aerial filaments. The latter give off special branches (*hyphæ*) bearing true *external spores* or *conidia*, which constitute the true organs of fructification, and on which mycologists largely depend for purposes of classification. In the imperfectly aerated submerged portion of a culture, numerous metamorphoses of the filaments are found, some of which are regarded by some observers as various phases of reproductive organs, and of corresponding importance.

The study of these various changes in sections of the cultures is not satisfactory. The Continental method of examining the mycology of these ring-worm-fungi has been for the most part the 'hanging drop,' but by this method the aerial hyphæ tend to be imperfectly developed. Sabouraud by this method concluded that the microspora belong to an entirely different family from that of the trichophyta. Thus, in the latter, he describes the fructification as taking a bunch-of-grapes formation, while that of the microspora is on a different plan. Colcott Fox and Blaxall, by making *Klatsch* or impression-specimens of the aerial filaments from plate-cultures, demonstrated that both the microspora and trichophyta were closely related by these organs of fructification. In each group delicate hyphæ form, supporting external spores or conidia, and though these spore-bearing organs differ slightly in detail, the plan is similar in all.

For immediate *microscopical examination* a suspected *hair* should be carefully extracted, if possible entire. Should the root-sheath come away with the hair, the relations of the fungus are very completely shown. The hair, from which grease can be extracted by ether, should be immersed in a drop of Liquor Potassæ, B.P., on a glass slide, and care must be taken not to press down the cover-slip unduly or the relations of the fungus to the hair are disturbed. The clearing of the specimen should be watched. A low power will display the general aspect, and a magnifying power of about 800 diameters is desirable for a study of details. If it is desired to preserve the specimen, the potash can be washed out with a 15-per-cent. solution of spirit and water before staining. Sabouraud advocates potash-solutions up to 40-per-cent. strength. *Scales* can be examined in a similar manner, after dissociation with needles. *Pus* can be investigated immediately, after being spread out between two glasses. *Nails* require preliminary powdering with a sterilised nail-file. The fungus is conveniently *stained* on a slide by the following method. Stain in gentian-violet aniline-water and fix in Gram's iodine-solution; decolourise in aniline-oil, watching the process; dissolve out the aniline-oil with xylol and mount in Canada balsam in xylol. The microsporon-fungus stains well in a few minutes, and the epithelial tissue needs, therefore, less decolourisation; but the endothrix trichophyton requires a prolonged soaking, sometimes one hour, and a corresponding decolourisation of the hair, which may be advanced by mixing a drop of nitric acid with a few drops of aniline-oil, and afterwards soaking the acid out with pure aniline-oil.

A few words may be added on *the method of examining the scalp*. The patient should be placed in a good light, and with the blade of a pair of

epilating forceps the hair should be turned over in a direction against the lie of the hair. The elastic healthy hair flies back to its place, while the diseased stumps do not. The operator should use a magnifying glass, preferably a watchmaker's glass, as it leaves both hands free. In this way, with a little practice, the eye detects any signs of disorder in the scalp, such as scales, and the presence of any hair which departs from the normal in length, shape, or colour. Scales should be lifted, as they often hide very short or incurved stumps.

DIAGNOSIS.—From a clinical point of view, a lengthy section might be devoted to the diagnosis. In the first place, all round or circinate, scaly or congestive, or vesiculo-pustular eruptions must be considered, and these would include pityriasis alba, eczema seborrhoicum, erythema multiforme, psoriasis, lupus, syphilides, leprides, circinate impetigo contagiosa, &c. Further, we have to consider the more marked inflammatory phases, and alopecia, with its atrophied 'note of exclamation' stumps. In untreated cases the task is comparatively easy, but the difficulty arises when complications such as eczema mask the typical features, or when the areas of disease are broken up and defaced by treatment, or, lastly, towards the termination of a scalp-case, when only a few isolated stumps crop up. It is essential for a correct diagnosis that the observer should be thoroughly skilled in the detection of the fungus and the characteristically diseased *hairs*, for without this no amount of detailed description will avail.

Tinea due to Microspora (*Gruby-Sabouraud*).—This ringworm contributes something like 90 per cent. of the cases of ringworm of the scalp in London, and most cases are due to the fungus described by Gruby as *Microsporon Audouini*. A microsporon, however, has been cultivated from the horse, and another from the dog, which may be contracted by human beings. So also a ringworm derived from the cat (Fox and Blaxall) is not infrequent in the child, and is probably a microsporon. The so-called *Microsporon minutissimum* of Erythrasma and the *Microsporon furfur* of Pityriasis versicolor do not belong to this family.

The *Microsporon*-family is easily distinguished by the objective characters of the eruption and of the diseased hairs, by the morphological characters of the parasite in the lesions, and by the cultural peculiarities of the fungi.

The *Microsporon Audouini* is apparently exclusively human, and attacks the scalp-hair with avidity (*T. tonsurans*), the glabrous skin only slightly (*T. circinata*), *but never the beard or nails*. It is rarely contracted before three, and more rarely still after fourteen, years of age. Puberty seems to determine its extinction, but within these limits its duration is apt to be prolonged over years, during which period it remains highly contagious.

The characteristic of this ringworm is the predilection for the scalp and the formation there of considerable, more or less rounded, scaly areas, over which almost every hair becomes invaded by the fungus and thus rendered fragile, lustreless, decolourised, and broken off about 5-7 millimetres above the skin. Hence the qualifying term *tonsurans* applied to this and other ringworms in which the scalp-hairs are so diseased. These stumps may be straight, bent, or twisted by entanglement in the scales, and lie about in different directions. One can extract between the fingers a bunch of diseased

stumps which break off in the follicle, leaving a portion of the diseased hair. A further distinctive feature is a grey sheath on the stump extending upwards for about 3 millimetres from the mouth of the follicle. This adherent sheath is due to a mosaic of spores, and must not be confounded with an occasional sheath of epithelial scales. When the hair is cut in a typical case the pattern of one or more large parent-patches with numerous satellites in all stages of evolution is notable. Sometimes when the case comes under observation there may be only a single patch, or at other times by dissemination and confluence of patches the greater part of the scalp may be involved. The degree of inflammation set up is very slight, and the areas are only occasionally reddened and ringed. In the scalp the marked inflammatory effects, however, known as *kerion*, and lesser degrees, may on rare occasions be associated with this family of fungi, possibly due to members of animal origin. Lastly, the objective features may be masked on the one hand by the effects of scratching, weeping eczema, seborrhoea, and pus-inoculation from pediculosis, and, on the other hand, stumps may be worn down by rubbing, scales removed by treatment, and towards the end of a case only a few hairs or perhaps only a single diseased hair, and that a comparatively long one, may remain. It is, therefore, obvious that the medical man must be thoroughly versed in the detection of the diseased hairs.

On the *glabrous skin* reddened scaly rounded macules, sometimes ringed, are not infrequently seen about the face, neck, and shoulders at the outset, and in the course of neglected cases, but tend to die away spontaneously. M. Audouini does not care about the glabrous skin, but the species isolated from the cat by Fox and Blaxall cause striking multiple circinate lesions of the skin. Adults in intimate contact with the children may also contract a lesion, but the scalp is very rarely affected in them.

The *microscopical appearances* of the diseased hairs are also highly characteristic. On the surface of the bulb will be found columns, two or three deep, of spores extending upwards towards the shaft, and at the lower part of the latter they join a dense mosaic of spores, each 2-3 μ diameter and polyhedral from mutual pressure. This mosaic adheres to, and encases, the hair, and, as we have pointed out, extends beyond the intrafollicular portion of the shaft some 3-5 millimetres. Beyond that again to the free end a few collections of spores will be found dotted over the shaft. Careful focusing will convince the observer that these spores are outside the hair. Beneath this sheath, however, and in the hair, a certain amount of mycelium is found. It ends, except in some dead hairs, just above the bulb in clubbed feelers forming a well-marked fringe. It is more or less obscured higher up by the mosaic of spores, but characteristic little pieces with irregular branching are seen again towards the free end. The mycelial threads are generally plain, but occasionally more or less sporulated. It should be stated that Sabouraud describes the mycelium in the hair as giving off lateral branches, and these others, until very fine ones penetrate the cuticle of the hair and end by giving rise to a series of spores attached to one side of the branch (an organ of fructification). The writer controverts this view.

Tinea due to *Megalospora* (*Trichophyta*, *Trichophytosis*; Fr. *Trichophytie*).—The *trichophyton*-fungi form a family of which many different fixed species are already known. Some are rare, and as investigations proceed in other countries no doubt a considerable list will be formed. We already know that some are specially prevalent in particular countries or places. These trichophyta are arranged in two great groups. In one (*Endothrix*) the fungus attacking a hair becomes localised exclusively within such hair. In the other the fungus either remains outside the hair in its intrafollicular portion (*Ectothrix*), perhaps invading the epithelium of the follicle, or also enters the hair and is found both within and without (*Endo-ectothrix*). The writer doubts the existence of a pure ectothrix type. Some fungi, however, as in the case of the *Microsporon furfur*, do not appear to attack the hair at all, e.g. the one causing *T. inguinalis*. Only certain varieties attack the nails. When the hairs are infected they are rendered fragile and break off to form stumps, as in the microsporon-infection.

The mycelium of the trichophyta can be easily distinguished from that of the microspora, in that it is for the most part sporulated and forms characteristic beaded filaments, and almost exclusively so in the hair and nail. Then again, the diameter, and consequently the size, of the 'spores' is invariably larger (4-5 μ to 8-9 μ), and the qualification *megalosporon* applies with few exceptions. In some endo-ectothrix species a marked variation in the size of the spores is noticed.

The trichophytic lesions appear under two aspects—one practically without inflammatory reaction, so that in the regions of the scalp and beard the hair-lesions are the prominent feature; the other characterised habitually by more or less marked inflammation, which is focussed about the follicles and makes the hair-infection a secondary feature. An endothrix trichophyton, which with the *Microsporon Audouini* causes the bulk of the ringworm in children, is, like the latter, exclusively human. The rest are probably of animal origin, and among them are those causing the marked inflammatory reaction and pustular folliculitis.

***Endothrix Trichophytosis*.**—Special attention must be directed to the common *large-spored Endothrix trichophyton* of childhood, giving yellow crateriform cultures on Sabouraud's proof-medium. This fungus, which appears to be exclusively human, attacks the scalp and glabrous skin of exposed regions, but never the beard and nails (Sabouraud). It is almost as common in the elementary schools of Paris as the *Microsporon Audouini*, but among hospital out-patients in western London it forms only about 2 or 3 per cent. of the scalp-cases. In certain institutions, however, it is very common. It attacks children especially, but may survive puberty to perhaps twenty years of age. The glabrous skin of the adult may be occasionally involved, but not the scalp (Sabouraud).

The clinical picture is characteristic. More frequently than microsporon, this fungus causes multiple lesions of the *glabrous skin* (face, neck, and hands), and they are apt to be larger, but still small and ephemeral, more often circinate, and longer-lived. They begin as lenticular, prominent, rosy patches, punctate owing to more active congestion about the glandular orifices. They extend to form circular areas with raised red borders, finely scaly or faintly vesicular, while the centres fade with

some scaling. Let it be noted that the occurrence of such lesions where children are congregated always calls for a careful examination of the heads.

In the *scalp* the initial symptom is a rosy circinate lesion of rapid extension and short existence, so that it usually escapes observation. The fungus enters the follicles and then the hairs, but, contrary to the microsporon, it selects some hairs only. If an infected scalp be carefully and systematically examined, a number of little scaly areas will be found disseminated over the surface, each bearing a single stump or groups of two to ten darkened swollen stumps interspersed among healthy hairs. These stumps are so fragile that they tend to break off close to, or within, the mouth of the follicle ('black-dot ringworm'), and the desquamation present often hides the growing stump and causes it to become incurved or twisted in a spiral. Nevertheless, straight stumps, quite as long as those seen in microsporon, may be met with, and also light-coloured ones in fair-haired children. There are, therefore, no large *initial* patches, over which almost every hair is broken off, as in microsporon-infection. However, the small areas tend to enlarge and gradually to infect more and more hairs, so that in long-standing or severe cases the greater part of the scalp may be covered with large confluent areas.

Microscopical examination of scales discloses mycelial threads dividing dichotomously, some plain and others sporulated, the latter composed of equal-sized, rounded, or oblong segments, flattened at the junction with the next cell. *Hairs* in the early stages of infection show sporulated mycelium winding over the intrafollicular portion of the shaft and entering the hair beneath the cuticle. In the fully-infected hair all this outside fungus disappears, as may be ascertained with certainty when the root-sheath remains attached, and the shaft is found packed with monomorphic rectilinear sporulated filaments (4-6 μ broad). They terminate in a fringe above the bulb. The cuticle remains intact for a long time, and the chains do not break up readily. Thus the size of the cells, the chain-formation, and the exclusive location in the hair, except in the early stages, and the absence of a mosaic sheath clearly differentiate the picture from that of microsporon.

Sabouraud says that *other endothrix trichophyta* are met with exceptionally, and are only differentiated by culture, though there may be certain clinical differences, such as the formation of an initial large patch. In London there is a well-marked form of *kerion* of the child's scalp due to an endothrix trichophyton of uncertain origin, and the same or another may set up a vesiculo-pustular ringworm of glabrous regions.

Ectothrix and Endo-ectothrix Trichophyta.—These fungi are of animal origin, and those more commonly met with in this country set up marked inflammatory reaction about the follicles, culminating in the agminated pustular folliculitis which we have described as *kerion*. Thus there is an important group giving characteristic white cultures on Sabouraud's proof-medium. One isolated from the cat sets up vesiculo-pustular circinate lesions in man. A horse-specimen is not at all infrequent, especially in the beard, and causes raised inflammatory patches of agminated suppurating perifolliculitis. A third from the calf is a frequent cause of angry pustular ringworm of the hands, forearms, face, and neck in some country districts. Belonging to a second

category is another horse-fungus, setting up a lesser degree of inflammation, which may simulate crusted eczema. To a third group belongs a fungus contracted from birds, which sets up a very slight degree of dry inflammation. And, fourthly, a fungus of unknown origin simply affects the hair without causing any notable reaction. Lastly, we may mention a ringworm almost indistinguishable from the common endothrix, except that a large parent-patch is formed on the scalp, surrounded by satellites, each studded with swollen black stumps broken off in the follicles. Sabouraud indeed formerly described this as an endothrix fungus, and called the ringworm *peladoid*, from a certain simulation of Alopecia areata.

Microscopical examination discloses the sporulated filaments characteristic of the trichophyta. The constant presence of the fungus outside the hair in the follicle or in its wall will distinguish it from the endothrix group, and confusion can only arise with an endothrix-infection in its early stage before the fungus has died away from the follicle. The size of the fungus-elements and the almost exclusive presence of sporulated threads will facilitate the distinction from microsporon. Error can only arise from the dense massing of the filaments around the hair, so that the chain-formation is obscured. This sheath is not in mosaic. In rare cases, too, the fungus is comparatively small, and not strikingly larger than microsporon. The fungus has an intra-follicular location, and the sheath around the hair does not extend well beyond the follicle.

TREATMENT.—There is no method of dieting or internal medication known which will so alter the soil as perceptibly to retard or prevent the growth of the fungi, or directly kill the parasite. Obviously, however, it will be proper to correct any departure from the standard of health presented by the patient.

The spread of these diseases would be greatly curbed if all children were systematically inspected before admission to schools or other institutions, and at stated intervals afterwards. So also hair-dressers and barbers should take special precautions to prevent contamination.

Every child found to be suffering from ringworm should be isolated, as far as possible, from other children, and separate toilet-requisites should be provided and kept disinfected. The source of contagion should also be traced if possible.

The principles only which should govern the *local treatment* can be discussed here, as it would be impossible to give in detail all the remedies and methods so strongly recommended from time to time. We know that the fungi can be destroyed by many agents, for instance a culture is readily killed by formalin-vapour. The difficulty in effecting our purpose is almost entirely the problem of making the parasiticide penetrate to the fungus.

Ringworm of the glabrous skin can as a rule be readily exterminated, because the fungus grows in the superficial layers, and we can remove these by causing exfoliation, so that our remedies easily reach the parasite. Thus repeated painting with tincture of iodine is very successful, and any one of the numerous parasitocides can be applied in the form of lotions, liniments, pigments or ointments, care being taken to regulate the strength so that unnecessary pain or inflammatory reaction is avoided. Invertebrate areas of ringworm, as in chronic T. inguinalis, sometimes require a combination of remedies which

are resolvent and parasiticide, and cause desquamation. Goa powder in ointment, or moistened with citric acid or lemon-juice, is a favourite application for tropical ringworm.

Ringworm of the scalp is the phase which causes most trouble. The following general directions may be given: (1) Where the disease is limited to a single patch or two or three areas the hair should be kept cut well round these places. If, however, more patches exist—and careful search should be made—it is advisable to keep the hair over the whole scalp cut or clipped very short, leaving perhaps a bordering fringe for the sake of appearance, or even to shave, with antiseptic precautions, at intervals. The latter proceeding removes all disease above ground, so to speak, but the diseased areas must be previously noted or marked. Epilation of the zone of healthy hairs around the patches seems unnecessary. (2) The head should be thoroughly washed at the outset with soft soap, or some medicated soap, and all scales and crusts removed. Subsequent washings are useful occasionally to cleanse out plugs from the follicles. (3) Fresh auto-inoculations should be prevented by rubbing over the whole scalp daily some parasiticide application, such as weak formalin-ointment or a glycerine of carbolic acid. (4) A light head-covering should be worn night and morning, and lined with waxed paper to prevent soiling of the cap, pillows, &c. (5) The diseased areas can then be specially attacked. Various principles have been tried, such as the exclusion of oxygen, the application of parasiticides, and the removal of diseased hairs (*a*) by causing them to atrophy, (*b*) by withdrawing them (*epilation*), (*c*) by causing their fall by setting up perifolliculitis.

With regard to *atrophy of the hairs*, this happily occurs now and again accidentally, so to speak, but cannot be produced at will. It has most commonly followed a treatment by a thorough daily washing with soap and water and the mopping in of Cayley's boracic-acid lotion ($\frac{1}{2}$ Acid. Borici, $\frac{3}{4}$ vel q.s.; Etheris Methylati, $\frac{3}{4}$ x; Olei Rosmarini, $\frac{1}{2}$ j; Spiritum Methylatum, ad $\frac{3}{4}$ xl, eight times a day (Aldersmith); or the evil-smelling parasiticide gas-water sulphide of ammonium (in an excess of ammonia) dabbed on three or four times daily.

There is an endless number of parasiticide applications to select from, such as the perchloride, biniodide, oleate, nitrate, and oxides of mercury; the acetate, sulphate, and oleate of copper; silver nitrate; sulphur, sulphurous acid, hyposulphite of sodium, and iodide of sulphur; iodine-preparations; carbolic, salicylic, and acetic acids; chrysarobin, resorcin, β -naphthol, creosote, thymol and menthol, tar-preparations, formalin, &c. These can be used in various combinations and alternations, in the form of lotions, liniments, pigments, ointments, pastes, or plasters.

The selection of a parasiticide and its mode of application must depend on the age and sensitiveness of the child, the degree and character of inflammatory reaction produced, and the extent of diseased area. Thus equal parts of Ung. Sulphuris and Ung. Acid. Salicylici can be rubbed in freely for prolonged periods over extensive areas. Ung. Chrysarobin, however, will require care, and will often need weakening. A favourite ointment is one composed of an ounce of phenol, of olive oil, and of white wax respectively, two ounces of citrine ointment, and half an ounce of sublimed sulphur.

A pigment much used consists of equal parts of tincture and strong solution of iodine applied after the area has been cleansed and soaked with turpentine. When the coating gets too thick it can be removed with vaseline. A very important principle has now to be considered. We must carefully distinguish between the purely parasiticide and the inflammatory effects produced by applications. If we consider that the diseased hairs fit closely into the follicles, are infiltrated with fungus, and embedded to a considerable depth, we need not be surprised to find that there is an almost insuperable barrier to the penetration of the parasiticide into the whole extent of the hair. Consequently experience teaches us that, in contrast to what we see with ringworm of glabrous regions, it is almost impossible to cure ringworm of the scalp with purely parasiticide remedies; at any rate the treatment is very prolonged. Attempts have been made to surmount this difficulty by using media which are supposed to penetrate, such as glycerine, turpentine, ether, chloroform, acetone, benzol, &c., but avail us little. On the other hand the majority of parasiticides are irritants, and it is the constant irritation set up about the follicles which cures ringworm by causing the fall of the diseased hairs. Setting up mere desquamation or superficial serous catarrh is useless, and the latter to be avoided entirely. The ideal effect is to excite a deep-seated folliculitis. Unfortunately, scalps react so differently that we cannot easily command the effect we aim at. Thus with a saturated solution of Hepar Sulphuris in spirit very extensive cases may sometimes be rapidly cured by setting up folliculitis, but the remedy mostly fails. When we have to deal with a single patch—and extensive areas may be treated piecemeal—it is often convenient to set up considerable inflammation by parasiticide pigments, such as Coster's paste, composed of Iodine, $\frac{3}{4}$ j in $\frac{3}{4}$ vj of Rectified Oil of Tar, or Biniodide-of-Mercury pigment (Hydrarg. iodi rubri, gr. iv ad gr. vij, Sodii Iodid. $\frac{7}{8}$ ss, Sp. Chlorof. $\frac{3}{4}$ j ad $\frac{3}{4}$ iv, Aquam ad $\frac{3}{4}$ j). Or one of the following ointments may be used, viz. Ung. Cupri Oleatis ($\frac{3}{4}$ –iv to $\frac{3}{4}$ of base) or Ung. Hydrarg. Oleatis (Hydrarg. Oleatis, $\frac{3}{4}$ ss ad $\frac{3}{4}$ ss; Lanolin. Anhyd. $\frac{3}{4}$ ss ad $\frac{3}{4}$ j; Acidum Oleicum ad $\frac{3}{4}$ j) (Aldersmith). In this connection we will discuss the important principle of *epilation*. If the entire hair with its bulb, and preferably with its root-sheath, can be drawn out with forceps we have at hand a radical method of curing a patch. Every follicle so emptied is cured. Unfortunately we can, as a rule, only achieve our object when the hair-papilla is invaded by inflammatory exudation, and the attachment of the hair is weakened or completely severed. If the hairs break, epilation is a waste of time, but in the course of any case of scalp-ringworm it is well to try from time to time if the hairs can be drawn. When we excite deep-seated inflammation by the applications just mentioned, we greatly expedite the cure if the dried crust is carefully removed and the hairs epilated before renewing the application.

This brings us to a further development of this method. It is well known that ringworm-patches characterised by pustular folliculitis and the agminate lesions of it, known as kerion, heal spontaneously. The diseased hairs fall, and with the casting out of the fungus the source of inflammation is gone. Aldersmith, many years ago, elaborated a method

of exciting pustular folliculitis and kerion by the painless use of croton oil; and the writer has long been a keen upholder of the value of this method. Isolated patches, not bigger than half-a-crown, are painted with croton oil, and the area is continuously poulticed with linseed meal, which should be fixed on the part by elastic bands, and not allowed to shift. From time to time further applications of croton oil may be made, until a raised boggy area is formed, and then all the diseased hairs fall out or can be epilated entire. It is essential to prevent any accumulation of pus, and this should be bathed away as fast as it forms. The experienced hand never produces scars. In many cases the writer finds that the rubbing in of an ointment containing one drachm of croton oil to the ounce of parasiticide ointment does equally well, and is less risky in inexperienced hands. Fingernail-sized areas can be painted with the croton oil. Where single stumps are disseminated over the scalp, these can be removed by dipping a darning-needle in croton oil and needling the follicle.

In conclusion, it may be said that experience teaches that the expeditious cure of ringworm demands detailed attention on the part of the practitioner or some intelligent attendant whom he has instructed. Merely writing prescriptions and giving general directions end most unsatisfactorily to all concerned.

A cure can only be pronounced after new hair has grown, and repeated examinations have failed to disclose any isolated diseased hairs. The latter, though breaking easily, may sometimes escape recognition, as they tend to grow long and may cling to a healthy hair. Cases prematurely certified as cured are a frequent source of unpleasantness to all concerned.

Ringworm of the beard demands different treatment in different cases. Kerion, as elsewhere, soon subsides if boric-acid fomentations are applied and the surrounding skin is protected from auto-inoculations. The less inflamed lesions may require a strong ointment. The rarer cases without any inflammation are very obstinate, and the hairs need individual treatment by needling.

Ringworm of the nails is extremely tenacious, and may persist for many years. Dubreuilh says that the aspect of the nail is not a true guide to the extent of infection, for the fungus usually completely invades the nail. Treatment, to be efficacious, must attack the fungus by penetrating down to the matrix and well behind the subungual fold. Penetration of the parasiticides through the nail is practically impossible. The nails may be removed under chloroform, and a parasiticide applied, but even then it is essential to kill thoroughly any trace of fungus left under the subungual fold. C. Pellizzari and Dubreuilh advocate the plan of setting up a suppurative inflammation of the nail-bed, and so causing the fall of the nail. For this purpose an application composed of equal parts of pyrogallol acid and olive oil is made twice daily all round the nail. An indiarubber finger-stall increases the reaction. The operator must direct this treatment daily himself. Short of such strong measures there is nothing for it but to soften the nail by constant soaking in as strong a potash-solution as can be borne, and gradually file or scrape or cut away all the horny portion of the nail. When the quick is reached parasiticides can be applied. Radcliffe Crocker recommends the treatment advocated by

Harrison, of Bristol, for ringworm. Between the scrapings he applies a solution of Liquor Potassæ and Aqua Distillata $\bar{a}\bar{a}$ \bar{z} ss., Potass. Iodid. \bar{z} ss., oiled silk for fifteen minutes; this is immediately followed by a solution of Hydrarg. Perchlor. gr. iv, Sp. Vini Rectif. Aq. Dest. $\bar{a}\bar{a}$ \bar{z} ss. similarly applied for twenty-four hours. T. COLCOTT FOX.

TINEA FAVOSA.—SYNON.: *Favus* (Lat., the cells of honeycomb); *Dermato-mycosis achorina*; Fr. *Teigne favéuse*; Ger. *Erbgrind*.

DEFINITION.—A contagious affection of the skin of man and some animals caused by the growth of a fungus, the *Achorion Schönleinii* ($\acute{\alpha}\text{-}\chi\omega\rho\iota\omicron\nu$, from the difficulty in detecting the double-contoured cellulose wall).

SYMPTOMS.—Favus may attack the epidermic structures of hairy regions, glabrous parts, and nails, but the scalp is the most important, as it is the most frequent site affected, and on account of the intractability and destructive effects of the disease in this region. On the scalp the fungus may first extend in the epithelium, and occasion a circinate inflammatory eruption of mild intensity, but usually it rapidly finds its way into the hair-follicle and enters the epidermic wall and the hair. It develops with special luxuriance around the infundibulum, and soon occasions a little whitish elevation. In some weeks the latter enlarges to form a pathognomonic, sulphur-yellow, intra-epidermic, superficial, dry, umbilicated or cupuliform disc, which has been compared to a lupine-seed (the *godet favique*, *scutulum*, *favus*); lying in a red, moist, cup-like bed, fashioned by the pressure of the growth; and having a hair in the centre. Such a disc may remain isolated and on occasion attain a diameter of half an inch or more. The disease is, however, extensive, and other discs tend to form, but may remain disseminated, or become confluent into honeycomb-like masses. As these lesions enlarge and age, the overlying epithelium ruptures, their consistence becomes more friable, the yellow colour fades, the characteristic aspect is lost, and a mortar-like crust results. As they crumble and fall succeeding formations are less perfect, the growth of hair becomes less vigorous, and atrophic baldness results from pressure. The picture, however, is often marred and complicated by the effects of scratching and pustulation, perhaps from pediculi, and the production of ulceration and scars. It is remarkable that in the most extensive cases a fringe of hair is left around the head. A peculiar mousy smell is also noticeable, which must not be confounded with the stale scent of old dried-up pus.

From the follicle the fungus invades the *hair*, which gets lustreless and decolourised from the introduction of air, but does not become so disintegrated and broken off as in ringworm. When extracted, the hair usually comes away with its root-sheath. Such diseased hair may be found apart from *godets*.

It is now recognised that the formation of *favi* is not invariable. Three atypical forms of scalp-favus are especially distinguished (Dubreuilh, Sabouraud) in which *godets* and obviously infected hairs are absent. In an *impetiginiform* variety yellow impetigo-like crusts lead to a cicatrix and form around the latter. In a *pityriasis* variety irregular, defined, scaly patches of rapid extension are the feature. In a third *alopecic* variety, very difficult to diagnose, a quiet chronic follicular irritation causes the fall of the hairs and gives rise to a delicate cicatrix.

Glabrous regions may be attacked primarily, but generally follow the scalp-infection, and extensive areas may be involved. Here, too, favi form, surrounded by inflammatory halos, or are preceded by a circinate ringworm-like eruption (erythematous or vesico-pustular). One or several *nails* of the hands, or even of the feet, may be involved without favus elsewhere. The favi may form beneath, and gradually erode the nail, but usually there is a dystrophy indistinguishable from that of ringworm.

Kundrat has recorded a case in which the *mucous membrane* of the oesophagus and stomach was involved.

When the infected hair is soaked in Liq. Potassæ (7–20 per cent.) the fungus is found *microscopically* under two mycelial forms, and it is remarkable that in a given case all the hairs are infected by one type to the exclusion of the other (Sabouraud). In the one case the hair is nearly filled with parallel, non-flexuous tubes, from 2 to 3μ wide and partitioned at lengths of 12–15 μ , running in the direction of the long axis of the hair, dividing dichotomously, and staining with difficulty. In more frequent cases the mycelial tubes are comparatively scanty, very multi-form in each hair, and consist of flexuous filaments of all sizes, sporulated (mycelial endospores in chain-formation) or not, dividing by tri- and tetra-comy (*tarses faviques*), and as regards their protoplasm easily stained. The polymorphism of the filaments and of the segments when dissociated is a distinguishing feature of the fungus in all situations.

The *godet* consists of mycelial threads, like one another, packed side by side, with some granular débris, and is best displayed in a stained section, or the elements may be pressed out in 40-per-cent. potash-solution. The fungus ramifies in the epidermic wall of the follicle, and on a level with the infundibulum multiplies in the epidermis with great luxuriance to form a mass like the head of a daisy. The threads become more and more sporulated as they approach the surface.

For the complicated subject of the *culture* and *mycology* of the Achorian-fungus the reader is referred to Sabouraud ('La Pratique Dermatologique,' t. 1, 1900), and to Sabrazès ('Sur le Favus de l'Homme, de la Poule, et du Chien,' 1893). The conclusion reached by the former is that at present we are not in a position accurately to define the favus-fungus either clinically, culturally, or mycologically.

ÆTIOLOGY.—Favus may be met with at all ages, and a case has been known to last throughout life to eighty-four years of age. It rarely commences after twenty, and nearly always arises in children and in those living amid sordid surroundings. Cases in human beings are seen more frequently in the great centres of Scotland and Ireland than in England, where it is rare. In New York foreign immigrants contribute the greater proportion of cases.

Affected mice and fowls, however, are not rare in England. Favus is more common in France and especially in Holland, in Italy, among the male Jewish population of Russia, Poland, Galicia, and the Levant, and in the Mohammedans of Turkey, Asia Minor, Syria, Persia, Egypt, Algiers, and Morocco; also in parts of India, China, and Brazil.

Contagion occurs usually from child to child, and is exceptional from animals, though many cases are on record, and its possibility has been proved by

experiment with the fungus from the mouse and the dog (Sabrazès). The difficult study of the plurality of favus-fungi has given conflicting results. Some observers contend for the plurality in man, though corresponding clinical types are not identical. Sabrazès, after laborious work, has, however, isolated only one fungus in 'spontaneous human favus,' and this can reproduce *godets* in series in woman and in the mouse (an animal peculiarly susceptible to favus from all sources), and superficial ones in the rabbit and fowl. It determines a mycotic pseudo-tuberculosis when injected into the peritoneum of a guinea-pig. He finds also that a favus in the dog (*Oospora canina*, Cost-Sabrazès) is inoculable on the human being, and gives rise to a favic pseudo-tuberculosis when injected into the auricular veins of a rabbit. There is also a favus common in fowls. Their saprophytic existence is hypothetical, but the fungus can remain in a state of latent life for long periods. Sabouraud, without denying the plurality, has only found one species in over eighty cultivated cases. He is not quite convinced of the distinct favus of the dog and fowl.

DIAGNOSIS.—In the scalp in the absence of the pathognomonic favi the diagnosis may be difficult and only assured after repeated microscopical examination. Mortar-like crusts, lustreless decolourised hairs, a mousy odour, and irregular alopecic areas should always attract attention. Favus, however, may appear under such manifold guises and with so many complications that the possibility of this infection should be kept in mind in all chronic scaly, impetiginous, crusted, or scarring conditions of the scalp. The fungus itself, when found, is generally sufficiently characteristic for identification, but sometimes, as in the nails, cultivation can alone decide. See p. 1054.

TREATMENT.—Favus of the scalp and nails is a persistent and rebellious affection, and the problem presented is similar to that of ringworm of the same regions. Luckily the diseased hair is so little disintegrated that it can be extracted entire with its vitreous sheath, and the most experienced practitioners hold that epilation is the only effective means of cure. This operation must be systematically carried out. For the rest all crusts must be removed by boracic-starch poultices, or boracic acid fomentations, or soaking in carbolic oil, or curetting. All eczematous inflammation, excoriations, and ulcerations should be healed, but a degree of more deeply-seated inflammation or folliculitis may be encouraged as causing shedding of the hair. In addition to the epilation, the scalp should be treated with antiseptics and parasitocides as in ringworm. The treatment of the nails is also similar to that for ringworm of these parts. See pp. 1716 and 1054.

T. COLCOTT FOX.

TINEA IMBRICATA. — SYNON.: Solomon Island or Tokelau Ringworm; *Herpes Desquamans* (Turner).

DEFINITION.—An epiphytic skin-disease, produced by a fungus resembling the trichophyton, and characterised by concentric rings of imbricated scaly desquamation.

GEOGRAPHICAL DISTRIBUTION.—As far as is known, this disease is at present confined to the islands and countries included in the area within 140° W. and 95° E. longitude, and the north and south tropics; but, as it spreads with great rapidity

when introduced into districts with a favourable climate, it is not improbable that, as communication extends, it will in time become endemic in all tropical countries possessing a damp atmosphere and a temperature ranging between 70° and 90° F. In certain places within the endemic area it is exceedingly prevalent; in the Florida Islands, for example, where one-half, and the Treasury Islands, where four-fifths, of the inhabitants are affected (Guppy). Throughout the Malay country it is common, and cases have frequently been noted on the Chinese seaboard as far north as Foochow. It attacks foreigners as well as natives.

SYMPTOMS.—Usually the disease occupies a wide area of skin. In old-standing cases the entire integument, with the exception, perhaps, of the palms of the hands and the soles of the feet, the axillæ, crutch, and part of the hairy scalp, is covered with the characteristic thin, tissue-paper-like scales arranged in concentric parallel lines. These scales vary in size, according to their situation and the amount of friction they have been subjected to, from one-sixteenth to half an inch in breadth, by a quarter of an inch to one inch or more in length. They are firmly attached to and continuous with the healthy epidermis at the periphery or advancing edge of the circle they belong to, and free and ragged at the other edge. At and just beyond the line of their attachment, the skin is darkened from aggregation of the fungus, which, in its advance, is raising and throwing off the epidermis. The parallel lines of scales may be from an eighth to half an inch apart.

The pattern, so to speak, of the disease is readily understood from an inoculation-experiment. By rubbing scales from a case into abraded healthy skin the fungus is easily implanted. In about ten days thereafter it has so multiplied that it forms a brown layer underneath the epidermis. As this layer extends, the epidermis over its centre breaks down, and a scaly ring is formed. Gradually the ring so formed enlarges, and a second brown spot forms in the centre. This, in its turn, extends, its centre also breaking down. Then a third ring forms in the same way, and a fourth, and so on in never-ending series—like the waves made by a stone thrown into a pond.

Where two or more systems of rings impinge, a gyrated or scalloped pattern is produced.

Itching is sometimes complained of, but there is rarely any sign of inflammation of the skin, as in common ringworm.

The fungus is readily demonstrated by placing a scale moistened with liquor potassæ under the microscope. It closely resembles the trichophyton, but may be distinguished from it by its prodigious profusion, its position just under the epidermis, and, perhaps, by the presence in the interior of the conidia and mycelium of many brown particles. Unlike trichophyton, it has no special predilection for the hair or hair-follicles; in fact, it seems to thrive best on the non-hairy parts of the body.

Tribondeau describes the fungus as not a trichophyton, but as allied to aspergillus, and calls it lepidophyton; he states, however, that its full development is rarely seen in the body. He made unsuccessful attempts, using many media, to cultivate it outside the body.

DIAGNOSIS.—*Tinea imbricata* is distinguishable from ordinary ringworm by the size of the scales,

by the numerous, closely approximated, concentric parallel rings, by the absence of inflammatory redness, and by the extreme profusion of the fungus. From psoriasis and ichthyosis it is diagnosed by the presence of the fungus, the concentric rings, and by the attachment of the scales being at one edge only.

TREATMENT.—Painting the affected parts—taking a limb or part of the body at a time—with iodine-liniment is at once effective. All clothes must be boiled or destroyed, and relapses at once treated. In the labour-ships of the South Pacific, inunction of sulphur-ointment is the treatment adopted, and with success. Dr. Tribondeau finds treatment by chrysophanic acid to answer best.

PATRICK MANSON.

TINEA VERSICOLOR.—**SYNON.** : *Pityriasis versicolor*; *Chromophytosis*.

DEFINITION.—A chronic affection of the epidermis due to the presence of a fungus, the *Microsporon furfur* (Eichstedt) in the cuticle, characterised by a slight dissociation of the superficial scales and the formation of excentrically spreading macules, generally of a peculiar fawn colour.

DESCRIPTION.—*Tinea versicolor* mostly affects the covered parts of the body, and notably the trunk, whence it may extend to the groins, and rarely to the lower and upper extremities, and very rarely to the face. The colour of the lesions is most characteristic. It differs with the degree of pigmentation of the skin. In the fair skin it is a light fawn, in more pigmented Europeans it may be darker, and rare cases are on record in which the colour is a deep dirty brown. In coloured races the patches are grey. The presence of the fungus excites but little reaction, only some dissociation of scales, which becomes apparent on scraping a diseased area. Sometimes, however, especially if the body be unduly heated, the patches may appear more or less reddened. The eruption begins as punctate lesions about the follicles, and macules are formed by excentric spread. These coalesce and form extensive sheets, and a symmetrical distribution is effected. The macules are very rarely discoid or ringed. The hairs and nails are never affected. Itching is not very pronounced as a rule.

ÆTIOLOGY.—*Tinea versicolor* is due to the presence of a characteristic fungus, which loves warmth and moisture, and some other conditions of soil which are not yet well understood.

It is of more frequent occurrence in warm countries, and in Great Britain appears most often in those who clothe themselves warmly in flannel or wool. Hence it is particularly frequent in delicate people, such as phthisics. Its growth is fostered also in those who wear warm clothing by day and night, sweat freely, and do not wash their body thoroughly. The affection is very rare in childhood. It is only slightly contagious, but may affect husband and wife occasionally, or several members of a family.

Description of Fungus.—The fungus is very characteristic, and easily recognised under the microscope by soaking a scale in liquor potassæ. It consists of irregular clusters of mycelial spores (20–50) like fish-roe, each spore being 5–7 μ diameter, double-contoured, with a highly refractile nucleus, and often showing signs of budding. Proceeding from these clusters are short curved mycelial threads partitioned into long segments. The fungus

presents great difficulty in cultivation, and its mycology awaits study.

DIAGNOSIS.—Experience teaches that *Tinea versicolor* is most commonly confounded with the macular syphilide, though the colours are usually so distinct. The other trouble is the discoid and circinate eczema seborrhoicum (*Lichen annulatus* of Wilson) of the chest and back, which leaves dirty stains. *Pityriasis rosea* can hardly be confounded. Pigmentations such as 'liver spots' might also be mistaken. The microscope will readily decide in any doubtful case.

TREATMENT.—Parasitocides readily penetrate the superficial layers of the cuticle and kill the fungus, and desquamation removes the fungus mechanically. Repeated scrubbings with soap and water are therefore useful as a preliminary and accessory treatment. Besnier recommends the thorough application of the following ointment: Resorcin, Acid. Salicylici, āā gr. xv–xlv; Sulph. Precip. ʒss; Lanolin, Vaseline et Adipis, āā ʒvj. A more cleanly remedy is, however, often used, such as vinegar, followed by a lotion of hyposulphite of sodium (saturated solution), or that recommended by McCall Anderson (*Hydrarg. Bichloridi*, gr. xx, *Saponis Viridis*, ʒij, *Spiritus Rectificati*, ʒij; *Ol. Lavandulæ*, mxx). The vests should be boiled or disinfected with formalin. It is very important to keep up the treatment for some time, so as thoroughly to eradicate the fungus, or the eruption spreads again.

T. COLCOTT FOX.

TINKLING, METALLIC.—A sound of a peculiar quality, which the name sufficiently defines, occasionally heard on auscultation in connection with cavities in the lungs, or when air and fluid are present in the pleura. See PHYSICAL EXAMINATION.

TINNITUS (Lat.).—SYNON.: Fr. *Bourdonnement d'Oreilles*; Ger. *Summen*; *Klingen*.—Tinnitus, a term which is commonly used when speaking of noises in the ears, is a frequent symptom in many diseases of the external, middle, and inner ear. It is usually present in all those conditions where there is undue pressure on the labyrinth; for instance, when there is pressure on the tympanic membrane from cerumen, imperfect entrance of air into the tympanum, due to obstruction of the Eustachian tubes, or effusion within the tympanic cavity. It accompanies most inflammatory diseases of the external or middle ear; follows injuries to the tympanic membrane, and blows on the head or ear; may occur in aneurysm at the base of the skull; and is a prominent symptom in all nervous affections of the auditory apparatus, as well as in many states of disordered hearing where the ear is healthy. So infinite are the degrees and variations in this symptom, that there is probably no known sound to which it has not been compared by patients. When tinnitus is due to some curable local cause, the symptom rapidly disappears with its removal. When, however, it accompanies the deafness in nervous affections, it is often the more troublesome symptom of the two, and the less amenable to treatment. Strychnine is the most useful tonic in ear-affections, and quinine the least suitable, as this drug exercises a distinctly injurious effect, if taken in large doses. See EAR, Diseases of; HEARING, Disorders of; and VERTIGO.

W. B. DALBY.

TISANE (*ptisana*, peeled barley).—SYNON.: *Ptisan*.—A generic term applied, especially in France, to weak decoctions or infusions of barley and other farinaceous substances, whether used for domestic or medicinal purposes.

TITUBATION (*titubo*, I stagger).—A term for staggering or stumbling gait. See CEREBELLUM, Diseases of; and VERTIGO.

TOBACCO, Poisoning by.—SYNON.: Fr. *Empoisonnement par le Tabac*; Ger. *Tabakvergiftung*.—The minor effects of tobacco-poisoning—nausea, depression, vomiting, vertigo—are well known to the incipient smoker. Fatal poisoning by tobacco rarely occurs, except through its ignorant administration by mouth or rectum for the purpose of drugging. Cases of nicotine-poisoning are rare, though this, the volatile active alkaloid of tobacco, is now readily procurable for the purpose of fumigating plants.

ANATOMICAL CHARACTERS.—After death from tobacco-poisoning the organs and tissues have a tobacco-like odour, and the odour of nicotine becomes more pronounced on treating them with liquor potassæ. Turgescence of the brain has been described; but, beyond the odour, there is nothing diagnostic in the appearances.

SYMPTOMS.—When a strong decoction of tobacco or snuff is administered, either by mouth or rectum, very speedily—usually in about five minutes—the patient is seized with vertigo, acute abdominal pain, nausea, and vomiting. The skin is pallid and bathed in perspiration. Stupor supervenes, with partial or general convulsions, and stertorous respiration; and death may result in fifteen or twenty minutes, preceded by dilatation and insensibility of the pupils. When the alkaloid, nicotine, is swallowed, insensibility supervenes almost immediately; the pupils are widely dilated; respiration is speedily suspended; and the patient dies in three or four minutes.

The toxic effect on vision of the continued use of tobacco is described on p. 513, and that on the heart on p. 643.

DIAGNOSIS.—The odour, coupled with the above-described symptoms, would leave no doubt as to the nature of the case. Usually there is a history of administration.

PROGNOSIS.—The prognosis is in all cases of acute poisoning unfavourable. *Fatal dose.*—Thirty grains of tobacco are said to have proved fatal. A drop or two of nicotine would doubtless prove fatal.

TREATMENT.—The treatment of poisoning by tobacco consists in the exhibition of emetics, followed by tannic acid freely in any form, to render the alkaloid insoluble. Strong tea, coffee, and stimulants should also be administered. Iodine, dissolved with iodide of potassium, has been recommended; but is probably of little efficacy, and is undoubtedly irritating to the stomach. Twenty to thirty minims of tincture of nuxvomica may be given, and repeated at intervals; or, better, a hypodermic injection of $\frac{1}{32}$ grain of the nitrate or other soluble salt of strychnine may be administered.

THOMAS STEVENSON.

TOKELAU RINGWORM.—See TINEA IMBRI-CATA.

TONE, Want of.—This expression, although commonly employed in a somewhat loose and unscientific manner, is sufficiently understood in the main. To appreciate its meaning, it is first necessary to inquire what tone is. In the widest sense of the term, a person may be described as being *in tune* when his organs individually discharge their functions in a perfect manner, and act harmoniously as a whole, just as a violin is said to be *in tune* when melody can be educed by striking its individual strings. More correctly, tone is applied to a condition of the muscular system, as signifying that state of tension in which voluntary muscular efforts can be produced and continued with a healthy and pleasurable feeling; and also to muscular organs, to indicate a certain degree or power of contraction of their walls.

ÆTIOLOGY AND PATHOLOGY.—Various factors combine to produce and maintain muscular tone. First, this state is dependent on a proper supply of *nervous energy*; secondly, *nourishment* and *oxygen* must be furnished in abundance; thirdly, the *products of waste* must be thoroughly removed from the system; and fourthly, the *work* required of the muscular tissue must not be excessive, that is, a certain amount of rest must be afforded to it.

Want of muscular tone results, then, from failure of any of these conditions.

1. *Nervous failure.*—Whatever view may be taken of the nature of nervous and muscular force, modern research has shown that they are intimately connected with each other. If the nerve-supply be cut off, muscles waste; and *vice versâ*, if the muscles remain unemployed, their nerve-centres suffer. The effect of nervous disease or disorder in producing loss of muscular tone is illustrated by such neuroses as hysteria and epilepsy, by some forms of mental disease, and by the large but indefinite class of cases known as 'nervous debility,' of which mental strain, anxiety, sexual excess, masturbation or alcoholism are frequently the exciting causes.

2. *Failure of nutrition.*—Deficiency of the blood-supply immediately lowers muscular activity, in consequence of interference both with the nutrient and the oxygenating processes. It is on this account that want of tone is found in anæmia, in convalescence from acute diseases, and to a certain extent in chronic dyspepsia. Want of oxygen and impurity of the atmosphere lead as distinctly to lassitude; and, if long continued, to lowering of muscular energy and loss of tone, as among the inhabitants of large towns, and in persons employed in close, ill-ventilated rooms.

3. *Retention of waste products.*—When muscles are called into action certain compounds are formed within them, which must be eliminated by being passed back into the circulation and excreted. The lungs, skin, kidneys, liver, and bowels must, therefore, discharge their functions properly to keep the muscular system in tone. We have here the explanation of a very common class of cases of want of tone. Many persons, either from choice or from necessity, habitually take an amount of active bodily exercise insufficient for the removal of the waste products from the muscular and other systems. In the former case this is the result of indulgence in abundant rich food, combined with lazy habits, confinement to warm 'relaxing' rooms, and the avoidance of 'bracing' exercise. In the latter case the metabolic inactivity is refer-

able to enforced confinement in sedentary employments, often of an exhausting kind, carried on perhaps in an impure atmosphere, or throwing a continuous strain upon one set of muscles, such as those involved in standing or sitting. Both these classes of cases also are met with chiefly in large towns, and they constitute a considerable proportion of the persons who 'require tonics.'

4. *Muscular exhaustion.*—Excessive muscular exercise leads to loss of tone: first, by interfering with nutrition, which is most active during rest; secondly, by wear and tear; and thirdly, in the case of hollow muscular organs, such as the intestines (the muscular walls of which have to resist internal pressure), by gradual exhaustion of muscular irritability from continuous excitement, or possibly even by over-stretching and dislocation of the fibres. The first two forms of muscular atony are well illustrated by certain instances of cardiac exhaustion; the third form is met with not only in the alimentary canal, but in the bladder, in the blood-vessels, and indeed in all muscular tubes and ducts, when over-distended by solid, fluid, or gaseous contents.

5. *Combined causes.*—In many cases two or more of the causes mentioned under the preceding head are combined. Thus in a large class of cases of debility with which practitioners in large towns are familiar—and which especially includes young female subjects engaged in business—overwork, impure air, insufficient light, badly cooked or otherwise improper food, the constant strain of the muscles of the legs and back without sufficient movement, and frequently many other circumstances injurious to the nervous system, are all combined. Again, the subjects of chronic nervous affections, such as epilepsy and hysteria, are too frequently overfed, nursed in warm rooms, and spared every form of healthy exertion, with the result of producing a flabby, atonic state of system.

SYMPTOMS.—Want of tone in the muscular system generally is characterised by a number of symptoms, which are all more or less ill-defined and difficult to describe, being chiefly of a negative and subjective kind. The chief of these are a peculiar feeling of want of muscular vigour; weakness, heaviness, and even aching of the limbs; languor, inability and unwillingness to undertake or to continue any kind of physical or mental exertion, and a desire to remain passive and undisturbed. This reacts upon the mind, causing depression of spirits, melancholy, and other subjective symptoms.

The symptoms of want of tone or atony of muscular organs vary greatly with the part affected. Thus atony of the stomach is characterised by a familiar form of dyspepsia, which is called 'atonic'; atony of the bowels is chiefly attended by constipation and flatulence; atony of the bladder is associated with retention of urine. Ulcers are said to 'want tone' when the healing process flags.

TREATMENT.—It will be gathered from the preceding remarks that want of tone, whether general or local, is a condition which calls for very different kinds of treatment, according to its cause. One of the principal reasons of the want of success which frequently attends attempts to restore tone to the system is failure on the part of the practitioner to appreciate this truth, and to discover and remove the cause or causes of the morbid state. Tonic drugs suggest themselves only too readily as the proper means to be employed; and so great is the number of remedies which go by this name, and so

complex are the combinations in which they are now presented by the pharmacist, that recourse is often had to them before an accurate estimate has been made of the direction in which the system or the affected organ is really at fault, and hence injury, not benefit, results. These remarks apply both to loss of tone generally, and to atony of special organs. Thus it happens that the best tonic measure in one case may be rest, in another case exercise ; in a third case food and stimulants may be urgently called for ; in a fourth case depletory measures are essential at the commencement of treatment. Time is an equally important factor in the process of restoration to tone. This is especially true in the instances where rest is necessary ; but even in the very opposite class of cases, where exercise is demanded, this regimen may need to be carried on for a long time, being commenced with caution and slowly increased.

The details of tonic treatment are indicated in a special article (*see* TONICS). Here it need only be added that when the nervous elements are distinctly deficient in activity, strychnine, cinchona, phosphorus, and cod-liver oil appear to be specially indicated, while galvanism and massage may be useful. Massage is a most potent agent in increasing bodily tone. But it requires careful regulation, as in some patients it proves too exhausting—it may be from too quick destruction of the muscular tissues, and insufficient elimination of the waste products (*see* MASSAGE). On the other hand, Weir Mitchell's treatment, where massage is combined with forced feeding and seclusion, is of great value where failure of tone arises chiefly from a badly nourished nervous system. Alcoholic stimulants and iron are best adapted to cases in which nourishment and oxygenation have fallen below par. When the activity of the organs is diminished from accumulation of waste products, we must have recourse to moderate cholagogue purgation, to such diuretics as digitalis, to diaphoretics, and especially to change of occupation, and exercise of such a kind in an open healthy atmosphere as shall bring all the voluntary muscles into action, and stimulate if possible every bodily function. In the converse class of cases, where exhaustion is the result of over-exertion, we have, after removing the cause, to exhibit antispasmodic or even sedative drugs, such as belladonna and opium, which are especially useful in the first stage of atony of the stomach and alimentary canal, as well as in atony of the bladder.

Finally, no class of remedies is so likely to prove efficacious in restoring tone as that of mineral springs and baths. Where these are chosen with due discrimination, every one of the indications for treatment may be fulfilled. In *nervous failure*, whatever may have been the exciting cause, the change of air and scene, the regulated life and the freedom from daily cares, all tend to restore a proper working of the nervous system and thereby a due tone of the whole system. The same remarks apply to *failure of nutrition*, where early hours and exercise, which form a part of the regimen at every Spa, are so conducive to an improved tone of the muscles, voluntary and involuntary, of the body. But it is in cases of *retention of waste products* that natural mineral springs and baths play so important a part. Doubtless the principal agent is water, and the different saline or other ingredients are merely subsidiary helps. Yet even the mere flushing of the system is not to be despised ; and in no other fashion can it be so thoroughly—if not always very

pleasantly—secured. The fourth cause—*muscular exhaustion*—is one also which can be very successfully combated at a watering-place. One of the most necessary injunctions which require to be laid down by the bath-physician is attention to graduation of the amount of exercise. The improved sleep, too, following on better digestion, inhalation of pure air, and increased elimination, tends greatly to give tone to the system by ensuring sufficient intervals of rest. Enough has been said to show that mineral waters, bathing, and the modern system of massage available at all Spas, must do much to counteract the causes of 'want of tone.'

WILLIAM BRUCE.

TONGUE, The.—*SYNON.* : Fr. *La Langue* ; Ger. *Die Zunge*.—Apart from its own particular diseases, which are described in a separate article (*see* TONGUE, Diseases of), the tongue, as is well known, gives important clinical indications regarding various morbid conditions affecting the general system, as well as many local diseases.

In general terms it may be stated that we examine the tongue, for clinical purposes, with reference, first, to its *subjective sensations* ; secondly, to its *movements* ; and, thirdly, to the *objective characters* which it presents.

1. The *subjective sensations* chiefly include ordinary tactile sensation, and the sense of taste. In most cases we rely for information on these points upon the statements of patients ; but under certain circumstances common sensibility may be tested experimentally by some suitable instrument ; and taste, by applying different articles to the tongue with a brush, or in other ways. *See* p. 1065 ; and TASTE, Disorders of.

2. The *movements* of the tongue are studied by watching them directly ; and by noticing any abnormal affection of speech or deglutition arising from defect or disorder of these movements. A peculiar thickness of speech, or an inability to swallow properly, may result from this cause ; and in extreme cases articulation and deglutition may become impossible. To examine the tongue directly as a motor organ, it should first be looked at while in the mouth, both at rest and when the patient moves it from side to side, or in other directions ; then it should be directed to put it out, and to perform similar movements when the tongue is protruded. This mode of investigation gives important information in certain cases. *See* p. 1066.

3. The *objective examination* of the tongue in itself is of far more frequent application than the methods just considered, being indeed called for and commonly practised in every case, although it may not necessarily afford any positive information. The examination is usually carried out by inspection ; but it may also be requisite, and very instructive, to feel the tongue with the finger. In looking at the organ, an endeavour should be made to inspect its entire upper surface, and for this purpose the patient should be directed to open the mouth, and protrude the tongue as far as possible, a good light being also needed for observing it. In some instances, as in infants and rebellious children, as the result of congenital malformations or wearing false teeth, in many low febrile cases, and in certain nervous diseases, the tongue must be examined while in the mouth, as the patient either cannot or will not put it out properly ; for this purpose it is sometimes necessary to open the mouth

somewhat forcibly, but with due care, and it may be desirable to employ some artificial light. For more minute information in some cases it is requisite to scrape the surface of the organ, and to examine microscopically what is thus removed. The points to be noticed in the objective examination of the tongue are: (a) Its size and shape as a whole, as well as the characters of its point and margins. (b) Its condition as to firmness or flabbiness. (c) The colour of the mucous membrane. (d) Whether the surface is normal, smooth and glazed, being more or less denuded of its usual epithelium, or presenting a dry membranous covering, furrowed, fissured, or otherwise altered. (e) The condition and appearance of the papillæ, especially the fungiform papillæ. (f) Whether the tongue is moist, sticky, or dry. (g) The absence or presence of any accumulation on the dorsum of the organ, commonly known as 'fur'; and, if present, its arrangement, thickness, colour, and other general characters, as well as in some cases its microscopical appearances. It may be remarked that in relation to this examination of the tongue it is often advantageous to notice the condition of the mouth generally, but especially of the gums and teeth, and of the lips. Further, the patient may afford information with regard to the objective conditions of the tongue, not coming immediately under the notice of the practitioner, such as whether it is much furred on waking in the morning, or if it is inclined to dryness.

It is desirable to offer a few remarks respecting abnormal covering or *fur* on the tongue. This varies much in its extent, distribution, thickness, and characters. As regards its general distribution, it may cover the whole surface of the organ; or only its posterior or anterior part, one lateral half, or even a limited patch when due to local causes. The covering may be a mere film, or of considerable thickness. Its chief colours are white, whitish-yellow, yellow, yellowish-brown, brown, brownish-black, and black. It is either moist and easily separated, sticky and viscid, or dry, being then often cracked and peeling off in fragments. It usually clears gradually from the tip and sides towards the centre of the tongue, sometimes in strips; sometimes it breaks away abruptly in scales. Under certain circumstances fur appears and disappears with great rapidity. See p. 1709.

In a very instructive classification of tongues, Dickinson employs the following terms: (1) *Stippled* or *dotted*, where the papillæ are separately capped with a minute white patch. (2) *Coated*, where the spots coalesce and become confluent, so that the covering is continuous, the intervals between the papillæ being also more or less filled up. (3) *Plastered*, where the coat is thick, uniform, and conspicuous, and often looks as if laid on with a trowel. (4) *Furred* or *shaggy*, in which there is great elongation of the papillæ, which remain separate from each other, at least at their extremities, so as to give a shaggy look, or one suggestive of coarse hair or fur. (5) *Encrusted*, in which the papillæ are concealed by an incrustation, or thick felted coat, usually dry and brown, by which the surface is overlaid.

As regards the nature of the changes in the varieties of abnormal tongues just indicated, microscopical examination shows that in most of them the papillæ are elongated. The white coating is found to consist mainly of accumulated epithelium, which,

according to Dickinson, is the result chiefly of overgrowth. In the superficial layers of many accumulations on the surface of the tongue, especially the dark encrusted form, there are also present the remains of food, amorphous material, fat-globules, blood or altered blood and pigments, different micro-organisms, especially bacilli and micrococci, and sometimes the *Oidium albicans*. In the deeper parts of the epithelial structure, more especially in the Malpighian layer, there is often much profusion of nucleation or cell-growth, and the corium is in many cases distinctly hyper-nucleated and often hyperæmic. More rarely leucocytes are extruded within the papillæ and elsewhere (Dickinson).

With reference to the immediate causation of these abnormal conditions of the tongue, Dickinson concludes that the formation of more or less coating, with lengthening of the papillæ, depends partly on disuse of the organ, with want of rubbing and washing, and consequent deficient removal of the epithelium; but mainly on increased overgrowth, associated probably in some cases with a morbid poison in the system, but chiefly with pyrexia, the coat increasing in degree in proportion to the temperature, up to a certain point. Dryness of the tongue he attributes principally to deficient secretion of saliva; but it may also be due partly to habitual openness of the mouth during sleep, to pyrexia, or to general dehydration of the body, from deprivation of water or excessive discharge, as in diarrhoea and diabetes. The condition to which this observer specially applies the term 'furring,' as well as incrustation, he considers as essentially connected with want of saliva. Incrustation is a secondary process, in which various matters accumulate on the surface of the tongue, including parasites. The brown colour he refers chiefly to dryness, as many animal substances dry brown; partly to staining by food and medicines.

The condition of tongue in which its surface is abnormally smooth, bare, and denuded, also calls for brief notice. This may be general or partial, and usually follows the removal of a coating or incrustation; but it may be a primary change. It presents various degrees, the organ being at the same time more or less red, and generally dry. A glazed, shining, or polished appearance is common. In extreme cases this variety of tongue becomes intensely red and raw-looking, being compared to raw beef; and it may be excoriated or cracked. In describing the minute changes, Dickinson states that the epithelium and the papillæ are removed down to the level of the Malpighian layer, but this usually remains, and becomes covered with fresh horny epithelium, forming a thin membrane. Should the denuding process extend further, the Malpighian layer itself is removed, exposing the corium; and this structure is sometimes encroached upon, even almost down to the muscular fibres. Vascular injection, hypernucleation, and the extrusion of leucocytes often take place; and in some cases there is a general inflammatory infiltration of the superficial parts. A completely bare tongue is comparatively rare, and such a degree of change is generally limited in extent. The variety of tongue now under consideration is that on which aphthous growths are most liable to occur. It implies failing nutrition. The appearances are due partly to want of epithelial covering; but the exposure resulting from loss of this covering also

causes irritation and dryness. Dickinson attributes the changes partly to want of saliva.

CLINICAL INDICATIONS.—In the following remarks it is intended to call attention to some of the principal conditions in which the tongue affords useful information, and to indicate the main characters associated therewith. Dickinson affirms that 'the tongue is an index of constitutional states, seldom of individual diseases'; 'it seldom points to solitary organs or isolated disorders, but is rather a gauge of the effects of the disease upon the system than an indication as to the locality of it.' Allowance must always be made for individual peculiarities in the shape or size, and in the appearances presented by this organ; for the effects of certain habits, such as excessive smoking, or chewing tobacco and other substances; for changes in colour due to taking iron or other medicines; and for the results of any local irritation. Moreover, most people, but especially those who sleep with the mouth open, have a more or less furred tongue in the morning, which is of no special importance, or it may tend to dryness; while in some individuals its surface presents constantly a thick coating, without evident disturbance of any organ, appetite being excellent, and the digestive functions performed in a most satisfactory manner. On the other hand, a perfectly clean and healthy-looking tongue may be associated with severe dyspeptic symptoms, or even with serious organic disease of the alimentary canal or its related organs. Many persons have the surface of the tongue more or less furrowed as the normal state.

1. Nervous Diseases.—In this class of diseases the tongue often affords information of much value, and it is here that its sensations and movements are mainly disordered. In many cases of cerebral lesion, one half of the tongue is paralysed in its muscles, so that the organ is unsymmetrical in the shape of its two sides; and deviates when in the mouth to the healthy side, but when protruded towards the paralysed side. In exceptional cases the entire organ is affected, so that it cannot be protruded or even moved. The way in which a patient attempts to put out the tongue, when asked to do so, may be made use of to indicate the state of consciousness in various conditions affecting the brain. In many cases of cerebral disease the tongue shows a marked and speedy tendency to become thickly furred, and very foul. This is well seen in cases of apoplexy due to hæmorrhage in connection with the brain.

The tongue is specially affected in certain peculiar nervous diseases, particularly labio-glossolaryngeal paralysis, many cases of diphtheritic paralysis, general paralysis of the insane, and extreme cases of wasting palsy. Beginning with slight indications of loss of power, as tremulousness, thickness of speech, and difficulty in swallowing, the affection is liable to end in complete paralysis of the organ, which may also involve its sensibility. These results depend on disease involving the roots of the nerves supplying the tongue. The organ may also be thus affected in various degrees, owing to some morbid condition implicating its nerves in their course or at their origin. When completely paralysed, the tongue in time comes to present the appearance of a sodden mass lying in the mouth. In cases of severe neuralgia of one side of the face, the tongue occasionally presents peculiar appearances, such as unilateral furring, thickening of the

mucous membrane, or enlargement of the papillæ; coating of one side of the tongue has also been noticed in connection with painful teeth (Hilton). The tremulous and foul tongue of acute or chronic alcoholism may be mentioned under this head. Dickinson has often noticed the tongue to be white and sodden-looking after an exacerbation of nervousness, but attributes this to a want of saliva. Signs of the organ having been bitten may be useful in the diagnosis of obscure cases of epilepsy. Jerking and irregular movements of the tongue are very striking in many cases of chorea. During attacks of megrim its surface usually becomes much furred. *See also* PAIN IN VISCERAL DISEASE.

2. General Conditions and Diseases.—The tongue is usually markedly altered in the febrile state, whether associated with specific fevers, or with inflammatory or other diseases. It becomes covered with more or less fur, often of considerable thickness, and usually either white or yellowish-white. In particular fevers the organ commonly presents peculiar characters. Thus, in many cases of typhoid fever it is small and irritable, with enlarged papillæ, and a thin whitish or yellowish fur; it may become red, smooth, and glazed or shining. In this disease it may also be peculiarly tremulous, which has been regarded as a bad sign, indicating deep ulceration of the intestine. In scarlatina the papillæ tend to become peculiarly prominent as well as injected, projecting through the fur, the tongue presenting the so-called 'strawberry' appearance; this condition may, however, be met with in other diseases. In diphtheria the tongue may exhibit a diphtheritic deposit upon its surface. There is generally a very thick creamy coating in acute rheumatism, as well as before and during attacks of gout, and in the latter disease especially it often becomes yellowish or brownish. In acute pneumonia also the tongue is often thickly plastered, but presents much variety. In the 'typhoid state,' whatever this condition may be associated with, the tongue tends to be dry, and usually covered with a brown or even blackish crust, looking as if it were baked. It is often very red and irritable in itself, and occasionally the typhoid tongue has little or nothing on its surface, but is very dry, deeply red, like raw beef, and fissured. The organ may be in such a condition that it can scarcely be moved at all. At the same time sordes are present on the teeth and gums. The red, raw, and dry tongue is generally associated with exhaustion, especially when this is due to exhausting discharges, particularly of pus; and it is linked with the constitutional state described as hectic. It not uncommonly occurs, however, in various conditions producing prostration and depression, apart from discharges, and these are often connected with the abdominal organs. In malarial fevers the margins of the tongue are said to present sometimes a faint bluish tinge.

It may be remarked here that the tongue not uncommonly affords evidence of constitutional syphilis, owing to the past effects of this disease upon the organ. It may also indicate the general tone of the system, being often large and flabby when this is below par.

3. Conditions affecting the Blood and Circulation.—The tongue often exhibits abnormal characters, due to the state of the blood or circulation. Thus, in anemia it is more or less pale; generally large, flat, broad, and flabby; and

frequently indented at the sides by the teeth. In the plethoric condition it is also large, but tends to be of a deeper colour than normal, and may present a venous tint. The anæmic tongue is frequently quite clean, though this will depend much on its associations; but the tongue met with in plethora is generally furred. A temporarily congested condition of the digestive organs and liver is supposed to be accompanied by a corresponding plethoric state of the tongue. Any cause of general obstruction to the venous circulation, or of interference with the due aëration of the blood, whether seated in the heart or lungs, is likely to give rise to enlargement of the tongue, and to make it assume a congested, or even a cyanotic appearance in marked cases, such as those of congenital malformation of the heart. It occasionally happens that some local obstruction, affecting the large veins in the thorax, as from the pressure of an aneurysm, produces a similar condition of the tongue. In his classification, Dickinson applies the term *cyanotic* to a particular variety of tongue, which is injected, hypernucleated, with excess of deep epithelium.

4. Affections of the Alimentary Canal and its Related Organs.—The tongue is commonly regarded as of peculiar importance in relation to morbid conditions of the digestive apparatus and liver, but Dickinson's observations do not support this idea, and he attributes the changes presented by the organ rather to the pyrexia or other constitutional disturbance associated with these conditions. As already stated, there is no definite relation between the state of the tongue and the performance of the digestive functions, or the presence or absence of even serious disease, but at the same time there are certain general indications which may be worthy of note.

(a) The tongue is peculiarly liable to be altered in local affections of the mouth and throat. In catarrh of these parts it is more or less coated. In tonsillitis there is usually a very thick covering; and it may be most marked on the side of the inflamed tonsil. Even a local irritation, such as that caused by decayed teeth, may originate a fur, and it is under such circumstances that it is liable to be localised. Associated stomatitis may explain the state of the tongue in some cases of gastric catarrh or inflammation.

(b) In any acute disorder of the alimentary canal the tongue tends speedily to become coated, usually either white or yellowish-white, but it may be more or less brown. This is seen in so-called acute dyspepsia, gastric catarrh, and hepatic disorders. The fur often clears away very speedily when the cause subsides. In severe acute gastritis the organ frequently presents a strikingly red and irritable appearance, especially at the tip and edges, with enlarged papillæ, and a tendency to dryness. In acute intestinal obstruction the tongue becomes stippled at an early period, or coated and dry.

(c) In chronic forms of dyspepsia and gastric catarrh, the tongue often presents abnormal appearances. In the atonic variety it is usually large, flat, soft, and flabby; frequently marked by the teeth; and more or less furred, though it may be quite clean. In the irritative form it tends to be small, elongated, and pointed; contracted and firm; red and irritable; with enlarged papillæ; and generally only having a thin white fur, through which these papillæ project, but it may appear unusually clean and raw-looking. The organ may

present characters more or less similar to those just described, in those cases where the food passes rapidly out of the stomach into the duodenum in an undigested state. In the more grave diseases of the stomach, namely, cancer and ulceration, the tongue has no special characters, and indeed is often very healthy-looking. Dickinson has not been able to discover any state of tongue especially connected with dyspepsia or ulcer of the stomach.

(d) The relation of the tongue to affections of the intestines is indefinite. The bowels are often much deranged in their functions, or diseased, without any abnormal appearances being exhibited by the organ. It may be said, however, that constipation, especially if habitual, tends to make the tongue large and furred, particularly if associated with portal congestion and deficiency of bile. Cases of prolonged constipation have not uncommonly been met with, however, in which it has remained perfectly clean and normal. Chronic accumulation of feces in the rectum seems to give rise to thick coating, which Dickinson attributes to general disturbance, and probably pyrexia connected with morbid absorption. Diarrhœa tends speedily to affect the tongue in various ways. There is scarcely any condition in which the tongue becomes more rapidly dry, coated, furred, and encrusted, than in severe diarrhœa. In dysentery, especially with hepatic abscess, it often becomes shrunken, red, smooth and polished, or fissured.

(e) As regards the hepatic apparatus, portal obstruction is believed to cause an enlarged and congested state of the tongue. It tends to become more or less coated in biliary disorders, especially when acute; and is often very foul in cases of obstructive jaundice, when it may also be coloured yellow.

5. Special Diseases.—In diabetes mellitus the tongue is often peculiarly irritable, red, clean, cracked, and dry. In acute peritonitis it is usually remarkably small and contracted, also red and irritable, with but little fur, and tending to dryness. In advanced cases of phthisis, especially with a high temperature, it frequently becomes red and raw, and exhibits enlarged papillæ; the occurrence of thrush upon its surface may also be a sign of approaching dissolution in this disease. These illustrations will suffice to point out the special information which the tongue may afford as regards particular diseases. FREDERICK T. ROBERTS.

TONGUE, Diseases of.—SYNON.: Fr. *Maladies de la Langue*; Ger. *Krankheiten der Zunge*.

The principal morbid conditions affecting the tongue may be thus enumerated in alphabetical order: (1) Chronic Abscess; (2) Adhesions; (3) Atrophy; (4) Cancer; (5) Cysts (mucous); (6) Hypertrophy; (7) Inflammation and Acute Abscess; (8) Leucoma, Leukoplakia; (9) Parasitic Affections; (10) Syphilis; (11) Tongue-tie; (12) Tubercular Ulcer; (13) Tumours; and (14) Ulceration. Aphthæ and thrush are discussed under their respective headings (see APHTHÆ; and MOUTH, Diseases of). The simpler disturbances of the surface of the tongue, of which the practitioner avails himself as an aid to diagnosis, are separately discussed. See TONGUE, The.

1. Chronic Abscess.—This may occur at any age, and its cause is generally obscure. It is most common in front of the circumvallate papillæ, and forms a tense, elastic, more or less prominent swelling, presenting beneath the dorsal mucosa. Its

outline is generally quite clear. The mucous membrane over it is free and normal in appearance; the swelling is neither tender nor painful. However prominent, it is not translucent. Growth is very slow, and the history of the swelling may extend over some years. The disease has to be diagnosed chiefly from mucous cyst.

The treatment consists in the application of cocaine, incision, and scraping out the abscess with a sharp spoon.

2. **Adhesions.**—Occasionally the tongue is attached more or less extensively at its sides and under-surface to the corresponding surfaces of the mouth. These adhesions may be congenital, but more frequently they are the result of ulceration or sloughing.

TREATMENT.—In congenital cases the membranous bands may be divided with scissors or scalpel. Sometimes a well-formed tongue exists, bound down laterally to the jaws: these cases do well. When the tongue is not really formed, treatment is of no avail. Adhesions consequent upon ulceration may be dealt with similarly, but the result is much less hopeful, unless a mucous flap, from a part which will not lie in contact with another raw surface, can be twisted into the wound made. The writer is not acquainted with any case in which the transplantation into the mouth of a piece of mucous membrane from another animal has succeeded.

3. **Atrophy.**—Atrophy of the tongue may be either unilateral or bilateral. It may result from either acute softenings or chronic sclerosis of the nuclei of the twelfth nerve in the medulla, and in both of these cases the palsy is usually bilateral, the two nuclei being so close together as to be almost necessarily involved by even a small lesion. Injuries to the nerve-tract between the centre at the lower end of the ascending frontal convolution and the nucleus cause paralysis, with but little and late wasting. Injuries below the nuclei, on the other hand, lead to rapid wasting of the tongue on the side of the injury.

TREATMENT.—Treatment must be directed to the cause of the complaint. See HYPOGLOSSAL NERVE, Diseases of.

4. **Cancer.**—**ÆTIOLOGY.**—Cancer of the tongue is most frequent between the ages of forty and forty-five; it may occur at any age after twenty-five, but is rare under thirty-five. It is more than twice as common in men as in women. Irritation from a tooth or hot smoke sometimes seems to be the exciting cause; again, the growth may supervene upon leukoplakia, glazed red tongue, a wart, or a chronic gummatous ulcer. Cancer of the tongue is much more prevalent in some districts than in others.

DESCRIPTION.—Squamous epithelioma is the only form met with in the tongue. Its usual seat is the edge in the middle third, but it may begin at any spot. It starts as an ulcer, a fissure, or a wart—sometimes the patient says, ‘as a lump in the tongue’; but growing as it does from the epithelium, this ‘lump’ is always intimately connected with the mucosa, and the epithelium is never normal over the whole mass, but is either destroyed by ulceration or is papillary. The earliest characteristic point is induration of the base of the lesion, from invasion of the mucosa by epithelial cells and round-celled infiltration about them; the edges of an ulcer or fissure become similarly thickened. The

epithelium on the surface usually undergoes degeneration and is cast off, thus leading to the formation of an ‘ulcer,’ at the base and edges of which the tissues are being progressively invaded by growing epithelial columns. This invasion is sometimes more marked along the surface, at other times it takes place chiefly towards the substance of the tongue, and may involve almost the whole organ. It is sometimes slow, again rapid, and is almost always so much more rapid than the ‘ulceration,’ mentioned above, that induration round the ulcer is well marked. Rarely papillary masses project from the surface of an epithelioma, destruction being reduced to a minimum; unfortunately, because often delaying a correct diagnosis, it is in these cases that infiltration of the base also is apt to be least marked, the products of epithelial multiplication escaping towards the surface instead of being pressed into the substance of the part. As the ‘ulceration’ and infiltration extend into the substance of the tongue, to the floor of the mouth, the jaw, the fauces or soft palate, the movements of the tongue become more limited, till ultimately it may be quite bound down. Sooner or later the submaxillary lymphatic glands, or those at the base of the carotid triangle, swell and become painful. They may be few or many, may remain of small or moderate size, or may grow rapidly and discharge or fungate through the skin, and this with but a small growth in the mouth. Extension to distant organs by the blood-path is rare. Pain may be slight or even absent, but, as a rule, it is severe, radiating over the whole distribution of the fifth nerve and often to the region of the small occipital. The tongue is tender and sensitive; when fixed, it fails to push food between the teeth for mastication. Ptyalism is constant, and may be very marked. The saliva is ropy, and is expelled with difficulty. The ulcer discharges into the mouth, while sloughs form upon its surface and putrefy; hence mouth and breath become offensive. Perhaps in relation with the increased secretion of ropy saliva the submaxillary salivary gland is large, firm, and easily felt. In consequence of inability to take sufficient food, of chronic putrid poisoning, of pain and anxiety and other influences connected with the nature of the growth, the patient loses health and strength steadily. Death may result from simple exhaustion; not uncommonly septic bronchitis and broncho-pneumonia hasten the end. Dangerous or fatal hæmorrhage from the epithelioma is rare. Cancer of the tongue is one of the most painful and most rapidly fatal forms of malignant disease. According to Clarke, its average duration is fifty-seven weeks. But the statistics of surgeons practising carefully the modern operation of removal of the growth, together with the nearest lymphatic glands, show a better result than this—including a fair number of cases of prolonged immunity. Cancer of the frænum and its neighbourhood should be mentioned, as it is credited with exceptional malignancy. This may be the consequence of imperfect treatment, due to a surgeon's reluctance to draw healthy front teeth (to get a good view), to resect the symphysis, and to remove the submental and submaxillary lymphatics on both sides. Cancer behind the circumvallate papillæ is, fortunately, rare. It may not be visible without a laryngoscope or palpable unless both the fore- and index-fingers are fully introduced through the mouth.

DIAGNOSIS.—The difficulties in recognising a cancer of the tongue vary according as it presents itself under the form of an ulcer, a wart, or a tumour beneath the mucosa. In all cases the diagnosis should be effected before the local disease is extensive, or glands are enlarged, or it will probably be too late for successful treatment. A cancerous *ulcer* must be distinguished from a simple ulcer, a hard chancre, a broken-down gumma, and a tubercular ulcer. A simple ulcer generally forms quickly, and bears an obvious relation to its cause—some injury, a sharp tooth, or a projecting part of a tooth-plate. It is less defined in outline than cancer, and induration is absent or slight; the edges are not thick, rounded, raised, or everted; the base is not warty and irregular. A scraping of its surface after cleansing shows but few epithelial cells, and they are of normal appearance. After removal of the irritant, and under suitable treatment, a simple ulcer should heal. Hard chancre affects the apex; is exceedingly rare; of rapid formation up to a certain size; very hard, defined, with smooth edges, and but slightly indurated base. The submaxillary glands very soon enlarge, and general symptoms follow. A gummatous ulcer is usually a deep ragged cleft on the dorsum, parallel to the raphé, with thin, irregular margins, undermined and gaping as the tongue is protruded, not at all indurated; in the cavity yellowish sloughs may still adhere; there are sometimes other masses in the tongue-substance, and the surface frequently presents evidence of previous ulceration or of superficial glossitis; a history and other signs of syphilis are perhaps obtainable; a scraping of the side of the ulcer after cleansing shows but few epithelial cells; appropriate treatment is successful. Both the simple and the gummatous ulcer may become cancerous; so, if progressive induration leads to the suspicion of cancer, either the ulcer should be at once freely excised, or a good piece should be cut out under cocaine and examined microscopically. A tubercular ulcer in a male over thirty-five may be indistinguishable from cancer. If the ulcer is secondary, the presence of tubercle elsewhere should make us careful. Primary tubercular ulcers of the tongue are rare. They are less indurated, but may, if clean, present pale pinkish granulations not unlike those of a clean epithelioma. Sometimes in deeper specimens muscular fibres may be recognised, laid bare by the progressing ulceration. The effect of medicinal treatment is usually *nil*. It is stated that these ulcers yield a scraping like that of a simple or syphilitic sore. Fortunately, the diagnosis is of less importance here than in the previous cases, for the primary tubercular ulcer, or a secondary ulcer with but slight lesions elsewhere, should be excised.

A *warty* epithelioma resembles a simple wart. The diagnostic point is induration at the base of the epithelioma. No wise man would keep even an undoubted wart on his tongue.

An epithelioma in form of a submucous *tumour* has to be distinguished chiefly from an unbroken gumma. A normal or smooth red epithelial surface over the mass, absence of definite outline, of marked induration, and of enlarged glands, the presence of syphilitic lesions on the tongue or elsewhere, and a history of syphilis, excite suspicion as to the nature of the growth. Full doses of iodide of potassium confirm it.

So much stress has been laid upon the importance

of induration in the diagnosis of cancer, that it is right to add that rapidly ulcerating epitheliomata rarely do occur in which there is but little induration.

In no case should the nature of a small ulcer of the tongue in a patient of thirty-five or over be allowed long to remain doubtful. If it does not heal after removal of any local irritant, upon the application of local antiseptics, especially borax and iodoform, and upon the administration of iodide of potassium, a small ulcer should be excised—the operation is so trifling. If there is any doubt about the nature of a larger mass, a portion should be excised for examination.

TREATMENT.—All epitheliomata, in which it appears possible to remove the whole of the disease, local and glandular, by an operation which the patient seems likely to survive, should be removed without delay by knife or scissors. In all cases, even the earliest, the lymphatic glands supplied from the seat of disease, and, as far as possible, also the tissue between them and the primary lesion, should be removed. The mortality after operation upon cases of all degrees of severity is about 12 per cent., rising from *nil* in slight, early cases to 25 per cent. in extensive cases. When there is a fair prospect of preventing local recurrence, it is still often right to remove that part which lies in the mouth, to relieve pain and the suffering which a cleanly patient undergoes on account of the foul state of the part. Excision of half an inch of the lingual nerve has been performed to relieve pain, and ligation of a lingual artery to check hæmorrhage. The treatment of incurable cases consists in the administration of anodynes in doses *sufficient to give relief*; in the use of antiseptic washes and powders for the mouth; and in careful feeding.

5. **Cysts.**—In addition to the rare lingual dermoids described under MOUTH, Diseases of: 4, and the parasitic cysts (*Cysticercus cellulosa*, extremely rare; and *echinococcus*, rare), cysts from dilatation of a mucous gland are sometimes met with, and at any age. They are most common where the mucous glands are largest and most numerous—behind the circumvallate papillæ, but they may occur elsewhere in the tongue. They form tense, elastic, circumscribed swellings, sometimes pushing their way into the tongue, at other times projecting sufficiently from the surface to render it evident that they are translucent. They cause no pain, and the mucosa over them is normal or simply stretched.

DIAGNOSIS.—When a cyst is prominent, the diagnosis presents no difficulty except from chronic abscess, which generally occurs in the anterior part of the tongue, and is never translucent. A puncture will decide. When it lies deep and far back, it may be difficult to be sure even that the mass is fluid; the situation, elasticity, and smoothness of surface of the swelling will always suggest a mucous cyst, and here, again, a puncture will prove its nature.

TREATMENT.—This consists in application of cocaine to the surface, and excision of part of the wall. The interior should be touched over with pure carbolic acid.

6. **Hypertrophy.**—**SYNON.** : *Macroglossia*.—Hypertrophy of the tongue is generally congenital; sometimes it follows an attack of inflammation. The enlargement seems to be due to blocking of the lymph-paths; the lips are sometimes similarly

affected (*macrocheilia*). In the congenital cases it is often complicated with imbecility or idiocy. The enlargement of the tongue may not be evident at birth. At first the enlarged organ has a normal appearance; but usually it becomes too large for the mouth, and part is constantly or frequently prolapsed. Gradually, from exposure to the air and constant irritation, the mucosa becomes dry, thick, and callous, or covered with a slimy secretion; the papillæ enlarge greatly. After a time, the pressure of the teeth acts as a line of constriction, and the protruding portion swells from mechanical congestion. The surface of the tongue becomes bluish or brown; the mucosa roughened and cracked; there is a tendency to ulceration and hæmorrhage; the muscles become palsied, and are unable to retract the organ. As time goes on, the lower jaw is pressed down by the superincumbent weight, and occasionally this goes so far as to produce dislocation. The teeth project forwards, the lips are everted, and there is a constant flow of saliva from the mouth. Altogether, the patient's appearance is most unsightly, and his condition very distressing; for with such a tongue mastication and deglutition are difficult, and speech is thick and indistinct.

TREATMENT.—The redundant part of the tongue must be removed by a V-incision, and the wound sutured.

7. Acute Inflammation.—**SYNON.**: *Glossitis*.—Sometimes the glossitis is *superficial*, only the mucosa being affected: again it is deep or *interstitial*.

ÆTIOLOGY.—Fifty years ago by far the most common cause of acute interstitial glossitis was the excessive use of mercury, happily now seldom seen. Sometimes it is due to septic wounds, to wasp-stings, or to taking putrid, corrosive, or acrid substances into the mouth; it may arise in the course of the acute specific diseases; usually no cause is discoverable.

SYMPTOMS.—Simple superficial glossitis needs no description: it occurs chiefly in young children. Sometimes vesicles form in patches—a kind of herpes. The earliest symptoms of mercurial glossitis, which may be taken as typical, are a foul metallic taste, peculiarly offensive breath, and a red line along the gums, at their junction with the teeth. The gums are tender, spongy, and apt to bleed. As the case advances, the gums, the tongue, and the inside of the lips and cheeks become much swollen. The tongue is sometimes so large as to protrude constantly from the mouth. At its edges it becomes deeply marked by the teeth, and it and the cheeks and gums often ulcerate. The flow of saliva is incessant; the salivary glands are swollen and painful; the teeth ache and become loose, but seldom drop out. The pulse and respiration are hurried. There is great thirst, but the patient has difficulty in swallowing; and he is wholly unable to speak. As a rule, this state of things subsides under proper treatment, but occasionally pus forms in the substance of the tongue, or it may become ulcerated or even gangrenous.

In the acute spontaneous form, the swelling and hardening of the tongue are greater than in the mercurial, and all the symptoms are more severe; the mercurial fetor is absent. There is a greater tendency to suppuration, localised or diffuse, and to sloughing of more or less of the organ. The

fever is often marked. Sometimes the swelling is chiefly at the base of the tongue, though the anterior less swollen part is pushed out of the mouth. General distress and difficulty in breathing are great. Abscess is probable in these cases.

TREATMENT.—In acute inflammation of the substance of the tongue, the first point is to discover any abscess which may be present, by special swelling, tenderness, and localised softening. The abscess is usually far back and hard to find. If found, immediate relief follows incision. If none be found, a sharp purge should be given; and either ice may be freely sucked or the mouth be frequently washed out with hot water—whichever is found to give most relief. Cold or heat may be applied to the submaxillary region. Two long cuts through the mucosa of the dorsum on each side of the raphe may give relief.

8. Leucoma.—**SYNON.**: *Leukoplakia Lingualis et Buccalis*; *Ichthyosis Lingue*; *Hairy Tongue*; *Smooth Red Tongue*; *Tylosis*.

DEFINITION.—These names have been applied to the results of a chronic superficial inflammation (probably) of the mucosa, resulting now in a white patch or patches; now in hypertrophy of the papillæ, giving the tongue a warty or hairy appearance; again in a swollen, smooth red surface.

ÆTIOLOGY.—Nothing is certainly known on this point. Mechanical irritation, hot spices and food, ardent spirits, smoking, syphilis, gout, and various forms of dyspepsia are all regarded as causes of this condition. It seems to run in families. It is rare among women, and among men under twenty. It does not begin after sixty. It occurs on the lingual mucosa chiefly; to a much less extent on the buccal. It is said not to occur behind the circumvallate papillæ.

DESCRIPTION.—The commonest form is that known as *leukoplakia*. Blue or yellowish-white patches (leucomata) form, oval or irregular in outline, smooth on the surface, and showing some degree of resistance when pinched between the fingers. There may be but one such patch. Usually there are no symptoms; sometimes the patches are irritable, casting their epithelial scales, and prone to form fissures and ulcers. With irritability there is more or less *ptyalism*. A much rarer form is that known as *ichthyosis*, in which the papillæ are hypertrophied and covered with horny epithelium. When the filiform papillæ have been specially hypertrophied, the name *hairy tongue* has been given. Lastly, the tongue in some cases, from rapid shedding of epithelium, becomes smooth, red, and slightly swollen, very sensitive and irritable, and liable to fissures or ulcers.

PROGNOSIS.—Once the disease is established, treatment avails but little as a rule. The danger of the trouble is that it tends in all forms to pass on into epithelioma; induration at the base, ulceration, or warty outgrowth being the signs to be watched for.

TREATMENT.—Every source of irritation must be removed, and any constitutional defect treated, in the hope that good may come. Borax-and-glycerine lotion, solution of bicarbonate of sodium (gr. xx ad ʒj), or chromic acid (gr. i-ij ad ʒj), may be used as a mouth-wash after meals. Honey of borax, bichloride of mercury (gr. ij-iv ad ʒj), chromic acid (gr. v-x ad ʒj), or salicylic acid (a saturated watery solution) may be applied directly over the dried part. On no account should irritant or caustic substances be used.

A single obstinate patch may be excised under cocaine. A developing epithelioma will require prompt excision.

9. **Parasitic Affections.**—The most important parasite connected with the tongue is the *Oidium albicans*, which is present in thrush (see MOUTH, Diseases of). *Hydatid cysts* are occasionally met with; and so is the *Cysticercus cellulose*. Among the nematodes the Guinea worm (*Dracunculus* or *Filaria medinensis*) and the *Trichina spiralis* have been found. The dracunculus may give rise to an abscess, which will require to be opened; and hydatid cysts may have to be incised and removed.

10. **Syphilitic Affections.**—These form five-ninths of all the lesions of the tongue which come under our notice. Primary sores are occasionally seen in this situation, but their occurrence is so rare that we need only mention them. For the sake of clearness, it is well to arrange these syphilitic affections into four classes: (A) *Superficial Ulcerations*; (B) *Mucous Tubercles*; (C) *Gummata and Deep Infiltrations*; and (D) *Chronic Morbid States of the Mucous Membrane*.

A. **Superficial Ulcerations.**—Slight superficial ulcerations of the tongue are very common in what is called the secondary stage of syphilis. They are usually situated on the sides, tip, and under-surface of the free portion of the organ; and are often associated with similar ulcerations upon the inside of the cheeks, the lips, and the angles of the mouth. They begin in small inflamed spots, and spread into linear cracks and fissures (rhagades). These are exquisitely sensitive; and, as it is very difficult to keep the tongue at rest, are a source of constant suffering. When these ulcerations heal, whitish scars and cicatrices are left, which are very persistent, and resemble leukoplakial patches.

B. **Mucous Tubercles.**—Mucous tubercles, when they occur on the tongue, are generally met with about the sides and under-surface of the organ; on the fold of mucosa that is reflected to the floor of the mouth; or on one side of the raphé far back. They occur in the early years of the disease.

C. **Gummata and Deep Infiltrations.**—Gummata are common in the tongue, varying in size, when they come under notice, from a pea to a marble. Not uncommonly they are multiple, or the principal mass may be set in a diffuse infiltration of the tongue. As a gumma enlarges and softens, the mucosa over it becomes red and smooth, and ultimately it gives way. A ragged opening is thus formed, through which fluid escapes, and adherent slough protrudes. The edges are irregular, thin and flexible; the walls are not indurated; the opening gapes in certain positions of the tongue. The cavity may heal, or may remain for an indefinite time if no treatment is adopted, and some induration of the walls may supervene. It is in these chronic cases that downgrowth of epithelium (epithelioma) sometimes takes place. So long as a gumma is unbroken, there is strong hope that treatment will cause its absorption. After this, no trace of it may be left upon the surface; but when a gumma has burst, a fissure-like scar results from its healing, and there is more or less induration about it. Sometimes, though rarely, a tongue becomes generally fibroid from the development of gumma-tissue throughout (*chronic interstitial glossitis*). A tongue may thus become deeply and irregularly scarred, enlarged or diminished in size,

or much deformed, by alternating contraction and swelling; while the mucosa presents, perhaps, patches of normal appearance, white or yellow scars with thickened epidermis, red areas where irritation is still active, and bluish surfaces indicating mechanical congestion from scar-contraction.

D. **Chronic Syphilitic Disease.**—Various morbid conditions of the mucosa of the tongue are often seen in association with the later stages of syphilis. Sometimes circumscribed patches of the epithelium become dead-white, and drop off, leaving a red raw surface beneath. The epithelium is speedily restored, but another patch becomes affected in a similar manner, and so the disease continues—one patch healing and another desquamating. This is the proper *psoriasis lingue*. Again, there is a much more extensive disease, to which the name *chronic superficial glossitis* has been given. At the commencement some portions of the membrane present their natural appearance, while others are of a deep red colour and raw-looking. These patches are often oval or oblong. Their surface is smooth and glossy. They are either entirely denuded of epithelium, or this is reduced to an extremely thin layer, and the papillæ are obliterated by distension. These patches are slightly elevated and hard to the touch, in consequence of interstitial thickening. The tongue is swollen. At its edges it takes the impression of the teeth, and the lines thus produced are prone to ulcerate. Sometimes the whole organ has a bluish, congested hue. The mucous secretion all over the affected part is viscid and glairy, giving the organ a peculiar, smooth, glazed appearance; and sometimes the patient's breath is so fetid that he is offensive to himself and to all about him. He complains of thirst; his mouth is parched, especially at night; and when he wakes in the morning his tongue feels dry and chipped. The disease is, in fact, a chronic superficial glossitis. If the more active mischief is checked, the swelling subsides, but the mucous membrane never resumes its healthy character. The patches that have been affected remain smooth and shining. The papillary structure has been impaired, and what is left is in fact cicatricial tissue, a tissue which is sensitive to the contact of hot, acid, or pungent substances, and apt to inflame easily. At a later date, portions of this cicatricial membrane become more completely fibrous, presenting a whitish appearance, and being callous to the touch.

TREATMENT.—In the treatment of all of these affections it is important to look to the general health of the patient; to see that he smokes little or not at all—any smoke reaching the mouth should be cool; to forbid alcohol, or allow it only in dilute forms; and to order a simple, nourishing diet, from which hot spices and condiments should be excluded.

Mucous tubercles and small ulcers of the secondary stage require a mercurial course. Drying the lesions and painting them once or twice daily with a solution of the bichloride of mercury (grs. ij—viij ad ʒj) is helpful.

Gummata and gummatus infiltrations disappear most quickly under iodide of potassium. With this, if the gummata are appearing early, or if the patient has never been satisfactorily treated with mercury, or, again, if the iodide does not act quickly, a little mercury should be given. Broken gummata should be treated with a borax-wash

used frequently, and dusted twice daily, after food and subsequent washing of the mouth, with a powder composed of grey powder, iodoform, and starch in equal parts.

The treatment of chronic superficial glossitis is far from satisfactory. The first object should be to improve the digestion, and to regulate the general health. When there is much superficial soreness, a mouth-wash of borax and glycerine, bismuth and glycerine, or chlorate of potassium, should be ordered. The patches may be painted with a non-irritating mercurial lotion. Irritants should never be used, in view of the danger that these cases may develop epithelioma. The treatment too often consists in combating soreness and irritation, and in watching for induration, indicating the down-growth of epithelium. Free operation should follow at once upon the discovery of this.

11. Tongue-tie.—The tongue is said to be 'tied' when the frænum is either too short or comes farther forward than it should, and thus restrains the movements of the tip, which often seems slightly bifid. The infant cannot put out its tongue, or use it in sucking; and, if allowed to remain, the defect interferes with speech.

TREATMENT.—Operative interference is required, as follows: Place the child with its head on the nurse's knees, towards the surgeon; raise the tip of the tongue and stretch the frænum with the left forefinger, and snip through the thin part of the frænum with scissors, which will, naturally, be pointed downwards, parallel to the ranine veins. A little pressure down and back into the wound with the left forefinger will still further free the tongue. Mothers often suppose that their children are tongue-tied when, in truth, they are only backward in speaking; so the surgeon should form his own opinion before operating.

12. Tubercular Ulceration.—This may be either primary or secondary; the former is very rare. The latter is secondary to laryngeal or pulmonary tuberculosis, suggesting the possibility of auto-inoculation.

DESCRIPTION.—Tubercular ulcers of the tongue are much more common in men than in women. They occur at all ages, are not uncommonly multiple, and rarely reach a large size (one inch square) or a great depth (quarter of an inch). They are most frequent upon the tip and edge adjacent, then upon the dorsum, and then underneath the free part. They begin as small nodules in the mucosa, which ulcerate, exposing a greyish or yellowish slough. Cheesy stuff may be seen on the surface. If the extension is slow, the edge becomes somewhat raised, red and rounded, the floor is formed of pale granulations, and the surrounding parts are little or not at all cedematous. There may be enough induration to raise a suspicion of cancer. When the spread is rapid, the edge is thin and ragged, often undermined; the base may be sloughy, or the structure of the eroded tissue may be clear; there is no induration. The symptoms are soreness, sensitiveness, and more or less ptialism; when advanced, the ulcers may be very painful. The lymphatic glands may enlarge, but this is by no means constant. Microscopically, they present all the characteristics of a tubercular ulcer.

DIAGNOSIS.—Many tubercular ulcers have been excised as malignant—a mistake of little consequence. Gummatus ulcers are distinguished chiefly

by a history of syphilis, situation on the dorsum, depth and thin ragged edges, absence of tubercle-bacilli in the discharge, and the effects of treatment.

PROGNOSIS.—A small tubercular ulcer may heal, but only to break out again. After suffering much from the ulcer, a patient usually dies from disease of the larynx or lungs.

TREATMENT.—If the ulcer is primary, or if the primary disease of lung or larynx is early, the ulcer should be excised under cocaine, and the sides of the wedge-cut sewn up. If there is advanced disease of lung or larynx, and the ulcer is not painful, iodoform and starch in equal parts may be applied after food. If there is much suffering, excision may be done, or phenol freely applied.

13. Tumours.—The mucous membrane of the tongue is occasionally the seat of simple warts; and fatty, fibrous, cartilaginous, bony, and nævoid growths have more or less rarely been removed from this situation. They are sometimes deep in the tongue-substance, or more or less polypoid. The lymphoid tissue beneath the mucosa in front of the epiglottis may hypertrophy and form a small protuberance on one or both sides of the mid-line, giving rise to little or no trouble. A few instances have been recorded (all in women) of simple tumours having the structure of the thyroid, growing in the base of the tongue and probably connected with the thyroglossal duct. Sarcoma is very rare; cancer is the tumour of the tongue.

TREATMENT.—Small warts may be dried and touched with 30-per-cent. solution of chromic acid till they shrivel and fall off; or they may be snipped off, together with the mucosa whence they spring. Larger masses require excision. The other tumours mentioned, if troublesome, all require excision. Eucaïne anaesthesia is often sufficient (*see* p. 59). Removal of a part of thyroid growths has been followed first by increase, then by wasting of the remainder.

14. Ulceration.—Ulcers of the tongue are best classified according to their causes, so far as we know them. We thus get the following groups: *simple, tubercular, syphilitic, and cancerous.* Under the heading 'simple' we include *traumatic, dyspeptic, and aphthous* ulcers, and the sores on the tongue which form in non-specific leukoplakia, or in ulcerative and mercurial stomatitis. Only the traumatic and dyspeptic ulcers remain undescribed; for the other varieties reference may be made to the special sections.

Traumatic ulcers may be due to injuries of all kinds, but the injury caused by teeth often leads to an ulcer difficult to recognise. A sharp tooth or tooth-plate, though constantly present, does not irritate equally at all times, but more (it is supposed) in dyspeptic or depressed states. The ulcer at first has the characteristics of a small spreading ulcer—sloughy or bright red base, sharp-cut low margins, more or less cedematous surroundings. It is irritable and painful. After weeks or months, the base becomes paler, the margins thicker and rounder, and more or less indefinite induration of the base appears. Naturally, the seat of these ulcers is almost invariably the edge or tip. In their diagnosis, the relation to an irritant, the absence of a history of syphilis or tuberculosis, the absence of cancerous induration, and the effect of removal of the cause and subsequent treatment, are the chief points.

Dyspeptic ulcers are apt to occur in ill-fed children, and also in adults who habitually eat and drink

too freely. Such ulcers are generally situated upon the sides or upper surface near the tip; but not infrequently they are on the frenum. They are encircled by an inflamed margin; shallow; their bases being flat and covered with a greyish slough. They are very sensitive to the touch, and painful when the organ is moved. Sometimes there is offensive discharge, with a good deal of swelling of the sublingual and submaxillary glands.

TREATMENT.—Defects of digestion must be attended to; a cholagogue purge is often a good beginning. The mouth should be kept scrupulously clean, and all sources of mechanical irritation removed. Honey of borax should be used frequently; and the ulcers dried and painted with chromic-acid solution (grs. v-x to ʒj) every two or three days.

STANLEY BOYD.

TONIC (τόνος, tension). — A distinctive term used in reference to the nature of spasms, which are usually divided into two classes, namely, *tonic spasms* and *clonic spasms*; the former being those in which the muscles concerned remain in a state of continuous rather than in one of intermittent contraction or clonic spasm. See SPASM.

TONICS (τόνος, tension, tone). — **SYNON.**: Fr. *Toniques*; Ger. *Tonische Mittel*.

DEFINITION. — Therapeutic agents which increase the strength of the body or its parts.

ENUMERATION. — Among the most typical medicinal tonics, which impart a feeling of strength, are Iron, Nux Vomica, Quinine, and Vegetable Bitters. As the strength of the body generally depends on the proper action of its various parts, tonics have been subdivided into those which have an especial action on the blood-circulation, digestion, and nervous system.

1. **Blood-Tonics.**—Cod-liver oil and other fats, and iron and its salts, are the most important of this group of tonic remedies. Perhaps also phosphate and hypophosphite of calcium, salts of potassium and sodium, arsenic, and phosphorus should be included. Light, fresh air, good food, bathing, and exercise are valuable adjuncts.

2. **Cardio-vascular Tonics.**—The principal vascular tonics are Nux Vomica and Strychnine, Digitalis, Strophanthus, Erythrophloeum, Squill, and Caffeine. The local application of warmth and cold, friction, and massage increase the effect of these medicines.

3. **Gastric Tonics.**—Small doses of Sulphuric, Nitric, Hydrochloric, and Phosphoric Acids, small doses of Arsenic, Alum, Bismuth, Copper, Silver or Zinc, Aloes, Bitter Beer, Chamomile, Cinchona, Cusparia, Cascarella, Calumba, Hops, Gentian, Orange, and Lemon-Peel, Quassia, Rhubarb, Strychnine, and Vegetable Bitters, generally all impart vigour to the gastric function. Valuable adjuncts are pepsin and hydrochloric acid.

4. **Intestinal Tonics.**—These are chiefly Nux Vomica, Belladonna, Rhubarb, the Mineral Acids and Metallic Salts just mentioned, and astringents.

5. **Nervine Tonics.**—Nux Vomica and Strychnine, Cinchona and its alkaloids, Coca, Phosphorus, Arsenic and its compounds, salts of Iron, Zinc, Copper and Silver, are all included under this head. The tonics which act especially on other parts of the system increase also the power of the nervous system, and act indirectly as nervine tonics.

ACTION.—The derivation of the word 'tonics' indicates the nature of their action. When a person feels limp and weak, and unfit for exertion, tonics restore the energy and strength, and render him again fit for work. The exact mode in which tonics act is not yet perfectly ascertained, but in all probability they increase the functions of the different parts of the body by aiding tissue-change, either by increased nutrition, increased tissue-metabolism, more rapid removal of waste, or possibly by all three taken together. See TONE, Want of.

USES.—Tonics are employed in conditions of debility, either of the body generally or of its different parts, the selection of each depending upon the part of the body affected.

In cases where the malnutrition of the body appears to be dependent on the want of the proper constituents of the blood, as in anæmia, struma, or general debility, without any affection of a particular organ, *blood-tonics*, including iron, cod-liver oil, phosphates, and hypophosphites are employed; and these are also useful where impoverishment of the blood is due to a definite constitutional disease, such as phthisis, or Bright's disease. In pernicious anæmia phosphorus or arsenic may be used. Where enfeeblement of the stomach appears to be present, as shown by loss of appetite and such signs of imperfect digestion as flatulence, weight and pain after eating, *gastric tonics* are used. Should its muscular coat be feeble or inactive, as shown by tendency to dilatation, and splashing of the contents on movement, strychnine is especially indicated, and galvanism or systematic kneading may be also employed. Where the stomach is too debilitated to respond sufficiently to this form of treatment, as after long-continued gastric catarrh, or in old age, its work must be partly done for it, and then such substances as hydrochloric acid and pepsin are useful. When the muscular movements of the intestine are sluggish, as indicated by constipation, and by a tendency to the distension of the bowel with gas, nux vomica and belladonna may be given; and when its mucous membrane appears to be relaxed and flabby, and secreting too profusely, the mineral acids, astringents, and metallic salts may be of much service. When the pulse is soft and feeble, and there is a tendency to vascular dilatation, either general or local, as shown by local congestion and cedema of dependent parts, or by drowsiness in the upright position and sleeplessness in the recumbent posture, *vascular tonics* are serviceable. *Nervine tonics* are used where the nervous functions are imperfectly performed, as shown by dulness, loss of memory, incapacity for work, languor, or tendency to spasm, as in chorea, and also in paralysis. As the functions of this system depend very greatly upon the quality of the blood with which the nervous system is supplied, and on the rapidity of the circulation, the other tonics frequently require to be given in addition to nervine tonics.

In administering tonics care should always be taken to ascertain that the case is suitable, for in very many cases of apparent debility the imperfect functional activity of the body or of its parts does not depend upon insufficient nutrition, but upon imperfect removal of the products of waste. The proper treatment in these cases is not to give tonics, but to remove the waste products by cholagogues, purgatives, and diuretics.

T. LAUDER BRUNTON.

TONSILS, Diseases of.—SYNON. : Fr. *Maladies des Amygdales* ; Ger. *Krankheiten der Mandeln*.

Of recent years increased attention has been paid to the tonsils as the starting-point of general infections. Just as large foreign bodies, such as fish-bones, &c., may become impacted in the tonsil, so pathogenic bacteria, contained in food or drink or taken in with inspired air, may find a lodgment, multiply and excite a local disease, which may be the commencement of a general infection. This is especially likely to happen if the tonsils be unhealthy, e.g. the seat of chronic hyperplasia. Thus the seat of inoculation of such diseases as scarlet fever, rheumatic fever and diphtheria is not improbably the tonsil, and the occurrence of pericarditis and infective endocarditis, immediately following attacks of tonsillitis, has led to the suspicion that the tonsil may afford the means of entry for the infecting virus.

Examination of chronically enlarged tonsils has led to the detection of tubercle-bacilli, and from this site the deep cervical glands may be infected and further progress may lead to infection of the bronchial glands and lungs.

Among the less common diseases of the tonsil are the following :—

1. *Neoplasms*.—Lymphomata, fibromata, papillomata, angiomata, cystic tumours and calculi (carbonate and phosphate of lime). Carcinoma is generally primary. Sarcomata are usually of the small round-celled variety.

2. *Tuberculosis*.—Lupus of the tonsil is generally associated with similar disease of the palate and fauces. Tubercular ulcers, lenticular in shape, with freely granulating sloughy bases, are of somewhat rare occurrence.

3. *Syphilis*.—The tonsil may rarely be the seat of the primary chancre, commonly of mucous patches, or of a gumma.

4. *Actinomycosis*. See p. 22.

5. *Diphtheria*. See p. 398.

6. *Herpes facialis*. See p. 685.

7. *Concretions*. See p. 334.

The acute and chronic inflammatory processes affecting the tonsils are of peculiar interest to the student and practitioner. For purposes of classification they may be divided into two groups, superficial and deep. In the former will be included acute and chronic lacunar (follicular) tonsillitis, membranous tonsillitis, and ulcerative tonsillitis ; in the latter acute parenchymatous tonsillitis and peritonsillitis. Hypertrophy of the tonsils will be described under a separate head.

Acute lacunar tonsillitis.—This and the allied conditions of membranous and ulcerative tonsillitis have to be sharply distinguished from diphtheria, and we would strongly urge the advisability of routine bacteriological examination in all such cases. By this method, and by this method only, can the diagnosis be certainly established.

Our knowledge of the ætiology of superficial tonsillitis has undergone considerable modification of recent years. While it is generally admitted that cold, rheumatism, gout and general debility may be predisposing causes, it is believed that the direct exciting causes of these attacks are micro-organisms, and cultures may reveal the presence of streptococci, staphylococci, *Micrococcus tetragonus*, *pneumococcus*, *Hoffman's bacillus*, *B. coli*, or the fusiform bacillus, either alone or with various associates. An explanation is thus afforded of the undoubtedly

infectious character of tonsillitis, and its causation by drainage-defects, septic surroundings, dust, &c.

SYMPTOMS.—Acute lacunar tonsillitis is marked at its commencement by high temperature (102°–104° F.), pains in the limbs, headache, and the usual accompaniments of fever. The patient complains of the throat being sore, and there is difficulty in swallowing. The tongue is coated and bowels constipated. A puffiness may be present at the angles of the jaw, and the neck is stiff and painful on movement. Inspection shows the tonsils enlarged and red, with the lacunæ plugged with yellowish-white exudation, consisting of dead epithelium, leucocytes, bacteria, &c. The palate and uvula share in the inflammatory process. This condition may persist from three to seven days, leading to a condition of extreme prostration. The enlargement of the tonsils subsides gradually, but occasionally a deep-seated parenchymatous or peritonsillar abscess may form (quinsy).

PATHOLOGY.—An inflammation limited to the crypts and covering mucous membrane.

TREATMENT.—A brisk saline purgative should always be given at once. The patient should be kept in bed so long as the temperature is above normal. A mixture of quinine, tinct. ferri perchlor. and potass. chlorat. used as a gargle and swallowed is very useful. Salicylate of sodium is also a valuable drug, given every three or four hours. *Locally* a gargle or preferably a spray (as gargling is so very painful) of solution of permanganate of potassium, formalin (1 in 250), hydrarg. perchlor. (1 in 4,000), resorcin (10 per cent.) to be used frequently, will remove all septic plugs from the lacunæ in three or four days in the majority of cases. As much non-irritating nutritious food as the patient can take is advisable.

Chronic lacunar tonsillitis.—In this condition the tonsils may or may not be enlarged or inflamed, but the crypts are seen to be distended with caseous material which may have a very offensive odour. There is constant faucial irritability, and often some pain in swallowing, but no febrile disturbance except when, as not infrequently happens, acute attacks of tonsillitis supervene.

TREATMENT.—Occasionally relief may follow the scraping of the crypts and subsequent dressing of the tonsil. Or we may plunge the galvano-cautery point into them. Frequently the best plan is to cut out or punch out the diseased gland.

Membranous tonsillitis.—This condition is seen in the acute exanthemata, such as scarlet fever. It may, however, arise quite independently. The membrane is of a yellowish-white colour, soft, contains much mucus, and is readily detached from the underlying surface which is not ulcerated. It may spread to the palate and larynx. The condition can be differentiated from diphtheria by repeated bacteriological examinations. The organisms usually found in simple membranous tonsillitis are staphylococci, streptococci, the fusiform bacillus, and a few other bacillary forms. The urine may contain a trace of albumen.

Ulcerative tonsillitis.—Two varieties of this condition are met with : (1) small superficial ulcers following coagulative necrosis (drain-throat) ; (2) larger single or double ulcers about the size of a threepenny-bit with sloughy base and punched-out edges.

Treatment is essentially the same as that described under acute lacunar tonsillitis.

Acute parenchymatous tonsillitis and peritonsillitis (Quinsy).—This condition is peculiarly common in rheumatic subjects. One or both tonsils may be attacked either simultaneously or in succession.

PATHOLOGY.—An inflammation attacking the lymph-nodes and peritonsillar tissue, frequently terminating in suppuration. Bacteriological examination of the pus shows the presence of micro-organisms, most frequently streptococci.

SYMPTOMS.—From the commencement of the attack fever is high, and when pus forms there may be a rigor. There is headache, pain in the neck and throat, radiating to the ear, due to cellulitis and periadenitis, difficulty in speech and swallowing, and, as the case progresses, in breathing. Much stringy mucus forms and flows from the mouth, the tongue is foul, the bowels constipated. The swelling at the angle of the jaw may lead to difficulty in opening the mouth. There may be delirium, and prostration is always marked.

On inspection, the tonsil and soft palate on one or both sides are seen to be red, swollen, hard, and tender, and more or less coated with mucus. The tonsils may meet in the middle line. As the swelling progresses it tends to bulge towards the upper and front part of the anterior pillar, and if pus is present the abscess may show signs of pointing here. The glands at the angle of the jaw enlarge.

The inflammation may undergo resolution, or pus may form and escape spontaneously. The condition may last for from seven to ten days, but in a great many cases we can either secure resolution before this, or open the abscess early, and so relieve the patient of this intense suffering.

TREATMENT.—The general condition is relieved by a purge, and by the administration of salicylate of sodium in 20-gr. doses every 4 hours. The mouth and throat should be frequently syringed or gargled with an alkaline or antiseptic solution. The local condition may be checked by the use of guaiacum-lozenges, sucking ice, or by painting the tonsils with a 10-per-cent. solution of eucaine, or with a 50-per-cent. solution of guaiacol in oil of almonds.

During convalescence tonics are indicated in the form of iron or bark.

If suppuration has occurred and there is sign of pointing, the abscess should be incised by means of a bistoury and sinus-forceps to reach the pus, which is often very deeply situated. The incision can generally be made with greatest advantage through the soft palate, or upper and front part of the anterior pillar, in a direction from without inwards. A hot antiseptic gargle should then be used for a day or two.

Chronic enlargement of the tonsil.—This condition is most common in strumous, tubercular and rachitic subjects, but it is often seen in perfectly healthy children. Bad hygiene and repeated attacks of follicular or parenchymatous tonsillitis may be causes, and not infrequently the tonsils enlarge subsequent to an attack of one of the exanthemata. Hypertrophy of the tonsils is commonly associate with nasal obstruction and adenoid vegetations in the naso-pharynx, and no examination of the throat can be regarded as complete which does not include careful investigation of the condition of these cavities.

PATHOLOGY.—When the tonsils are soft and spongy the condition is one of increase of the lymphoid tissue of the glands. As a rule in adults

where the tonsils are firmer there is also an increase of the fibrous connective tissue.

SYMPTOMS.—On inspection, one or both tonsils are seen to be enlarged, sometimes completely blocking the fauces. The mouths of the crypts may be filled with caseous exudation, or the tonsil may be traversed by fibrous-looking bands giving rise to a 'honeycomb' appearance. Occasionally the anterior pillar of the fauces is adherent to the tonsil, which, instead of projecting forwards, shows a broad flattened surface extending back towards the posterior wall of the pharynx. The deep cervical glands may enlarge. Beyond giving rise to a slight choking sensation or difficulty in swallowing and alteration of voice, enlarged tonsils do not directly trouble the patient. Gradually, however, from obstruction of the naso-pharynx, mouth-breathing is adopted, the voice loses its clearness, becomes muffled or nasal in character, and there is difficulty in pronouncing palatal consonants. As a result of the respiratory obstruction the lungs are imperfectly distended, and the chest may assume the narrow, pigeon-breast type. Deafness and cough are common accompaniments, because adenoid vegetations are so often associated. Children with enlarged tonsils are often lethargic, ill-developed, and badly nourished. This results not only from the imperfect oxygenation of the blood, but also from constant absorption of bacteria and their products from the distended lacunæ. The repeated attacks of acute tonsillitis to which such persons are subject must, too, contribute to the general malaise. It seems certain that enlarged tonsils may excite attacks of asthma, bronchial catarrh, and in children be responsible for disturbed rest, night-terrors, &c., but all these symptoms are greatly exaggerated where adenoids coincidently exist.

TREATMENT.—In some cases the hypertrophy disappears at the age of puberty, and no treatment is called for. On the other hand, where there is definite respiratory obstruction, and the health and development of the patient are obviously suffering, treatment is imperative. No local treatment is of any avail in diminishing the enlargement, and the usual remedies have only the effect of distressing and frightening the patient. Enlarged tonsils in children should be excised with the tonsillotome or with a tonsil-punch; and in adults, as a rule, the glands may be removed in the same manner, though some surgeons use the galvanocautic snare, or an écraseur, or cauterise with the electric point at one or more sittings. The last procedure is tedious, and our experience of anything approaching serious hæmorrhage is so very slight that the tonsil-guillotine may be looked on as a safe instrument, even in persons many years older than adult age.

J. BARCLAY BARON.

TOOTHACHE.—SYNON.: Fr. *Odontalgie*; *Mal de Dents*; Ger. *Zahnweh*.—Pain in connection with the teeth. See **TEETH**, Diseases of.

TOOTH-RASH.—See **DENTITION**, Disorders of.

TOPHUS (*tophus*, sand).—A term associated with the concretions, consisting chiefly of sodium biurate, which are met with in gout, in connection with the joints and other structures (p. 332). It is also sometimes applied to gravel in the urine, and to the collection of tartar on the teeth. See **GOUT**.

TORMINA (Lat. griping).—This word is applied to severe griping or colicky pains in the abdomen, due to flatus and other causes. See COLIC; DYSENTERY; and INTESTINES, Diseases of.

TORPOR (Lat. numbness).—**SYNON.**: Fr. *Torpeur*; Ger. *Torpidität*.—A condition of inactivity, bodily and mental, which may be met with in certain cerebral diseases or febrile states, more especially in aged persons. The cerebral condition associated with torpor is an unnatural state of consciousness, closely allied to that known as stupor. See CONSCIOUSNESS, Disorders of.

TORQUAY, in South Devonshire.—A mild, rather relaxing, and sedative marine climate. Sheltered from W., N., and E. winds. Mean winter temperature 44° F. See CLIMATE, Treatment of Disease by.

TORSION (*torquco*, I twist).—This word signifies a twisting, and is used in medical literature in the following associations:—

1. In relation to certain organs or growths, it indicates a form of displacement in which the mass is twisted on itself, a condition especially noticed in connection with the intestines. It gives rise to more or less narrowing of canals, and may close them completely, so as to cause absolute obstruction. Torsion also interferes with the local circulation, thus leading to congestion, inflammation, or ultimately even to gangrene of organs or tumours. See INTESTINAL OBSTRUCTION; and OVARIES, Diseases of.

2. As a method of treatment, torsion is employed in checking arterial hæmorrhage, the end of the bleeding artery being seized by the aid of suitable forceps and twisted. It is chiefly used in bleeding from small arteries, but may prove efficient even when arteries of some size are the source of the hæmorrhage. FREDERICK T. ROBERTS.

TORTICOLLIS (*tortum*, twisted; and *collum*, the neck).—A synonym for wry-neck. See WRY-NECK.

TORULA.—**DESCRIPTION**.—Torula is a form of microscopic fungus, belonging to the group *Saccharomycetes*. It consists of round or ovoid cells, of an average diameter of about $\frac{1}{3000}$ inch, without nuclei, but composed of masses of vacuolated protoplasm, confined within a definite cell-wall. Occasionally they are free, but they are frequently associated into branching chains.

Vinous, acetous, and other fermentations are due to the presence of organisms, of which the 'yeast-plant,' *Mycoderma* or *Torula cerevisiæ*, is the best known. Certain varieties of torula are of constant occurrence in the alimentary canal, and would seem to be normally associated with intestinal digestion. In those cases of vomiting where the ejected matters ferment, torulæ are always to be found, together with sarcinæ. These bodies are also of frequent occurrence in the urine of diabetes mellitus, if left standing; but they have likewise been found in non-saccharine urine. The pathological significance of torula, if any, is not known.

W. H. ALLCHIN.

TOUCH, Disorders of.—**SYNON.**: Fr. *Troubles du Tact*; Ger. *Störungen des Tactsinnes*.—The sense of touch may be considered as a compound of four distinct senses, namely, those

of contact, pain, temperature, and muscular activity; and it is not necessary that all these should be affected simultaneously or in an equal degree. Sometimes but one is the seat of disorder, and occasionally only one escapes. The lesion producing tactile disorder may be in any part of the sensory apparatus—in the peripheral end-organ in the skin, which receives impressions, in the trunk of the nerve which conveys them, or in the central ganglion, the reaction in which is represented in consciousness as feeling. For the most part disorders of touch must consist either in a defective or in an unnaturally heightened reaction to impressions—conditions which are termed respectively *anæsthesia* (or *hypesthesia*) and *hyperæsthesia*. But there are besides certain abnormalities of sensation which cannot be referred to either of these categories, as, for example, when a touch causes a sensation of burning, or the electric current is felt as something cold, and in these circumstances the term *par-æsthesia* is used.

1. **Increased Sensibility.**—**DESCRIPTION.**—

It is doubtful whether the sense of touch proper, the power of tactile discrimination, is ever morbidly increased, except possibly in certain cases of hysteria and mental disorder. The term *hyper-æsthesia* would be properly applied to such a condition instead of, as it is more commonly used, to excess of sensibility to painful impressions, which is better called *hyperalgesia*. In cutaneous *hyperalgesia* even a light touch upon the skin produces more or less exquisite pain. The patient often cannot even wash the skin, which is described as feeling raw or sore to the touch (see PAIN IN VISCERAL DISEASE). The symptom frequently occurs in connection with neuralgia (especially of the trigeminal nerve), and in hysteria, as well as in the various forms of local inflammation. It may precede by some days the characteristic pains of neuralgia; is often associated with excess of sensibility to heat and cold; and usually with diminution of sensibility of the tactile sense proper. It is seen in its severest form in connection with gunshot injuries of nerves.

There may be heightened sensibility to temperature, either as regards heat or cold singly, or in respect to both at the same time. This symptom is observed in connection with both peripheral and central disease—as an accompaniment of neuritis, as well as of degenerative changes in the cord or cerebral ganglia.

Heightening of the sense of contact is rarely observed, and is of but little practical importance. Perhaps the condition known as 'fidgets' is best explained as depending upon a heightened sense of muscular activity.

TREATMENT.—So far as is practicable, the lesion which is the cause of hyperalgesia, whether peripheral or central, must be discovered and become the subject of treatment. But the symptom itself may be mitigated by appropriate means. Such are the local application of moist heat by fomentation or poultice; of cold by means of ice; or of anodynes, such as veratrine-ointment somewhat diluted, or atropine-ointment; or, as a last resource only, to be avoided if in any way possible, the hypodermic injection of morphine (gr. $\frac{1}{10}$ to gr. $\frac{1}{8}$). Spongipiline may be sprinkled with a liniment composed of chloroform one part and belladonna liniment three parts; or equal parts of ether, sal volatile, laudanum, and eau de Cologne may be

applied. A piece of lint soaked in chloroform may be laid upon the painful portion of skin and covered with oiled silk, or the part may be rubbed with camphor-chloral and vaseline, equal parts; or painted with amyl-colloid. The application of one pole of the continuous current to the hyperalgesic spots, while the other is placed on an indifferent part, will often be of service, the power of bearing a gradually increased strength showing the improvement produced. Hysterical hyperalgesia can sometimes be successfully treated by the application of a strong induced current, by means of the wire brush, the patient, if necessary, being placed under the influence of ether.

2. Defective Sensibility.—DESCRIPTION.—Cutaneous anaesthesia may result from local abstraction of heat, as from exposure to a very low temperature. In such a case anaemia is produced, from spastic contraction of blood-vessels, followed by hyperaemia from their secondary relaxation. In the anæmic stage, while the other tactile sensations are lowered, that of temperature is heightened. Deficient sensibility may be caused by irritating applications, such as soda used by laundresses, and various chemicals employed in the arts. In such cases there is numbness in the hands and forearms, with a sensation of 'going to sleep' in the fingers. It may occur in connection with *herpes zoster*, the skin between the groups of vesicles being often partially anaesthetic. In *lepra anaesthetica*, in which there are enlargements of the cutaneous nerves, the senses of temperature and pain are often abolished, and severe burns may take place without being recognised. Anaesthesia may be produced by pressure upon sensory or mixed nerves by syphilitic and other growths in adjacent tissues. Narcotics, as chloroform and ether, may quell the sense of pain, that of contact being, to a certain extent, retained. Wounds and lacerations of the sensory or mixed nerves, followed by inflammatory processes, may, by irritation, cause pain to precede the anaesthesia arising from the interruption of conductivity in the nerve-fibres. Simple mechanical pressure upon a nerve, if long continued, will often, especially if its nutrition be impaired by constitutional causes, excite a low inflammatory condition. In traumatic cases, as also in *lepra anaesthetica* and in cases of new-growths pressing on the nerve, motor and nutritive disturbances are apt to accompany the anaesthesia, the nerve-trunks conveying not only sensory, but also motor, vaso-motor, and trophic fibres. Severe trophic disorder is usually associated with the anaesthesia occasioned by lesion of the fifth nerve; and to a less extent with that accompanying trigeminal neuralgia. *See FIFTH NERVE, Diseases of.*

Preceding attacks of neuralgia, the skin of the part about to be affected is often found to be anaesthetic, and during attacks of sciatica and cervico-brachial neuralgia there is often much diminution of tactile sensibility, in the foot and lower part of the leg, and in the fingers respectively; while the skin around the eye may be greatly deficient in tactile sensibility during severe supra-orbital neuralgia. It is important to discriminate anaesthesia of the skin caused by diseases of the nervous centres from that which is of peripheral origin.

Cutaneous anaesthesia is occasionally an important symptom of an approaching cerebral hæmorrhage. A sudden and increasing numbness is experienced in one half of the face, or in the limbs on one side

of the body, which may be followed shortly by hemiplegia and coma. An apoplectic seizure usually causes unilateral cutaneous anaesthesia, which is at first widely diffused, owing probably to the disturbance of circulation in, and consequent disarrangement of, the nervous molecules, and extends at first far beyond the site of the effusion. A few hours or days usually suffice for the clearing up of this anaesthesia, leaving, however, a subjective feeling of numbness, which may endure for a longer or shorter period.

The extent of anaesthesia bears no necessary relation to the amount of motor paralysis. It usually affects the paralysed side of the body, but in certain cases of hæmorrhage into or other lesion of the medulla oblongata and pons Varolii, it may occupy the opposite side. Complete hemi-anaesthesia of central origin may persist long after the paralysis of motion has disappeared, and in such a case a lesion is likely to be found involving the internal capsule. Occasionally, too, hemi-anaesthesia may from the first be unaccompanied by motor paralysis. Much more frequently, however, cutaneous anaesthesia (except for the first few hours) is of comparatively slight and transitory character, even in cases where there has been extensive disorganisation of the brain from hæmorrhage or softening, and where the resulting paralysis of the muscles is complete and permanent. Recovery is gradual, and proceeds downwards, the fingers sometimes retaining slight anaesthesia long after the rest of the arm has entirely recovered.

Cerebral tumours may give rise to cutaneous anaesthesia by pressure upon the Gasserian ganglion, or upon the trunk or branches of the fifth nerve as they traverse the floor of the skull. Like the motor paresis or paralysis which may be occasioned at the same time, the loss of sensibility is usually, but not always, gradual, tending to increase rather than to diminish as time goes on. It is not usually a prominent symptom in cerebral abscess.

Lesion of the spinal cord or of its membranes may give rise to cutaneous anaesthesia, which is frequently, in the lower extremities, extensive and complete; but it may be absent when—as, for example, in very advanced sclerosis of the antero-lateral columns—there is complete paraplegia. There is a form of progressive disease of the central and posterior grey matter of the spinal cord, giving rise to excavation, in which cutaneous sensibility is apt to be modified in a remarkable manner. The sense of touch, the sense of pressure, as well as the electro-muscular sensibility and the muscular sense, are preserved; but the appreciation of temperature and the sensation of pain (one or both) are lost in many situations. The condition is accompanied by paralysis and various forms of nutritional disturbances (*see SPINAL CORD, Diseases of: 22. Syringomyelia, p. 1559*). A varying amount of cutaneous anaesthesia, especially affecting the soles of the feet, is apt to occur in tabes. Anaesthesia of spinal origin is usually bilateral; but it is believed to affect that lower extremity alone which is opposite to the one paralysed in its motility, when the causative lesion is limited to one lateral half of the cord. Intercurrent complications from disturbances of circulation, the temperature of the limb, the extension or subsidence of inflammation, and the effusion of inflammatory products about the posterior roots, as well as the spread of sclerotic changes, may cause the extent and completeness of

cutaneous anæsthesia to vary considerably in cases dependent upon spinal-cord disease. Where the lesion lies tolerably high up, tickling the soles of the feet, although quite unfelt by the patient, is able to excite the motor nerves, and produce reflex muscular contractions, which the loss of muscular sense prevents him from recognising. It is extremely important to remember that cutaneous anæsthesia of spinal origin is liable to be associated with bed-sores. In certain cases, probably where trophic and vaso-motor nerves have been included in the lesion, this liability is excessive, and may defy all precautions.

Anæsthesia is of very frequent occurrence as a result of peripheral neuritis, both in its localised and multiple form. See NEURITIS, MULTIPLE.

Loss of the *sense of muscular activity* may occur in an isolated form, the other modes of tactile sensibility being unaffected; or it may be associated with impairment of some or all of them. The symptom is especially notable in progressive locomotor ataxy (see TABES DORSALIS). It may also occur in connection with paresis resulting from coarse disease of the occipital lobe of the cerebrum. Loss of muscular sense may accompany hemiplegia, attended by strongly marked and prolonged anæsthesia, from disease of the internal capsule. It occurs sometimes in hysteria. There is a form of anæsthesia occasionally met with in hysteria which it is important to recognise, so as not to confound it with a somewhat similar condition resulting from organic disease of the internal capsule. In this the patient may lose the power of perceiving impressions of contact, temperature, and pain throughout the whole of one lateral half of the body, sharply divided from the sound side by a line passing downwards from the vertex to the os pubis. Accompanying this *hemianæsthesia*, as it is called, there is often amblyopia and colour-blindness of the corresponding eye, loss of taste and smell, together with tenderness on deep pressure over the region of the ovary on the same side. In some cases, too, the skin is unnaturally pale and cold, and pricks with a pin are said to be not followed by bleeding, which readily takes place in corresponding circumstances on the opposite side of the body.

There is a curious form of disturbance of tactile sensation in which, the patient being blindfolded, a point of contact is referred not to its true locality, but either to some part of the opposite limb, or to a distant part of the same member (*allochiria*).

DIAGNOSIS.—As regards both hyperæsthesia and anæsthesia the most important consideration, after establishing the existence of either, is as to whether the cause be central or peripheral. It is impossible to do more than indicate the general principles upon which this inquiry is to be conducted. The patient's history, the condition of viscera and circulation, the existence or not of accompanying paralysis or of modifications of the organs of special sense, will lend important aid. As a rule, the anæsthesia of central origin is much more widely diffused, though less complete, than that dependent upon lesion of nerve-trunks, when it is also often accompanied by localised atrophy of muscles or other trophic disturbance. It is very rarely that hemianæsthesia of central origin is so complete as the hysterical, and it is not accompanied, like the latter, by tenderness on deep pressure over the ovarian region. There is no doubt that hyperæsthesia has often been mistaken for localised inflammation, and

treated accordingly. The absence of febrile movement, and the fact that it is mainly upon light surface-touching that the exquisite tenderness occurs, which fails to be felt when deeper pressure is made, coupled with the history, and a study of the concomitant condition, ought to suffice to prevent all mistakes.

TREATMENT.—Anæsthesia is a symptom of a lesion either in the central nervous system or in a peripheral nerve, and its treatment is bound up with that of the disorder which gives rise to it. But there are many cases in which, apparently as a result of disease, the sensory nerves fail to convey impressions for a considerable time after the lesion which interfered with their function has been healed. In such circumstances very much good can often be done by electrical treatment. The skin, carefully dried, should be brushed over for a few minutes every day with the wire brush, connected with an induction-machine; or the well-wetted rheophore connected with the negative pole of a continuous-current battery may be slid about over the affected surface, well moistened with hot water, the positive pole, also well wetted, being placed on an indifferent spot.

Static electricity is a valuable means of combating anæsthesia of this kind. The patient, seated on an insulating chair, is connected by a conducting chain with a frictional electrical machine, and sparks are drawn from the affected surface.

3. *Paræsthesia*. — DESCRIPTION. — The varieties in disorder of the different kinds of tactile sensibility—touch, pain, temperature, muscular activity—are very numerous. Pinches or pricks with a needle may be felt as touch only, while a very light touch with the finger is appreciated as heat, cold, or pain. Strong faradic currents (intolerable to the healthy) may be felt as cold. Heat may be felt as cold, but, being kept still longer applied, may be recognised as heat or warmth. A limb plunged into hot or cold water may get the feeling, not of heat or cold, but of pain. To such modifications, as well as to feelings of burning or cold, tingling, creeping of ants, or actual numbness, the term *paræsthesia* is often applied. A seamstress may be able to pick up and thread her needle, evincing thereby considerable delicacy of sense of contact, and yet be scarcely able to feel a prick of a needle in the finger-tip. Or the sense of contact may be in abeyance, as well as that of pain and temperature, and the movements may be then guided by the sense of muscular activity, aided by sight.

T. BUZZARD.

TOXÆMIA (τοξικόν, a poison; and αἷμα, blood).—This word literally signifies poisoning of the blood. It is not employed with any very strict or definite meaning, but most commonly implies blood-poisoning due to some pathological condition within the body itself, in contradistinction to that which results from the introduction of the ordinary poisons from without. As illustrations of toxæmic states may be mentioned pyæmia and septicæmia; uræmia; and certain forms of jaundice.

TOXINS.—The word 'toxin' was introduced by Brierger for certain poisonous bodies produced in connection with the vital processes of bacteria and chemically related to the alkaloids. It was afterwards used for all bacterial poisons, alkaloidal and non-alkaloidal. With the development of the

idea that these non-alkaloidal poisons are proteid in character, the term 'toxalbumin' was used as the collective name for bodies of this class, and included also certain vegetable poisons like ricin, crotin, and abrin, along with certain animal poisons like snake-venom. Still, the word 'toxin' is used loosely for poisons of varying origin and of different chemical constitution.

The origin of bacterial toxins may be considered from two points of view, which are fundamentally different. They are either produced as secretory products by bacteria, or they are contained within the bodies of bacteria and are integral parts of the protoplasm. In the first class the poisons exist and manifest their effects apart from the bacteria which produced them. In the poisons in the second group no toxic effect is produced when the bodies of the bacteria are removed by filtration. As these two types of poisons undoubtedly differ chemically, it is well to separate them as suggested by Buchner, who has proposed to call the endobacterial poisons 'proteins,' reserving the name 'toxins' for the soluble poisons in the first group. From a practical point of view the important bacterial toxins are those of diphtheria, tetanus, and botulismus, while closely allied to them are poisonous vegetable proteids like ricin, abrin, crotin, and certain poisonous proteids of animal origin like cobra-venom. Perhaps one should also include the complex hæmotoxins which are found in certain normal sera, the most important poison of this group being represented by ichthyotoxin, the poison present in the serum of the eel.

As these toxins are unknown as chemically pure products, one usually understands by the term a solution of the poison in some more or less indifferent fluid. For the bacterial toxins this fluid is usually some medium like bouillon or serum, from which the bacteria have been removed by filtration. From the researches of Brieger and Boer it does not appear probable that bacterial toxins are proteid in character, whereas, as far as is known, the vegetable poisons ricin, crotin, and snake-venom are proteids; at any rate, if all proteid is removed, toxic effects can no longer be obtained. In general, the differentiation of these toxins can be made only biologically, and of these biological characters the most important is the ability to produce antitoxin (*see* ANTITOXIN).

With the exception of snake-venom and ichthyotoxin, which act immediately, a definite period elapses between the introduction of the poison and the manifestation of its effects, this incubation-period depending on the nature of the poison to a large extent. In most cases the incubation-period is 6-24 hours; in the case of certain modifications of diphtheria-toxin (toxoid) it may be much longer (2-3 weeks).

The toxins are, as above mentioned, able to produce antibodies, a property which is not possessed by any of the poisons which have an ascertained chemical constitution (morphine, strychnine). This points to the view that the mode of action of the two types of poison on the organism must be different. Apparently the union of poisons like alkaloids with the tissues is slight, as is shown by the fact that the poison can readily be extracted by chemical reagents (Ehrlich, Mayer, Spiro), whereas the true toxins cannot be removed after union has taken place, and are thus probably firmly anchored to the tissues. This fixation takes place very rapidly, probably in

virtue of a specific haptophoric atom-group in the toxin-molecule, and the protoplasm is thus brought under the influence of the poison, the clinical and pathological effects of which are due to a toxophoric atom-group. This theoretical conception of the constitution of a toxin is also borne out experimentally in the case of the frog inoculated with tetanus-toxin. As long as the animal is kept at a low temperature tetanic symptoms do not break out, whereas they manifest themselves in a few hours if the animal's temperature be raised, the explanation of this apparently being that the haptophoric atom-group of the toxin-molecule acts at the low temperature, whereas the toxophoric group acts only when the temperature is raised. The separation of the toxin-molecule into a haptophoric and toxophoric group permits of the explanation of many of the phenomena observed in connection with toxins. Apparently the same haptophoric group may be present, although the toxophore varies. This is the case, e.g., with diphtheria-toxin (the poison of diphtheria, which produces marked lethal effects and local necrosis), and diphtheria-toxon, a poison which is also produced in the diphtheria-cultures, and which is not acutely fatal, but after a long incubation-period gives rise to paralysis. Both the toxin and the toxon possess the same haptophoric group, as immunisation with toxin produces immunity against toxon, and immunisation with toxon protects against toxin (Madsen and Dreyer). For these non-lethal modifications of toxins, Ehrlich has proposed the name 'toxoids,' and they appear to be important bodies which still require much investigation.

For some considerable time it has also been believed that the toxins are related to the ferments, and there is a good deal which supports this view, especially (1) the specific action of the toxins in extraordinarily small doses; (2) the attachment of toxins to precipitates; (3) the instability of toxins in the presence of injurious agents like heat, light, chemicals; (4) the fact that certain ferments, notably rennin, are capable of producing antitoxin, still further bears out the analogy, both toxin and ferment possessing a haptophoric group, and a toxophoric group in the case of toxins, and a zymophoric group in the case of ferments.

The conditions under which bacterial toxins are produced are complicated. There appear to exist toxigenic races of bacteria, from which the toxins are secreted. In some cases toxic bacteria are aerobic (*B. diphtheriæ*), in others anaerobic (*B. tetani*, *B. botulinus*). In most cases the cultures are grown under conditions of aërobiosis or anaërobiosis for 7-10 days, and then filtered through a Chamberland bougie, the filtrate ('toxin') being conserved in the absence of air and light.

The susceptibility of an animal tissue for a toxin depends apparently on the presence or absence of atom-groups in the protoplasm, which have an affinity for the haptophoric group of the toxin-molecule. These protoplasmic receiving-groups ('Receptors' of Ehrlich) vary in quantity and in quality, and the natural immunity to certain poisons probably depends on the absence of suitable receptors, and this absence or relatively slight development of receptors may occur in different animals or vary individually in animals of the same species. For example, the botulismus-toxin, which affects rabbits and monkeys in minute doses, is inert, even in large doses, in dogs. Further, crotin may be

toxic or non-toxic for rabbits. The suitable receptors may be widely distributed in different tissues, or they may be specialised in individual tissues, e.g. in the case of the central nervous system of the mouse and the guinea-pig in regard to tetanus-toxin. In this way one can recognise why nervous symptoms predominate in these animals after the injection of tetanus-toxin. The large local lesions produced by the injection of diphtheria-toxin or abrin would go to show that the receptors for the lymphophores of these toxins are not limited to special organs, and as a consequence that antitoxins against these toxins may be formed in the most varied sites; and this seems to have been proved by the experiments of Roemer as regards the formation of anti-abrin, the antitoxins being vital products of the cells and corresponding to Ehrlich's 'side-chains' or 'receptors' (see ANTITOXIN). The deeper study of toxins in the last few years has shown that they are much more complicated than was originally supposed, and it is not at all impossible that one and the same micro-organism may secrete different toxins, and may also be capable of producing different antitoxins (e.g. anti-tetanolyisin and anti-tetanospasmin). See TETANUS.

For the great majority of bacteria which affect man, and in all of which poisonous effects are manifested, the poisons belong to Buchner's 'proteins,' i.e. they do not exist apart from the bacteria producing them, and are not, so far as is known, secretory products. In most cases young cultures yield filtrates, which are not at all or only slightly toxic. With old cultures a certain amount of poisonous effect may be observed, and this is usually referred to the diffusion of certain quantities of poison out of the bodies of the bacteria which have died. For example, the filtrates of young cultures of Bacterium influenzae are only slightly toxic, whereas living or dead cultures produce signs of profound intoxication, and in man the symptoms of influenza must largely be toxic, when it is known that in the majority of cases the bacillus remains local in the respiratory system.

In some cases such as anthrax, gonorrhoea, and cholera, various poisonous bodies of complicated constitution have been obtained by precipitation of the cultures, but it has justly been doubted whether such artificially prepared products pre-exist in the cultures. In the majority of cases the introduction into the animal of dead or living cultures containing proteins does not lead to the formation of antitoxins, and the serum of such animals is capable of protecting other animals only to a very slight extent. For cholera and typhoid R. Pfeiffer has shown that such immune serums do contain antibodies, but these in themselves are unable to destroy the *Vibrio cholerae* and *Bacillus typhosus*. For this purpose another body, ferment-like in character, must be present, so that the destruction of such poisonous bacteria depends on the collaboration of antibodies ('immune body') and a ferment-like substance, known as the 'alexine' or 'complement.' For the complex hæmotoxins, which destroy the red blood-corpuscles and produce laking of the blood, Bordet, Ehrlich, and Morgenroth have shown that two similar substances are necessary—viz. a specific antibody produced by the immunisation, and a complement, which is normally present in the serum in relatively small amount. The immune body may be present in large amount, and yet fail to protect a healthy animal if there is not sufficient

complement. What apparently happens is, that the immune body is fixed to the cell (bacterium or blood-corpuscle) for which, as a result of the immunisation, it has a specific affinity; it also fixes the complement which is, in reality, the active agent of destruction. The complement itself does not become fixed to the cell directly, but only mediately through the immune body. The complement is thermo-unstable and rapidly breaks up when kept any time outside the body, and this explains why such antibacterial serums manifest extraordinarily slight bacteriolytic effects *in vitro*, unless they are perfectly fresh; and even when perfectly fresh their destructive power is limited, as the complement is used up and *in vitro* cannot be reproduced. In the living body such antibacterial serums may, however, be used as prophylactics. The most recent researches would also go to show that these cell-poisons are very numerous, and likewise that there exist many complements in one and the same animal. The exact chemistry of such poisons is at present, however, quite unknown.

WILLIAM BULLOCH.

TOXOID.—See TOXINS.

TRACHEA, Diseases of.—SYNON.: Fr. *Maladies de la Trachée*; Ger. *Krankheiten der Luftröhre*.—The trachea is but little prone to disease, except in association with affections of the larynx, bronchi, and neighbouring parts. The diagnosis and treatment of these several diseases are greatly facilitated by the laryngoscope. With this instrument a skilful manipulator can in many cases examine the trachea in its whole length; and an accurate diagnosis being thus attained, remedies may be applied, and instruments may be introduced for the removal or destruction of growths, or for other purposes, either through the larynx, or by an artificial opening made in the trachea. The principal morbid affections of the trachea will be discussed in the following order: (1) Malformations; (2) Inflammation; (3) Ulceration and Perforation; (4) Syphilis; (5) Tuberculosis; (6) Tumours; (7) Stenosis; and (8) Foreign Bodies.

1. **Malformations.**—Defects in the development of the trachea occur as rare causes of the death of newly born infants. The tube may be short and imperforate; or communication may exist with the œsophagus. These conditions are necessarily fatal. A fistulous opening through the skin occasionally occurs, giving rise to no serious symptoms. *Tracheocele*, a hernia of the mucous lining of the trachea, is a rare malformation, easily recognised, which may arise from a congenital defect, but is more frequently acquired.

2. **Inflammation.**—Tracheitis—simple, specific, or diphtheritic—may result from the extension of inflammation, either from the larynx above, or from the bronchial tubes below; it is rare except in this connection. Some degree of congestion is a usual condition of ordinary catarrh; and tracheitis is a frequent cause of irritable cough. See BRONCHI, Diseases of; DIPHTHERIA; and LARYNX, Diseases of.

3. **Ulceration and Perforation.**—Ulceration and perforation of the walls of the trachea may result from carcinoma of the œsophagus; from the pressure of an aneurysm, which ends by bursting into the air-passages, where it meets with least resistance; or from an abscess which has taken a

similar course. In the last case suppuration usually occurs in connection with a caseous bronchial gland. Occasionally, as witnessed by more than one writer, a caseous gland may become dislodged and impacted in the trachea, causing sudden death by suffocation.

4. **Syphilis.**—Syphilis, in its secondary and tertiary stages, may affect the trachea. In the tertiary stage it gives rise to a localised form of infiltration or syphiloma; and to ulcers, which contract in healing, and cause a formidable condition of stricture, to be presently considered. Tracheal syphilis, being in its advanced form so grave a matter, calls for active constitutional treatment before this irremediable stage is reached.

5. **Tuberculosis.**—Tubercle affecting the trachea occurs in connection with pulmonary phthisis, and is rarely found without advanced tubercular disease of the larynx. Two main forms may be distinguished, namely—multiple shallow ulcers, which often coalesce to form large sinuous tracts of ulceration, mostly affecting the cartilaginous portion; and deep infiltration and ulceration, confined to the posterior or membranous part of the tube. When the disease has proceeded to ulceration, it may cause the rare complication of general emphysema, the air being forced into the cellular tissue by cough and other expiratory efforts, made when the larynx is closed. In the treatment of this affection, palliative measures are alone available. See LARYNX, Diseases of.

6. **Tumours.**—(a) *Cancer.*—Primary carcinoma of the trachea is very rare, but the organ is frequently affected by the extension of the disease from neighbouring parts. The growth first causes the symptoms of stenosis, and then, as ulceration proceeds, it gives rise to expectoration and cough; whereas, as Gerhardt has pointed out, in syphilitic disease cough and expectoration precede the onset of dyspnoea, which develops very gradually. The diagnosis may be very difficult in the primary form, and can only be made with the aid of the laryngoscope. In the case of extension from neighbouring parts the diagnosis is comparatively easy. The only treatment available for prolonging life is tracheotomy, if the seat of the disease is high enough to admit of it. (b) *Non-malignant growths.*—Polypi are very rare. The symptoms are those of obstructed breathing, modified by the size and seat of the growth. A certain diagnosis can be attained only by tracheoscopy. Without treatment, a polypus is very likely to cause death by suffocation, its rate of growth depending on its pathological nature. Small growths situated high up may be treated by the galvano-cautery or by other applications through the larynx; larger tumours can only be removed through a free opening made into the trachea. A tumour may be so situated that tracheotomy, without extirpation, may ensure the safety of the patient.

7. **Stenosis.**—The calibre of the trachea may be lessened (a) by *stricture*, or by *tumours growing within it*; or (b) by *pressure from without*.

(a) *Stenosis from true stricture, or internal tumour.*—Tracheal stricture is almost always the result of syphilis; it may be annular and limited, but usually involves the tube for some length towards its lower end, and frequently extends into the bronchi. Tracheal narrowing is indicated by inspiratory stridor and dyspnoea, unaccompanied by the up-and-down movement of the larynx, and the affection of the voice characteristic of laryngeal

dyspnoea, and also in uncomplicated cases without the stethoscopic signs of pressure on, or plugging of, a bronchial tube. Under these circumstances, and in the absence of any tumour in the neck or thorax pressing on the trachea, the stenosis must depend on a stricture, or on a tumour within the tube. A syphilitic history would lead us to suspect the former; and a tracheoscopic examination may make the diagnosis certain.

Cicatrical stricture at times develops in consequence of the long-continued irritation of a tracheotomy tube.

In rare instances stenosis of the trachea may result from a chronic form of tuberculosis resembling lupus, as well as from leprosy, glanders, and rhinoscleroma.

Symptoms of stenosis are occasionally evoked by spasm of the trachealis muscle.

PROGNOSIS.—Stricture being usually cicatrical, the prognosis is most unfavourable.

TREATMENT.—Treatment other than operative is seldom available. If the stricture be high up, tracheotomy must be performed below it; or, an opening being made above the contraction, a long flexible tube may be introduced and passed through it. Stricture of the trachea is less amenable than laryngeal stenosis to treatment by mechanical dilatation with hollow bougies, but this method must be borne in mind for exceptional cases.

(b) *Stenosis from compression.*—The source of stenosis caused by pressure from without is usually obvious, as in the common case of enlargement of the thyroid gland, thoracic tumours being diagnosed by their physical signs and concomitant symptoms. The paroxysmal dyspnoea frequently caused by these tumours is not laryngeal in most cases, but depends, as shown by Bristowe, on the accumulation of secretion below the seat of obstruction. It is not relieved by tracheotomy, except where the upper part of the trachea is alone compressed. In cases of stenosis from pressure of a goitre, division of the isthmus or excision of part of the thyroid gland is sometimes very successful, and should always be tried, if possible, before tracheotomy is resorted to.

8. **Foreign Bodies.**—A foreign body entering the air-passages from the pharynx may lodge in the larynx, either becoming impacted or lying loose; but, unless prevented by its form or bulk, it usually falls or is drawn through the open glottis into the trachea. Here it may lodge; but it more frequently passes on into one of the bronchial divisions—most frequently into the right bronchus, the orifice of which is slightly larger than that of the left, and occupies more of the floor of the trachea.

SYMPTOMS.—Occlusion of the larynx by a foreign body, which from its bulk obstructs the passage, may cause instant death; and the same may be said of the trachea, as when a person vomiting, in a state of unconsciousness from intoxication, or from the action of an anæsthetic, draws in a quantity of food sufficient to choke up the air-passages. If the body be smaller, it causes dyspnoea, with severe exacerbations from spasm. A very small body, such as a sharp piece of bone or a pin, may be impacted in a position in which it causes only pain and dysphagia without dyspnoea. Speaking generally, it may be said that when the substance has passed into the trachea, the symptoms to which it gives rise depend on its bulk and weight. Rarely, it lies in the air-passage, giving rise to no symptoms; more frequently, varying its position with

the rush of air in coughing, &c., it gives rise to paroxysmal dyspnoea, light bodies being forced up to the glottis and exciting spasm. If the substance pass into the bronchus, it may become impacted there, and will give rise to characteristic physical signs, usually exciting a chronic circumscribed inflammation, with symptoms akin to pulmonary phthisis.

TREATMENT.—From the larynx a foreign body may be removed by the finger or a suitable forceps, its presence having been determined from the symptoms, aided by digital or laryngoscopic examination. Although different forms of long forceps are made for passing through the larynx into the trachea, it is seldom practicable to remove *per vias naturales* a foreign body which has once passed through the rima. A free opening must be made in the trachea, and its edges held well asunder, to give a chance of the body being expelled by cough. If this fail, a forceps must be introduced through the opening, and the body, if possible, extracted. Inversion of the patient, so as to allow a heavy substance to fall back through the glottis into the pharynx, is sometimes successful, but not as a rule without previous tracheotomy.

PERCY KIDD.

TRANCE (*transitus*), a going beyond—of the soul from the body).—**SYNON.**: Lethargy; Fr. *Léthargie*; *Maladie du Sommeil*; Ger. *Schlafsucht*.

DEFINITION.—A sleep-like state, which comes on spontaneously, apart from any gross lesion of the brain or toxic cause, and from which the sleeper cannot be roused.

The term 'trance,' in its derivative meaning, aptly expresses the apparent reduction to a vegetative life, but the popular use of the word refers rather to the separate activity of the mind than to the inactivity of the body. Hence many writers prefer the term 'lethargy,' which also, though etymologically exact, is currently employed in a modified sense. The condition is sometimes included under the generic term 'catalepsy,' according to its etymological meaning, 'a seizing'; but this term is usually restricted to those forms which present a peculiar rigidity. See **CALEPSY**, p. 255; **MENTAL STUPOR**, p. 766.

The common form of trance (which is not frequent) is one of many symptoms of a general state of the nervous system, seldom dangerous to life. In the 'African lethargy' the tendency to sleep is the chief manifestation of a disease, the gravity of which is extreme.

1. Common Trance.—**ÆTIOLOGY.**—The influence of heredity in relation to trance is to be traced only in the existence of a 'neuropathic disposition.' The state occurs chiefly in the female sex, between the ages of twelve and thirty; very rarely in young men or children. The subjects are seldom in perfect health; they usually present various manifestations of hysteria, and are often anæmic. The condition has been immediately due in some cases to exhausting diseases, as typhoid fever and influenza, to excessive brain-work, to insolation, or to mechanical obstruction to the supply of blood to the head. The immediate cause is either the cumulative effect of such persistent influence, exhaustion, or some emotional disturbance. It may succeed an hysterical convulsion. Rarely

no exciting cause may be discoverable. In still more rare instances the state has been voluntarily induced, as in the well-known case of Colonel Townsend, who could throw himself into a condition of apparent death, lasting several hours. Such voluntary induction is occasionally seen in the East. Lastly, minor degrees of trance may, without difficulty, be artificially produced in most hysterical persons, and less readily in many others, by the methods described in the article on **HYPNOTISM**. The state now designated 'hypnotism' is really induced trance, and trance has been accurately termed 'spontaneous hypnotism.'

Its various causes seem thus to involve impaired or deranged nutrition, or the action of a toxic agent (as after acute specific diseases), or an influence that disturbs the function of an ill-nourished brain.

SYMPTOMS.—The onset of the state of trance is usually sudden. For instance, in a case which came under the writer's notice, a girl went into a room by herself, and was found, shortly afterwards, in a state of trance-sleep, which lasted for thirty-eight hours. In another case (Madden) a young lady went into a room to change her dress, and was presently found on the bed in a state of trance which lasted for a fortnight. As already stated, it may succeed an hysteroid convulsion, and in some other cases the onset has been attended by an aura, resembling the globus hystericus. In the cases which succeeded typhoid fever (Madden) the delirium of the fever passed gradually into comatose sleep, which continued for several weeks. The condition is analogous to the speechlessness which may succeed typhoid. At the end of the acute stage of influenza spontaneous trance has suddenly come on, lasting hours or days.

During the state of trance, the countenance is usually extremely pale. The limbs are relaxed; although brief initial rigidity, and sometimes occasional recurring cataleptic rigidity, or transient convulsive spasms, tonic or clonic, have been noted. In a few instances distinct hysteroid fits have occurred from time to time during the course of the trance. The eyelids are usually closed, and may resist and quiver on attempts being made to open them. The eyeballs are directed upwards in most cases; they often deviate from the middle line, and sometimes diverge slightly. The pupils are usually moderately dilated; rarely they are somewhat contracted. The state of reflex action varies according to the depth of the trance. That from the limbs is sometimes excessive, so that cutaneous stimulation produces tonic rigidity. Much more frequently reflex action is lost; snuff blown into the nostrils causes no sneezing, ovarian compression has no effect, and pressure on 'hysterogenic' points, which may have existed before, no longer causes the usual convulsive symptoms. Reflex action from the conjunctiva, and even from the cornea, is commonly absent. The pupil may contract to light, but in lessened degree, and sometimes no distinct action can be observed.

The mental functions seem, in most cases, to be in complete abeyance. No manifestation of consciousness can be observed, or elicited by the most powerful cutaneous stimulation, and on recovery no recollection of the state is preserved. But in some cases volition only is lost, and the patient is aware of all that passes, although unable to give the slightest evidence of consciousness. The senses

may be even preternaturally acute, as in the analogous phase of induced hypnotism; or there may be spontaneous mental action, irrelevant to external impressions, and analogous to, probably identical with, the state of ordinary dreaming; it is manifested by exclamations, and even by movements. Rarely the 'obedient automatism' seen in induced hypnotism may be present; hallucinations occur, and actions are performed, according to suggestions made to the patient. The usual condition, however, is that of an entire absence of all evidence of mental activity.

The pallor of the face is the result of a profound depression of the vascular system. The pulse may be less or more frequent than normal, but it is invariably weaker, and it may be imperceptible. The cardiac impulse may disappear, although the heart-sounds are still to be heard, sometimes much weakened. Very rarely they have been inaudible. The breathing may be tranquil, slightly quickened, or slowed, or it may be so feeble and deliberate that no movement of the thoracic walls can be observed, no respiratory murmur can be heard in the lungs, and a mirror held over the mouth is undimmed by moisture. Temperature, when observed, has been normal in the central parts, lowered at the periphery. The secretions go on; the urine may be retained in the bladder, or passed into the bed. The catamenia are usually absent, but menstruation has been known to occur without modifying the course of the trance-sleep. In the cases in which the depression of the vital functions reaches an extreme degree, the patient appears dead to casual and sometimes to careful observation. This condition has been termed 'death-trance' (*Scheintod*). Persons have certainly been buried in this state, and during the recent epidemic of influenza an Italian narrowly escaped interment during the consequent trance.

DURATION AND COURSE.—The duration of trance has varied from a few hours or days to several weeks, months, or even a year. When of short duration, the trance-sleep may be unbroken; but when it lasts for more than a few days, there are usually remissions of a greater or less degree, in which, for instance, the patient will half-wake, take food in an automatic manner, and then relapse into stupor. A long trance-sleep may be more profound at first than later. Recovery may be sudden or gradual. Occasionally it is attended by some vaso-motor disturbance; in a well-authenticated case of death-trance the intense mental excitement produced by the preparations for fastening the coffin-lid occasioned a sweat to break out over the body. After the trance is over, nervous prostration remains for a time. In some cases repeated attacks occur, at intervals of days, months, or years. Most cases end favourably. The depression of the vital functions enables life to continue with a very small amount of nourishment, but occasionally death occurs in persons previously weakened.

PATHOLOGY.—The very few *post-mortem* examinations which have been made after death in trance throw no light on its nature. The theoretical pathology of the subject is involved in the obscurity which envelops all the psychical processes in health and disease, the nature of volition, and ordinary sleep. The lowered action of the brain in sleep, and its lessened blood-supply, have suggested the existence of cerebral anæmia, which the meagre results of anatomical investigation have been sup-

posed to confirm. It is certain that the condition is sometimes associated with defective cerebral nutrition; but that much more than cerebral anæmia is needed to explain the state of trance is evident from the facts that, on the one hand, it may occur when there is no preceding sign of defective blood-supply to the brain, while, on the other hand, the occurrence of cerebral anæmia without trance-sleep is a matter of daily observation. The phenomena of hypnotism also afford little support to the theory of the dependence of trance-sleep on cerebral anæmia; together with the symptoms of catalepsy, they suggest that the primary element is a peculiar state of inaction ('inhibition,' 'increased resistance') of some of the nerve-structures concerned in associating the highest cerebral functions with those of the lower cortical centres of motion and sensation.

DIAGNOSIS.—The diagnosis of trance rests on the impossibility of rousing the sleeper, combined with the absence of any evidence of a local cerebral lesion or a toxic cause. Other diagnostic symptoms are the pallor and vascular depression, the occurrence of convulsive phenomena of hysteroid type, and the history of other manifestations of hysteria. These symptoms sufficiently distinguish trance-sleep from apoplexy, for which, at the onset, it is sometimes mistaken. The distinction from catalepsy rests on the absence of the *flexibilitas cerea*, but catalepsy is merely a variety of trance. The peculiar tendency to brief sleep termed *narcolepsy* is distinguished from trance by the shortness of the periods of unconsciousness. Thus a man had from youth fallen asleep for a few minutes under various influences, and always did so when a probe was passed down a nasal fistula. It is to be remarked, however, that the term *narcolepsy* has been also applied in America to cases of true epilepsy, in which the attacks of *petit mal* are characterised by sudden somnolence.

In cases of 'death-trance,' in which no sign of vitality can be recognised, the presence of life may be ascertained (1) by the absence of any sign of decomposition; (2) by the normal appearance of the fundus oculi as seen with the ophthalmoscope; (3) by the persistence of the excitability of the muscles by electricity. This excitability disappears in three hours after actual death. In a case observed by Rosenthal, thirty hours after supposed death the muscles were still excitable, and in forty-four hours the patient awoke. See DEATH, Signs of.

Deepening sleepiness, not amounting, however, to coma, and scarcely to be called stupor, has attended some cases of subacute inflammation of the region of the oculo-motor nuclei described by Wernicke—a curious fact considering the manner in which relaxation of the levator is associated with ordinary sleep. Lastly, a benign form of 'summer somnolence' observed among the Swiss has been termed 'Gerlier's disease.'

PROGNOSIS.—In cases of hysterical lethargy the prognosis is fairly good. The attack usually passes off. In very rare cases death has occurred. The slighter the degree of the trance, the shorter is likely to be its duration. The prognosis is grave only when lethargy has been preceded by a state of great physical depression, and is the most serious when the condition succeeds an acute disease.

TREATMENT.—The treatment has to be directed to two ends: the maintenance of life, and the arrest

of the trance. Advantage must be taken of any intervals of semi-consciousness to give nourishment in a concentrated form. If swallowing is continuously impossible, food must be given by the nasal tube, or by enemata. Warmth should be applied to the extremities, and care taken to prevent bed-sores. In severe cases, every attempt at arrest is often fruitless. Errhines, as snuff, have usually no influence, and it is only in slight cases that this, or stimulation of the skin, as by sinapisms, is effective. The most powerful cutaneous excitant is strong faradisation. In a case under the writer's notice, which had lasted for thirty-six hours, strong faradisation to the arm quickly roused the patient. In another case, which lasted for several months, this treatment had, for a long time, no influence; afterwards the patient could be partially roused for a short time by faradisation, and by repeating the application at the same hour every day a tendency to periodical waking was established, the remissions became longer and more complete, and the attack was ultimately brought to an end. Nerve stimulants, such as ether and valerian, may be given by the bowel, or sulphuric ether may be injected subcutaneously. Alcohol must be given with caution and in small quantities; enemata of strong coffee are often more useful. A remedy which, from its effect on the vascular system, would certainly deserve trial in trance, is the inhalation of nitrite of amyl or the administration of nitroglycerin; of the latter $\frac{1}{100}$ to $\frac{1}{50}$ grain may be given in alcoholic solution three times a day. Transfusion of blood has been proposed, and would be justified in very grave cases following exhausting disease. The recurrence of attacks must be prevented by the improvement of health, physical and moral.

2. **African Lethargy.**—This form of trance is described separately. See NEGRO-LETHARGY.

W. R. GOWERS.

TRANSFUSION OF BLOOD (*trans*, across; *fundo*, I pour).—**DEFINITION.**—The pouring of blood from one animal into another.

This method of restoring patients believed to be dying was in vogue for nearly 300 years, but has now fallen into disuse. Often when an emergency calling for transfusion arose, no donor could be obtained and no apparatus was at hand. Most commonly the donor was bled into a clean bowl, the blood was at once taken up with an ordinary 2 or 3 oz. syringe, air was expelled and the blood was injected into a vein of the recipient—the injection being repeated till 10 or 12 oz. had been given. Galabin, relying upon the blood-pressure in the veins of the donor, improved upon the suggestion of Libavius by connecting the two cannulae with a short rubber tube. Aveling added a 2-drachm rubber bulb in the centre of the tube; the whole apparatus acted like a Higginson's syringe, fingers being used to compress the tube first on the recipient's, then (during compression of the bulb) on the donor's side of the bulb. This was, probably, the best of the many instruments invented for *direct* transfusion. Air was expelled from all tubes by filling them with a solution of salt or phosphate of sodium, which was usually allowed to escape before the entering blood.

In spite of all speed the blood sometimes coagulated during the transfusion, which could not be completed; sometimes it was supposed that clots were injected and that embolism occurred; some-

times air was thought to have entered the veins and right heart, but this danger was probably exaggerated; finally, in some cases hæmoglobinuria or hæmatinuria, fever, rigors, symptoms of septicæmia and even death occurred. In more than one instance the donor died, doubtless from some general septic infection, for evidence of infection of the wound was not uncommon.

To avoid the dangers connected with coagulation phosphate of sodium (Braxton Hicks) or ammonia (Richardson) was added to the blood; or it was decalcified by oxalate of ammonium (Wright); or the blood was defibrinated and strained through fine muslin before injection, Panum having shown that the absence of fibrin made no difference to the success of the transfusion. In spite of this a preference for entire blood continued to be felt.

Gradually it was shown that there were unavoidable dangers connected with transfusion. Landois, C. Ludwig, and others gave reasons for believing that all red corpuscles injected were destroyed within a few days, the hæmoglobin being dissolved in the serum—whence the hæmoglobinuria noted. Sachsendlahl found that a solution of hæmoglobin induces rapid destruction of leucocytes and consequent accumulation of ferment in the blood with symptoms of ferment fever and possibly thrombosis in great vessels. On the other hand it became increasingly clear that in the treatment of hæmorrhage, which was the main indication for transfusion, the essential point was to refill the vessels with some innocuous fluid—such as normal saline. Consequently, it has come to pass that, at all events in the treatment of hæmorrhage, transfusion of blood has been replaced by the infusion of normal saline solution. See SALINE SOLUTION, Infusion of.

STANLEY BOYD.

TRANSFUSION OF MILK.—This operation, or, as it is more correctly termed, *Infusion or Intravenous Injection of Milk*, was recommended in America by Thomas and others, as a substitute for transfusion of blood. Saline solutions have more recently replaced milk.

TRANSFUSION OF SALINE FLUIDS.—See SALINE SOLUTION, Infusion of.

TRAUMATIC (τραῦμα, a wound). — That which is associated or connected with a wound or injury.

TREMOR (Lat. trembling).—The most delicate form of clonic spasm, consisting of successive movements of very small amplitude. Tremors are seen principally in the hands, the head, the tongue, or the facial muscles, as a result of disease or of old age. They are commonly spoken of as 'coarse' or 'fine,' according to the amount of movement which they involve. See ALCOHOLISM; DISSEMINATED SCLEROSIS, p. 1553; GENERAL PARALYSIS OF THE INSANE; MERCURY, Poisoning by; PARALYSIS AGITANS; and SENILITY.

TRICHIASIS (τριχίς, the hair).—A morbid condition in which the eyelashes are inverted towards the eye. See EYE, AND ITS APPENDAGES, Diseases of, p. 518.

TRICHINA (τρίχινος, made of hair). — See ENTOZOA.

TRICHINOSIS or **TRICHINIASIS**. — *See* ENTOZOA.

TRICHOCEPHALUS (τριξ, a hair; and κεφαλή, a head). — *See* ENTOZOA.

TRICHOCLASIS (τριξ, a hair; and κλάσις, fracture). — *See* HAIR, Diseases of.

TRICHOMONAS VAGINALIS (τριξ, a hair; μονάς, a monad; and vaginalis, connected with the vagina). — A ciliated infusorial animalcule, discovered by Donne in the vaginal mucus, and somewhat resembling a spermatozoon. *See* RAPE.

TRICHOPHYTON (τριξ, a hair; and φυτόν, a plant). — A species of parasitic fungus, which attacks man and some animals. *See* TINEA, p. 1713.

TRICHORRHEXIS NODOSA (τριξ, a hair; ῥήξις, breaking; nodosus, knotty). — *See* HAIR, Diseases of.

TRICUSPID VALVES and **ORIFICE**, Diseases of. — *See* HEART, VALVES AND ORIFICES OF, Diseases of.

TRIFACIAL NERVE, Diseases of. — *See* FIFTH NERVE, Diseases of.

TRIONAL-HABIT. — *See* SULPHONALISM.

TRISMUS (τριζω, I gnash). — Lockjaw, or tetanic closure of the jaws; a prominent symptom in tetanus. *See* TETANUS.

TRISMUS NEONATORUM (Lat.). — A form of tetanus occurring in newly-born children. *See* TETANUS.

TROPHIC LESIONS. — **DESCRIPTION**. — This name is given to various departures from healthy nutrition, which are caused (a) by the cutting off, from certain tissues or parts, of some customary nervous influence, as in the production of 'secondary degenerations' in the nervous system (*see* SPINAL CORD, Diseases of, § 6), or in the production of rapid muscular atrophy, consequent upon the severance of or severe damage to motor nerves or their related ganglion-cells in the anterior cornua of the cord; and also to lesions or morbid changes which are caused (b) by some irritative or perverted influences passing *outwards* along sensory nerves to certain tissues, so as to weaken or otherwise disturb their nutrition. In this latter way, the nutrition of the skin and its appendages may be variously affected, leading to eruptions of different kinds, to atrophy, to ulceration, or undue proneness to inflammation, as well as to altered pigmentation of the skin or blanching of the hair. Or the nutrition of the joints may be affected, as in some forms of hemiplegia, and in locomotor ataxy more especially. In these various cases there may be disease, secondary or primary, of the grey matter of the spinal cord, or some irritative lesions of the sensory nerve-roots or trunks.

PATHOLOGY. — Much dispute has taken place during recent years as to the modes in which nutritive changes are brought about. Some have endeavoured to establish the existence of special 'trophic nerves,' and have taught that the various trophic lesions referred to above are to be explained

by a cutting off or a perversion of the influences usually operating upon the tissues through such nerves. Others believe that these nutritive changes can be accounted for by altered states of excitation of the vaso-motor nerves, leading to spasm or dilatation of the vessels supplying the parts affected, and, as consequences, to the nutritive changes themselves. Much evidence, however, could be cited against both these modes of explanation; and it seems, on the whole, more probable that trophic lesions are due either (a) to the cutting off of certain accustomed influences (*viâ* motor channels), or (b) to the action upon the tissues of perverted or unnatural influences (travelling in a peripheral direction *viâ* sensory channels).

On the subject of these trophic lesions *see also* SPINAL CORD, Diseases of; NEURITIS, MULTIPLE; and FACIAL ATROPHY.

H. CHARLTON BASTIAN.

TROPICAL DISEASES. — Diseases incident to hot climates. *See* AINNUM; BERIBERI; BLACK-WATER FEVER; CHOLERA, ASIATIC; CLIMATE; DENGUE; DISTOMA RINGERI; DYSENTERY; ECSTASY; ENTOZOA; EPIDEMIC DROPSY; FILARIASIS; FRAMBESIA; KALA-AZAR; LIVER, Diseases of; MALARIAL DISEASE; MYCETOMA; NEGRO-LETHARGY; ORIENTAL SORE; PLAGUE; PSILLOSIS; SUNSTROKE; TINEA IMBRICATA; and YELLOW FEVER.

TUBERCULAR. — This term was formerly applied to eruptions consisting of small prominences of the skin. This use of an expression suggesting a relationship to tuberculosis is open to serious objection, and should therefore be discontinued. 'Tubercular' should signify 'of the nature of tubercle,' e.g. *tubercular meningitis*; 'tuberculous,' 'full of tubercle,' e.g. *a tuberculous lung*.

TUBERCULAR MENINGITIS. — A form of meningitis dependent on the presence of tubercle-bacilli. *See* pp. 979 and 988.

TUBERCULOSIS (from *tuberculum*, a little lump). — **SYNON.**: Fr. *Tuberculose*; Ger. *Die Tuberkulose*.

Tuberculosis is an infectious disease caused by the invasion of the tubercle-bacillus. It is characterised by the formation of 'little lumps' or 'tubercles,' which show a tendency to unite and to undergo caseous, fibroid, or other degenerative changes. The organ most frequently attacked is the lung, but the pleura, the peritoneum, the meninges, the intestinal tract, the generative organs, and the bones are all common seats of the disease. Indeed, no tissue or organ in the body enjoys complete immunity from attack.

Frequency of the Disease. — Tuberculosis of the lungs has been known from the earliest times. To this disease Hippocrates (460–375 B.C.) first applied the term 'Phthisis,' while a classical description of its clinical manifestations may be found in the writings of Aretæus (first century A.D.). That the disease should thus have been well known to the ancient physicians is not surprising when we consider its extraordinary frequency. It is stated that one-seventh of mankind die of tuberculosis, and though this statement is not literally correct when applied to our own country, it is undoubtedly approximately true as regards the world in general.

For England and Wales the following are the exact figures during the decennial period (1881-1890), the last for which complete data are available:—

Total deaths from all causes	5,244,771
Deaths from phthisis	473,968
Deaths from 'other tubercular and scrofulous diseases'	115,422
Total from all tubercular diseases	589,390

From these figures it results that during these ten years approximately 1 out of every 11 deaths in our own country was caused by phthisis, and 1 out of every 9 by tubercular diseases in general.

Age and Sex.—No age is exempt from the ravages of the disease. In young children the glands, bones, and alimentary canal are chiefly attacked, while in the adult pulmonary tuberculosis is far more frequent. The age at which the greatest mortality from the latter is seen differs somewhat in different countries, but in England the maximum incidence occurs between the ages of 35 and 45. Between 20 and 60, however, the disease is very common.

Geographical Distribution.—Tuberculosis flourishes in every country and in every clime. It is, however, less frequent wherever the population is scattered and leads an open-air life; more frequent where overcrowding in large towns is common. Probably damp and variable climates are more favourable to the disease than bright and dry ones, but it would seem that aggregation together of the population is a factor of greater importance in determining the incidence of the disease than the exact nature of the climate. That *high altitude* may possess some antagonistic influence is not to be denied, but the extent of the rôle played by it has probably been exaggerated.

The Tubercle-Bacillus.—The experiments of Villemin (1865) proved conclusively that the old ideas as to the ætiology of tuberculosis were erroneous. Villemin showed that human tuberculous material injected into the rabbit was capable of setting up in this animal a generalised form of the disease, and further that the tuberculosis thus produced could be communicated in series from rabbit to rabbit by repeating the process of inoculation. These experiments were confirmed and amplified by other observers, and their result was to prove definitely that tuberculosis, so far from being a constitutional disease, the result of a special 'Diathesis' or 'Dyscrasia,' as until then had been believed, was in reality an infectious disease, produced by a definite and specific virus. The exact nature of the virus was, however, long debated, and it was not until March 1882, when Koch announced his discovery of the bacillus, that the question was finally set at rest.

Staining Properties.—The tubercle-bacillus differs from the majority of pathogenic micro-organisms in not staining by ordinary simple methods. Koch himself succeeded in colouring it by using a concentrated alcoholic solution of methylene blue made *alkaline* with caustic potash. The method, however, was tedious, and a better was speedily introduced by Ehrlich, which, with various modifications, has since held the field. Ehrlich's method depends upon the fact that though the tubercle-bacillus takes up stain with considerable difficulty, yet, having once imbibed it, it parts with it

only with reluctance. Hence, to stain the organism, strong dyes are necessary, while to decolourise the surrounding tissues and other bacteria strong acids are permissible. To express this unusual resistance on the part of the bacillus to the decolourising action of strong acids, the term 'acid-fast' (Ger. *sauer-fest*) has lately been applied to it. The method of staining as generally performed at the present day is as follows: The tissue to be examined is dried upon a cover-glass, and then stained in Ziehl's carbol-fuchsin (concentrated alcoholic solution of fuchsin, 11 c.c.; 5-per-cent. aqueous solution of carbolic acid, 100 c.c.). The staining solution must be warmed until steaming occurs, and should be allowed to act for 5 minutes. The specimen is next washed in water, then placed for a few seconds (5-10) in 25-per-cent. hydrochloric acid. When no further colour is discharged it should be transferred to 70-per-cent. alcohol. After a few seconds, if no further decolourisation takes place, it should again be washed in water, counterstained in Loeffler's methylene-blue (10-20 seconds), washed once more in water, dried between blotting-paper, and finally mounted in Canada balsam. Stained in this way, the tubercle-bacillus acquires a bright pink colour, and is sharply differentiated from the surrounding blue tissues. See also pp. 132 and 1575.

It should be at once stated, however, that this method of staining is not specific. As Koch himself showed, the bacillus of leprosy stains in an identical manner, and quite recently numerous other bacilli having similar staining properties have been discovered (see p. 1575).

Morphology of the Bacillus.—The following are the morphological appearances presented by the bacillus. As a rule the micro-organisms, whether occurring in the sputum, the tissues, or derived from cultures, take the form of minute rods 1.5-3.5 μ in length (about a quarter to half the diameter of a red blood-corpuscle), and .3 μ in breadth. They may be straight, but very commonly they are somewhat curved. When stained they either take the dye uniformly, or, as frequently happens, may present a beaded appearance, portions of the bacilli taking the colour well, while the intervening parts remain unstained. Koch himself regarded these unstained portions as spores, but it seems on the whole more probable that they are really minute empty spaces within the bacillary sheath, produced by the aggregation into little masses of the cell-protoplasm.

The above description does not, however, by any means exhaust the morphological appearances of the bacillus. Recent researches by Metchnikoff, Coppen Jones, and others have shown that sometimes in the secretions, and always in old agar-cultures, certain of the bacilli become much elongated and filamentous, and show also *true branching*. Further, in not a few cases, the terminal ends of these long forms, or of their branches, present definite *club-formations*. These appearances suggested to Metchnikoff that 'the bacillus, as ordinarily met with, is not the end-stage, but only a stage in the developmental cycle of a filamentous fungus.' This view has lately received much support from the work of Babes and Levaditi. These observers injected tubercle-bacilli into the subdural space of rabbits, and found that after thirty days the foci presented appearances very closely resembling those of actinomycosis, a central mass of bacilli and

filaments being observed, surrounded by a radiating zone of clubs. Similar results have also been obtained by Friedrich and by Schultze, and it would seem therefore that the bacillus should be regarded not as a simple bacillus, but as really belonging to the large *Streptothrix*-group, among which the *Actinomyces* or *Ray-Fungus* takes its place. It should be added, however, that though this view seems on the whole the most probable one, yet certain critics regard these less common morphological variations of the bacillus not as representing its highest developmental form, but indicating, on the contrary, degenerative changes.

The Chemistry of the Bacillus.—Concerning the chemical composition of the tubercle-bacillus but little knowledge has hitherto been available. It has generally been assumed, following the researches of Unna and Klebs, that the bacilli contained a considerable percentage of fat, and to the presence of this body was attributed their peculiar method of staining, but nothing really definite was known. A very important communication has recently (July 1901) been made to the Pathological Society of London on this subject by Bulloch and MacLeod. These observers show that a certain amount of *neutral fat* is present in the bacilli, as had been believed, but that the acid-fast property of the organisms (their inability, that is to say, to be decolourised even by strong acids, unless the action of the latter be unduly prolonged) is not due to this substance, since even after its complete extraction with boiling methylated spirit the bacilli retain their appearance and staining properties unaltered. These properties, however, are completely lost if now the micro-organisms are further extracted with boiling chloroform or benzene. If this be done, a substance possessing all the characters of a *wax* is obtained. This body itself is extremely acid-fast, while the residue of the bacilli, now an amorphous mass, is found to have lost this characteristic, and to stain easily with methylene-blue. The conclusion, therefore, that the peculiar staining properties of the bacillus are due to the presence in it of the wax seems unimpeachable.

Besides the neutral fat and wax thus discovered, certain *fatty acids*, *proteids*, and *salts* (chiefly phosphates) were also found. After their complete elimination a residue still remained behind, apparently allied in nature to *chitin*. In addition to the above a *lipochrome* was also isolated, which in strong alcoholic solution presented a golden yellow colour. Dissolved in chloroform, the liquid showed a distinct band at β , a little to the right of the E band of the spectrum, while the violet end was also absorbed. To this pigment is probably to be attributed the colour acquired by tubercular cultures.

The exact proportions in which these various constituents are each of them present within the micro-organism cannot as yet be stated. It may be noted, however, that according to Bulloch and MacLeod the fat, the fatty acids, the wax, and the lipochrome account altogether for 43.7 per cent. of the total weight of the bacillus.

For further details concerning the methods followed by the observers in this interesting and valuable research, reference must be made to their original paper.

Cultivation of the Bacillus.—Koch himself was successful in first cultivating the bacillus which he had discovered. For this purpose, finding that nutrient gelatine and broth were in this case un-

suitable, he introduced as a culture medium *blood-serum*, solidified at a temperature of 65° C. He showed that if material containing tubercle-bacilli were rubbed over the surface of this medium, and the tubes kept at a temperature of 37°, after 8-10 days colonies visible to the naked eye make their appearance. These have the aspect of minute dry scales, which later coalescing form a thin brownish crinkled growth. The serum is never liquefied, and the growth never penetrates below the surface. Under the microscope the colonies, especially those near the edges of the growth, present a very characteristic appearance. They consist of innumerable winding lines, often having the shape of the letter S, and by their interwindings giving rise to beautiful serpentine figures.

Koch had found that ordinary broth was but little adapted to the growth of the tubercle-bacillus, and the same is also true of nutrient agar. Nocard and Roux, however, discovered that both became admirable media for subcultures, if 6 per cent. of *glycerine* be added to them. The growth so obtained on the glycerine-agar is dry and crinkled, and resembles closely that occurring on blood-serum. On the broth a similar yellowish crinkled growth occurs on the surface, and from time to time sinks to the bottom. The liquid itself remains always clear. Another valuable medium, and one hardly sufficiently known, is *glycerinated potato*. The growth on this medium is more luxuriant than usual, and for obtaining cultures of the bacillus direct from tuberculous material, it may be recommended in preference to blood-serum. In milk also the bacillus grows well (Klein).

It will be seen therefore that the micro-organism may be readily cultivated at a temperature of 37° C. on glycerinated potato-agar or broth, in milk, and also, though not so luxuriantly, on serum. Media containing gelatine are not suitable for its cultivation, since under ordinary circumstances the bacillus does not grow at a temperature below 29° C. It must be added, nevertheless, that Sander claims to have obtained growth in potato-broth even at a temperature of 22° C. The fact is of interest, but should hardly be taken as indicating the likelihood in any but the rarest circumstances of a saprophytic growth of the organism outside the human body. Only very occasionally could all the circumstances necessary combine to be present in nature, and even should this occur we must remember what a potent aid to the destruction of the bacillus we always possess in the germicidal action of direct sunlight.

Resisting powers of the Bacillus.—The tubercle-bacillus shows towards certain destructive agencies unusual power of resistance. This resistance is not indeed so great as that possessed by spore-bearing organisms, and is probably to be explained by the peculiar chemical composition of the bacillus, and the large amount of wax which it contains. *Putrefaction*, for example, has but little effect upon it. Thus sputum has been found to retain its virulence, though allowed to putrefy for more than a month in the air, while portions of tuberculous material, buried and dug up again after an interval of 167 days, have still been able to produce the disease when inoculated into suitable animals. *Desiccation*, if prolonged for six months, leads to the destruction of the organism (Cornet), but sputum, dried at the ordinary temperature of the air for shorter periods, still remains virulent. *Extremely low temperature* seems to produce no result. Thus Swithinbank

found that direct contact with liquid air during 42 days (temperature $-186^{\circ}\text{C}.$) produced absolutely no effect whatever, subcultures, perfectly typical in every way, growing from the bacilli so exposed. Repeated freezing and thawing, and prolonged immersion in water, are similarly without result. No more efficacious is the *gastric juice*, the bacilli still remaining alive after an exposure of six hours to this secretion. *Heat*, on the other hand, is more effective. The bacilli are destroyed in milk by raising the liquid to the boiling-point (Bang), while similar results are also obtained by longer exposure at lower temperatures ($70^{\circ}\text{C}.$). Dry heat, however, is not nearly so certain in its results. Of the agents which in nature make for the destruction of the bacillus, the action of *direct sunlight* is by far the most important. As Koch showed many years ago, the bacilli can resist diffused daylight for some days, but are rapidly killed (sometimes within a few minutes) by the direct action of the sun's rays.

Concerning *antiseptics* it may be stated that carbolic acid (1 in 20) directly applied to the bacilli destroys them within one minute. It has been further shown that many substances can inhibit in culture the growth of the organism, and among these cyanide of gold is one of the most effective. No antiseptic, however, has as yet been found capable of arresting tuberculosis when injected into animals already suffering from the disease.

Experimental Tuberculosis.—The final proof that the bacillus discovered by Koch was the actual cause of the disease was effected by means of inoculation-experiments. Koch showed conclusively that the micro-organism, whether isolated from tubercular lesions of the lung or joints, or from scrofulous glands, or from lupus, was capable, even after numerous subcultures, of producing tuberculosis in susceptible animals, and that in the lesions so produced the bacillus could again be demonstrated and re-obtained in pure culture. These original observations have met with universal acceptance, thus proving indubitably the causal connection of the micro-organism with the disease.

Of the animals which may be used for such experiments, or for demonstrating the presence or absence of bacilli in suspected material, the one most usually chosen is the *guinea-pig*, for although spontaneous tuberculosis occurs but rarely in this animal, to inoculation it is extremely sensitive. If the tuberculous material be injected *subcutaneously into the groin*, the site generally chosen, the course of events noted is usually as follows. After about a week a local swelling appears at the seat of inoculation. Later the surface over this breaks down and gives entrance to a small cavity filled with caseous material. About this time also the inguinal glands become swollen and palpable. The animal then commences to emaciate, and finally dies at a period varying from six weeks to three or even six months from the date of inoculation, the exact time depending upon the dose of the virus injected, and in part upon individual differences in susceptibility. After death enlargement and caseation of the inguinal and lumbar glands will be found, tuberculosis of the liver and spleen, and finally, if the animal survive long enough, tubercular infiltration of the bronchial and posterior mediastinal glands, and of the lungs. In the guinea-pig it may be noticed the kidney is never attacked, though in the cat disease of this organ is frequently seen.

Such then are the classical appearances presented

in a guinea-pig inoculated subcutaneously in the groin, appearances which may be seen at any time in almost any laboratory, the method being now constantly employed for diagnostic purposes in connection with suspected sputum, and more especially suspected urine.

Other methods of inoculation, however, and indeed other animals, may be used instead of the preceding. Thus in the rabbit *intravenous injection* of the bacilli has been often practised, while inoculation into the *anterior chamber of the eye*, a favourite proceeding with the earlier observers (Cohnheim and Salomonsen) since the resulting tuberculosis could be easily observed, may in some cases be of value. Again, the virus may be injected directly into the *peritoneal cavity*, a method which, in the guinea-pig, offers most trustworthy results.

The Toxins of the Tubercle-Bacillus.—It was shown by Koch that the subcutaneous injection of *dead* tubercle-bacilli gave rise in the guinea-pig merely to a local abscess. In 1891, however, Prudden and Hopendyl made the unexpected discovery that if intravenous injection be resorted to (in the rabbit), after a definite period tuberculosis develops in the lungs, the tubercles thus formed resembling most closely those produced by the living organisms. They were found to contain giant-cells, epithelioid cells and bacilli, but caseation, though sometimes present, was not nearly so marked a feature as usual. In addition they manifested no tendency to spread, since no multiplication of the bacilli contained within them could take place. These observations have been confirmed by Strauss and Gamaleia, and from them a very important consequence follows. We are led, namely, to admit that *the tubercular poison is chiefly intracellular*, that it remains in great part at least within the body of the bacillus, and even after death but very slowly diffuses therefrom.

Concerning the exact chemical nature of the toxin, or toxins, but little can as yet be said. Koch's original '*Tuberculin*,' which consists of a glycerine-broth culture of the micro-organism evaporated at a temperature of $100^{\circ}\text{C}.$ down to one-tenth of its original bulk, and then filtered through porcelain, obviously (from its action upon the animal body) contains certain poisonous substances derived from the bacillus. This liquid was analysed by Hunter, and found to contain various albumoses, as well as alkaloids, salts, and extractives. Of these the albumoses were shown by Kühne to be each of them capable of producing in tuberculous guinea-pigs the typical tuberculin-reaction, and it at first seemed as though they themselves constituted the true tubercular poison. But further observations showed that if the bacillus be grown in a proteid-free medium, the fluid after cultivation still possesses the properties of tuberculin, though it contains no albumoses, nor any proteid matter at all. It results, therefore, that these bodies are not themselves the toxin, but that the latter merely attaches itself to them. But beyond this negative fact our knowledge of the subject does not at present go.

Spontaneous Tuberculosis in Animals.—

Tuberculosis, as we have seen, may be communicated experimentally and with great ease to numerous animals. In addition to this the disease occurs spontaneously in many species, and is especially frequent among those which are brought much in contact with man himself. Thus it is very often

met with both in *cows* (Bovine Tuberculosis; *Perlsucht*; *Pommelière*), and also in *pigs*. It is not uncommon in the *cat* and *dog*, and it occurs, though but rarely, in the *horse*, the *sheep*, the *rabbit*, and the *guinea-pig*. Among *monkeys* in captivity, again, it is often seen. Lastly it is a very well known disease in *birds*, and attacks fowls with especial frequency. The following figures giving the exact incidence of the disease as observed at the slaughter-houses of Copenhagen during the four years 1890-1893 may be quoted from the Report of the Royal Commission on Tuberculosis, 1895: Of 132,294 oxen and cows examined, 17.7 per cent. were found to be tuberculous; of 8,292 swine, 15.3 per cent.; of 185,765 calves, 2 per cent.; and of 337,014 sheep, only .0003 per cent. The frequency of tuberculosis in pigs is here probably somewhat exaggerated, but the figures indicate sufficiently how common the disease is in this class of animal, and how very common it is also in cows.

For our present purpose it will not be necessary to describe in detail the lesions which characterise the disease in the various classes of animals. It may be said, however, that in *cows* the lungs and pleura are most often attacked, and on the latter the tuberculous masses often attain a large size, and are frequently penedunculated. They show a special tendency to calcify. The *udder* is rarely affected primarily, but in some 2.3 per cent. of cases it is invaded during the course of the disease.

In *pigs* the stress of the disease falls upon the alimentary canal, ulceration of the intestine, with secondary invasion of the other abdominal organs, being very common. The tubercular products, as a rule, undergo early caseation. Not uncommonly, however, in the pig, the virus enters through the tonsils, and the submaxillary and cervical glands become swollen and tuberculous. To this form of the disease the name 'scrofula of pigs' is given, and it throws a striking light upon the pathology of the similar affection occurring in the child.

In the *horse*, when the disease occurs, the alimentary canal, the abdominal glands, the peritoneum, liver, and spleen, are chiefly affected, the glands sometimes being converted into enormous tumours (Strauss). In some cases, however, the lungs are primarily diseased. In the *monkey*, lastly, in which the lungs are for the most part attacked, the disease is characterised by the rapid breaking down of the caseous patches into areas of semipurulent material.

Relation of the Human Tubercle-Bacillus to that of Bovine and Avian Tuberculosis, and to other Acid-fast Organisms.

1. *Bovine Tuberculosis*.—The frequent occurrence of tuberculosis in other animals besides man renders the question as to the identity of the micro-organisms found one of great importance. It has hitherto been accepted that, in spite of certain slight morphological differences and slight variations in virulence, the human tubercle-bacillus was identical with that found in other mammalia, and hence that the disease could be conveyed from animals, and especially cattle, to man, and that the reverse could occur. At the recent British Congress on Tuberculosis (July, 1901) this view was combated by Dr. Koch, who showed that, though the human bacillus can produce tuberculosis in rabbits and guinea-pigs, just like the bacillus from bovine sources, yet it differs from the latter in being in-

capable of generating the disease in the higher mammals, such as cattle, pigs, and sheep. He concluded, therefore, that in spite of their extraordinary superficial similarity the bacilli are really different, and that the bovine variety is not, as a rule, a source of danger to man. This view, it must be stated, has the support of Virchow, but does not commend itself to the majority of scientific observers. Further observation and experiment can, however, alone decide the question. Meanwhile, it will be well still to regard the bacilli from the two sources as really identical (and therefore each of them dangerous to man), though *temporarily* somewhat altered as the result of their different environment. (For further consideration of this important question, see paragraphs on 'Channels of Infection,' pp. 1751, 1752.)

2. *Avian Tuberculosis*.—As regards the bacillus of *Avian Tuberculosis* the question is more simple. The latter is identical in appearance and in staining properties with the bacillus derived from human sources, but differs obviously in its cultures, and also in the effect of inoculation. The hen, for example, is extremely sensitive to the avian stock, but proves refractory to the human variety. In the dog, on the other hand, the reverse is the case. There can be no doubt, therefore, as to the essential differences now existing between the two varieties of bacilli, and although these differences may be greatly diminished experimentally, as Nocard has most ingeniously shown, the conditions requisite are never likely to occur during life, and consequently the possibility of the human subject acquiring tuberculosis through the avian disease may be neglected.

3. *Other Acid-fast Organisms*.—The relation of the true tubercle-bacillus to the other acid-fast organisms, which have recently been discovered, forms a new and very difficult problem. These organisms, of which the best known are the *Timothy bacillus* and the *Grass-bacillus*, were first discovered by Moëller on certain grasses (notably the Timothy Grass), having a wide distribution in nature, and extensively used as fodder. Micro-organisms belonging to the same group have since been found in the dung of horses, goats, pigs, and especially mules (*Mistbacillus*), frequently in butter, sometimes in milk, and sometimes also in the urine, fæces, and nasal secretion of healthy people.

Morphologically and in staining properties these all exactly resemble the tubercle-bacillus, and on inoculation into guinea-pigs certain of them, notably the Timothy and Grass-bacillus, produce changes which both macro- and microscopically are quite indistinguishable from true tuberculosis. On cultivation, however, differences at once become apparent, the tubercle-like organisms growing more rapidly than the true tubercle-bacilli, and showing also other points of difference. It is evident, therefore, that these micro-organisms are not tubercle-bacilli, though they are very closely allied to them.

What the exact relationship may be we cannot as yet definitely say, but it should be noticed that they bear exactly the same relation to the tubercle-bacillus that the members of the Coli-family do to the typhoid-bacillus; and just as we have reason to believe that the typhoid-bacillus is but the most highly specialised member of this great group, all the members of which are derived from a common ancestor, so it is possible that the same obtains as

regards the tubercle-bacillus and its allies. On this view the various members of the group would form separate and distinct species, and no conversion of the Timothy bacillus into the tubercle-bacillus need be expected. Such a view, however, does not exclude the possibility of these tubercle-like organisms possessing some pathogenic power against the human subject, but to what degree such power, should it be shown to exist, may extend, we have as yet no knowledge. In the single instance in which so far a member of the group (the Timothy bacillus) has been inoculated into man, a local papule of inflammatory nature alone resulted (Lubarsch). But too much stress must not be laid upon a single experiment.

MORBID ANATOMY.—The pathological changes produced in man by the action of the tubercle-bacillus present in certain organs, and in the lungs especially, appearances which to the naked eye often differ markedly from one another. Thus miliary tuberculosis, chronic phthisis, and fibroid tuberculosis of the lungs are at first sight sufficiently distinct. A more careful examination, however, shows that their fundamental constitution is the same, and that their distinctive appearances are due to the different ages of the lesions and the varying changes which the latter have undergone.

The Miliary Tubercle.—The fundamental lesion resulting from the presence in the body of the bacillus is the so-called 'Miliary Tubercle.' In its most characteristic form this consists of a central giant-cell, surrounded by a varying number of epithelioid cells, these again being enclosed by a zone of ordinary leucocytes. The whole is non-vascular. Such tubercles are invisible to the naked eye, but are easily recognised with the microscope. They may be found, often in large numbers, in the liver in cases of general miliary tuberculosis.

As a rule, however, the tubercles do not remain isolated. Owing to the multiplication of the bacilli further tubercles develop around the one first formed, and the miliary tubercle, such as we know it in the *post-mortem* room, results. In appearance this presents the form of a small round body varying in size from .1 mm. up to 2 or 3 mm. in diameter. When first formed it is greyish in colour, and translucent, but as retrogressive changes set in, it becomes yellow and opaque. Under the microscope each individual tubercle comprised within it will be found to show with more or less distinctness the appearances already referred to—a central giant-cell, a surrounding zone of epithelioid cells, and most externally a layer of leucocytes. Of these the most characteristic, though not the most important, is the *Giant-Cell*. This body, which may attain a diameter of .3 mm., is irregular in shape and presents at its periphery numerous processes. These penetrate among the surrounding epithelioid cells and thus become lost to view. The substance of the cell is composed of slightly granular protoplasm, and is found to contain very numerous nuclei, sometimes even as many as thirty or more being present. These are sometimes scattered irregularly through the cell, but are more often arranged in a ring round the margin or grouped together near one extremity. The *Epithelioid Cells*, which form the second layer, are much smaller than the giant-cell, which they surround. They are somewhat irregular in outline and contain a granular protoplasm, within which one or more nuclei are embedded. The *Leucocytes* lastly, which form the peripheral zone,

present nothing characteristic. They are smaller than the epithelioid cells and seem to be nothing more than ordinary leucocytes, or inflammatory cells, attracted by chemiotaxis to the seat of the disease. If sections be prepared and suitably stained, tubercle-bacilli will be found scattered among the cells of the tubercle, or perhaps lying within the giant-cells, but in the human subject their occurrence within the latter is somewhat rare. As a rule also, the micro-organisms seen are not so numerous as might be expected. The tissue surrounding the tubercle is commonly hyperæmic, but the new formation itself is non-vascular.

Such then are the characteristic appearances of what may be spoken of as a typical tubercle. It must be clearly understood, however, that *giant-cell-formation, usually regarded as so characteristic of the disease, does not by any means always occur*. The essential feature of the tubercle, as will be shown, is the production of epithelioid cells, and if caseation takes place very rapidly, as in the so-called 'Caseous Pneumonia,' giant-cells will be but rarely found. On the other hand, if the tubercle-bacilli in question be not very virulent, or if the organism be somewhat resistant, then giant-cell-formation becomes a more marked feature, while on the contrary the invasion of leucocytes to form the circumferential zone is correspondingly less obvious, or may be even completely absent.

Histogenesis of Tubercle.—We may now consider more exactly the manner in which the tubercle comes to be developed. This question has long been debated between the rival schools of Germany and France, Baumgarten, on the one hand, holding that epithelioid cells and giant-cells originate from the *fixed cells* of the tissues (endo- and epithelial cells, and connective tissue cells); Metchnikoff, on the other hand, maintaining that they are derived from the *wandering cells* or leucocytes. The question at last seems finally settled in favour of the former. Briefly, the evidence which Baumgarten has brought forward is as follows: He produced tuberculosis in the iris (as well as in other organs) in rabbits, and examined with great care the changes thus induced. Nothing could be noticed for about a week, but at the end of this time he found that the bacilli injected were in very close apposition to, or even within, certain of the connective-tissue and epithelial cells of the tissue. The cells so affected were noticed also to be swelling up and to be assuming the appearance of epithelioid cells. Karyokinetic changes were also observed in the nuclei, and later cell-division followed. *The primary change therefore resulting from the action of the bacillus was not an influx of leucocytes, but the formation of epithelioid cells from the fixed cells of the tissue.* This fundamental connection of the latter with the epithelioid cells, it may be added here, is supported by the observation of Strauss that in experimental tuberculosis of the liver in rabbits the epithelioid cells often have a highly granular protoplasm, and contain also glycogen, thus testifying strongly to their origin from the hepatic cells. The secondary changes which next followed in Baumgarten's experiments were found to vary somewhat according to the intensity of the virus, and the resisting powers of the tissue. If the virus was very powerful then the invasion of leucocytes took place early, and the tubercle sometimes came to consist almost entirely of these cells. Caseation in such cases rapidly followed, and giant-

cells not uncommonly never made their appearance. If, however, the process was less acute, then giant-cell-formation occurred, and the leucocytic invasion was less marked, or even remained totally absent. *In no case were karyokinetic changes or cell-division observed in the wandering cells, and their relation to the tubercle would therefore seem to be definitely a secondary one.* Concerning the mode of origin of the giant-cells there may be still some difference of opinion. Some observers hold that they are produced by the union of several epithelioid cells, while Baumgarten believes that they result from the enlargement of individual epithelioid cells, and by the division of their nuclei, without the latter process being followed by cell-division. He was, however, unable to demonstrate karyokinesis in the nuclei of the giant-cells, so that, probable as his view is, it cannot be regarded as absolutely proved.

These results, obtained in the iris, were confirmed by similar observations in other organs, and there can be no doubt as to their correctness. *Consequently the true tubercle-cells, both epithelioid and giant-cells, must be in future regarded as originating in the fixed cells of the tissues, under the stimulus afforded by the presence of the bacillus. The share taken by the leucocytes, on the other hand, must be looked upon as quite subsidiary. It is limited to the formation of an inflammatory external zone, and even this under certain circumstances may be entirely absent.*

Retgressive Changes.—The tubercle having originated in the manner thus described does not retain its perfect form for any length of time. Certain degenerative changes soon set in, which we must now proceed to consider. These may be divided into two great classes, according as the degeneration assumes the caseous or the fibroid form. Of the two the former is by far the most common, and it may be added also the most important, seeing that in many cases its occurrence and the further changes which it undergoes are fraught with serious danger to the organism.

1. *Caseation.*—This term dates from the commencement of the last century (Vetter, 1803), and indicates, as the name implies, that the degenerated tubercular matter assumes to the naked eye an appearance somewhat similar to that of cheese. The tubercular deposit, transparent when first formed, is seen after a few weeks, or it may be even earlier, to show in its centre, when caseation is commencing, minute opaque spots. Gradually these spread until at last the whole patch assumes an opaque aspect, and becomes yellowish-white in colour. Under the microscope these changes are seen to be due to the death and destruction of the tubercle-cells. The protoplasm of these latter becomes homogeneous or slightly granular, while the outline of the cell first grows indistinct, and later gradually fades away. A similar process also affects the nuclei. As a result, therefore, the caseated mass assumes, when examined microscopically, a faintly granular appearance, in which no definite cell-elements can be made out. The whole stains feebly with ordinary dyes. Within the patch tubercle-bacilli may sometimes be demonstrated by appropriate staining, but unless the process has been very acute, they will usually be few in number. In very many cases, however, experiment upon animals proves the caseated material to be still virulent, though the microscope may have failed to reveal the specific micro-organism.

Such then is caseation which occurs with so extraordinary a frequency in tubercular formations. It would be an error, nevertheless, to believe that it is peculiar to this disease. On the contrary, it occurs in syphilitic gummata, and may also be seen in inflammatory exudations produced by the action of other micro-organisms ('pseudo-tuberculosis'). Concerning the cause which leads to the transformation it may be said that for many years it has been attributed to the non-vascularity of the tubercular nodule. Such an explanation is insufficient, for caseation may occur in most minute tubercles, even the central cells of which could be easily nourished by lymph which had permeated from the periphery. Without doubt, therefore, the change is due to a direct poison emanating from the bacillus, which coagulates and destroys the cells, which its primary irritative action has produced.

The tubercular material having undergone caseation may occasionally remain in this condition for some considerable time. If this occurs the mass nearly always becomes surrounded by a definite capsule of fibrous tissue, which acts as a safeguard to the organism by preventing the further spread of the bacilli. Such a persistence, however, of the unaltered caseous material is by no means common. Far more frequently softening occurs. In this case the cheesy material breaks up into a molecular débris, consisting for the most part of fine fatty and albuminoid granules, which lie bathed in serous fluid. The amount of the latter varies greatly. In some cases only very small quantities may be present, and the softened tubercular mass may be really semi-solid and possess a putty-like consistency, while in other instances, as for example in the case of a psoas abscess, much larger quantities may be present, and the softened cheesy matter thus acquires the characters of thick, curdy 'tubercular pus.' All variations between these two extremes are to be met with.

Another well-known change which may follow upon caseation is *calcification*. When this occurs calcium phosphate and carbonate, but chiefly the former, become deposited within the degenerated material, and by their gradual augmentation eventually convert it into a mortary or stony mass. This change constitutes one of the most perfect methods of natural healing, for whereas the caseous matter remains infective and therefore dangerous to the individual, the calcified mass is harmless, owing to the bacilli contained within it having undergone destruction. Calcification only occurs in those forms of the disease in which the malady runs a chronic course. It is consequently never seen in the guinea-pig, is met with fairly frequently in man, and is often observed in the cow. How early in the course of the disease the change may occur it is impossible to say with any certainty. In the pig, however, it has been observed by Sidney Martin 106 days after infection.

Lastly, it is permissible to believe that sometimes *absorption* of cheesy material may at least in part occur. In the case, for example, of tuberculous glands in the neck, so common in children, it is very probable that in some cases the tubercular matter is thus eliminated.

2. *Fibrosis.*—As already mentioned, fibrosis is the other great change which tubercular products may undergo. In its most perfect form, in which the whole of the tubercular nodule is directly converted into fibrous tissue, it is infinitely rarer than

the caseous degeneration. Not uncommonly, however, it may accompany the latter, as when in large racemose tubercles little areas of caseation are found embedded, as it were, in a matrix of grey fibroid material. In this way the degeneration tends to check the further spread of the disease. Indeed, such formation of fibrous tissue is the ordinary method of spontaneous cure occurring in tubercular disease, while to assist the process in every way is the constant aim of the physician.

MORBID APPEARANCES OF PULMONARY TUBERCULOSIS.—When any organ in the body is attacked by tuberculosis, the resulting changes are fundamentally those that have been just described. Certain variations, however, will be noticed according to the organ or tissue affected.

As pointed out in their recent work by Fowles and Godlee, four sufficiently distinct pathological (and also clinical) varieties of pulmonary tuberculosis may be described, according as the disease assumes the miliary type, or as caseation, fibrosis, or a combination of the two latter with cavity-formation, constitute the chief feature. Of these several varieties a more detailed description now follows, and it will be seen that into one or other group will fall the numerous clinical types of pulmonary tuberculosis which have been from time to time described.

1. *Acute Miliary Tuberculosis of the Lungs.*—In this variety the lungs are found thickly studded throughout with very numerous miliary tubercles. Owing to the fact that death in this variety takes place very speedily, generally within three weeks from the onset of the disease, the tubercles are for the most part still transparent, or only just commencing to caseate. Under the microscope they show the typical appearance of miliary tubercles already described. The pulmonary tissue intervening between the tubercles is in general greatly engorged, but is otherwise healthy. Sometimes, however, there may be tubercular disease of older date at one or other apex. Discrete tubercles similar to those in the lung are not uncommonly found also upon the visceral surface of the pleura, and in many cases are seen as well in other organs of the body.

This variety of the pulmonary disease is always ascribed to the softening of a caseous focus, very commonly situated in a bronchial gland, and to the entrance therefrom of the infective material into the blood-stream. In the majority of cases this is no doubt the true pathology of the process. Where, however, the lungs alone are affected, as is not uncommonly the case, it is possible, the writer believes, that we may be really dealing with an aspiration-process, and not the penetration of bacilli into the circulating blood.

2. *Acute Caseous Tuberculosis of the Lungs.*—**SYNON.** : (among others) '*Acute Phthisis*'; '*Scrofulous Pneumonia*'; and '*Acute Tuberculo-pneumonic Phthisis*.'

This variety of the disease is chiefly characterised by the absence of fibrosis, by the large areas of the lung which become affected by tubercular consolidation, and especially by the rapidity with which the latter undergoes caseation. Two types may be distinguished—the lobar and the lobular.

(a) *The Lobar Type.*—This variety, perhaps most generally termed '*acute pneumonic phthisis*,' is extremely uncommon. In its typical form it attacks a previously healthy lung, but in some cases

'*caseous pneumonia*,' as the condition is often pathologically named, will be found as the terminal event in a case of ordinary chronic phthisis. The disease runs a rapid course, and the fatal issue is usually not delayed beyond two or three months, and may even take place earlier. After death the lungs present a very typical appearance. The affected lobe (in a primary case, as a rule, the upper lobe), or it may be the whole lung, is found to be in a condition of consolidation. This consolidation is not, however, like that of pneumonia, but presents a yellowish-white opaque granular appearance, due to the fact that the inflammatory products have already undergone caseation, while the capillaries also have been to a great extent obliterated. Should the patient have died early these will be all the changes noted. If, on the other hand, the case has been less acute, then some softening may have taken place, and one or more ragged, irregular cavities will be found.

Under the microscope the alveoli of the consolidated lung will be found in the early stages to be crowded with leucocytes and cells of an epithelioid type, embedded in a fine fibrin-network. When, however, caseation is well established, then no cell-elements remain visible, but the section presents merely a granular homogeneous appearance. By appropriate staining innumerable tubercle-bacilli may often be demonstrated. Owing to the acuteness and severity of the process giant-cells are but rarely seen.

This variety of the disease is apparently produced by the inhalation into one lobe, or it may be the whole of one lung, of numerous and very virulent bacilli, in a patient whose resistance is not great. As a result the tubercular process set up by each original bacillus spreads with great rapidity. Consolidation follows, and caseation rapidly ensues.

(b) *The Lobular or Broncho-pneumonic Type.*—This type, though much less rare than the preceding one, is still, in adults, at least, far from common. At the Brompton Hospital it constitutes, according to Kingston Fowler's statistics, 2·4 per cent. of all cases of pulmonary tuberculosis. In children, however, following after measles or whooping-cough, it is much more frequent.

In essentials it resembles the lobar form. The disease, that is to say, runs the same rapid course, and is characterised by the same early caseation of the tubercular products. The chief difference between the varieties lies in the fact, that whereas in the former entire lobes are affected, in this case the affected areas are smaller, so that the disease assumes the broncho-pneumonic type. Yellowish caseated areas, some as large as a shilling, are thus seen scattered through the lungs, while the intervening tissue remains comparatively healthy. Early softening also is rather more prone to occur, so that ragged irregular cavities are frequently met with. Not uncommonly also the necrotic process spreads to the pleura, and a pneumothorax results. It is to this variety of the disease that the names '*Galloping Consumption*,' or '*Phthisis Florida*,' have not infrequently been applied.

3. *Fibroid Tuberculosis of the Lungs.*—This in its perfect form is an extremely rare disease, and must not be confounded with '*Fibroid Phthisis*,' which is of comparatively common occurrence. Fibroid tuberculosis indicates a disease of the lungs in which tubercles become deposited at their apices, just as in an ordinary case of phthisis. These,

however, do not undergo caseation, but from the first take on the fibroid change, and, as a result, become converted into firm deeply pigmented bodies. These sometimes remain discrete, but sometimes become aggregated into little racemose masses, to which the name 'Carswell's Grapes' has been applied. Occasionally, also, larger areas of fibrosis may be produced. The lung-tissue in the neighbourhood of the tubercles undergoes, as a rule, secondary emphysema; hence it is often difficult or impossible to obtain during life definite physical signs of the disease. It will be seen from what has been said that this variety of pulmonary tuberculosis differs much from 'Fibroid Phthisis,' since in the latter, though fibrosis is always present, cavity-formation and falling in of the chest-wall are both also well-marked features of the disease.

4. *Fibro-caseous Tuberculosis, or ordinary Chronic Pulmonary Phthisis.*—The morbid lesions of this, the commonest variety of pulmonary tuberculosis, differ somewhat according to the chronicity or relative acuteness of the process, but in all cases we find caseation, followed by softening and cavity-formation, and in all cases, also, more or less fibrosis. The morbid appearances, in fact, show a combination of the lesions met with in the two preceding varieties of the disease, with the additional fact that cavity-formation always constitutes a marked feature of the process.

The disease commences in nearly every case near the apex of the upper lobe, where the primary tubercles are deposited. These are at first miliary in character, but as they enlarge they not uncommonly unite, and little 'racemose' masses are formed. These again join others, and finally largish areas of tubercular disease are produced. But meanwhile degenerative changes have set in. Caseation first occurs, followed later by softening. Finally, a communication with a bronchus is established, the liquefied caseous matter, containing numerous tubercle-bacilli, is coughed up in the sputum, and a cavity results. Owing, however, to the somewhat chronic nature of the process, some fibrosis is also seen. Areas of firm greyish fibroid material form around the cavities, and in the partly caseating racemose patches some fibrosis is often also to be made out, especially if Van Giessen's method of staining be employed. In this way the disease may be finally arrested at this early stage, and if examined some years later, but little will be seen beyond a puckered fibrous spot, containing a contracted cavity, with, perhaps, in addition, a small caseous or calcareous mass embedded in a firm capsule of fibrous tissue. Not uncommonly, also, the surrounding lung is emphysematous.

More frequently, however, the disease does not become arrested, but continues to spread, partly by means of the lymphatics, and partly through aspiration of the infected sputum into bronchi hitherto unattacked. In this way the disease invades first the apex of the corresponding lower lobe, next the apex of the opposite lung, and finally the opposite lower lobe. The pathological changes continue to be the same. Whenever the patient's strength ebbs, then we have fresh formation of racemose tubercles, the junction of these, caseation and formation of cavities; when his resistance increases, renewed formation of fibroid material, and an attempt to arrest the disease. Finally, however, unless complete arrest occurs, the patient succumbs to his disease. The lungs are then found to present nume-

rous cavities, of old or recent formation, while the remainder of the lung-tissue is strewn with small, greyish-yellow caseating racemose tubercles, or it may be patches of larger size. The lung-tissue intervening between these is often natural or simply engorged, but sometimes it may show a terminal miliary tuberculosis, or possibly be in a condition of pneumonia, either of the simple broncho-pneumonic variety, or, much more rarely, of the caseous type. In some cases the fibrosis, which to some extent is always present, becomes very marked, and as a result the excavated lung becomes contracted, the chest is drawn over, the side falls in, and we have the clinical picture of '*Fibroid Phthisis*,' as drawn by Sir Andrew Clark.

The cavities which form so conspicuous a feature of this type of tuberculosis are described elsewhere. See CAVITY.

CHANGES IN OTHER ORGANS FOLLOWING PULMONARY TUBERCULOSIS. — In chronic pulmonary phthisis the tubercular lesions are very rarely limited to the lungs. Thus the *pleura*, as a rule, becomes invaded and inflamed, and its layers adherent, while later it may become greatly thickened. Occasionally, however, adhesions fail, and then, should the pleura necrose, a pneumothorax results.

Again, the *trachea* and *bronchi* are very often affected. In all cases they are injected, and it is not uncommon also to find their mucous membrane studded with recent miliary tubercles, or shallow ulcers resulting from the caseation and softening of the latter. In rare cases the tubercular ulceration may be more extensive, and the cartilaginous rings of the trachea may be exposed. In 47 per cent. of cases the *larynx* also shows at the time of death definite signs of tubercular disease.

Very common, too, is some change in the *bronchial glands*. These are nearly always swollen and enlarged, and may show in their substance scattered miliary tubercles. Sometimes, also, small patches of caseation or small calcareous masses may be found in them. It is very rare, however, in chronic pulmonary tuberculosis, in spite of statements to the contrary, to find the bronchial glands in a general state of caseation.

In a very large proportion of cases (77·4 per cent., according to the records of the Brompton Hospital) *tubercular ulceration of the intestine* may be observed, produced by the careless swallowing of the infected sputum. The ulceration is most frequently situated in the ileum and cæcum, but the disease may extend as high as the duodenum; and in some cases spread downwards even as far as the rectum and anus. The appendix is very commonly attacked, but the stomach is only most rarely affected. The ulcers are for the most part circular, but, unless they originate in a Peyer's patch, show some tendency to spread transversely. Their appearance is sufficiently characteristic. The heaped up thickened edge and nodular floor suggest at once their tubercular nature, while the presence of numerous miliary tubercles on their peritoneal surface serves as a rule to confirm the diagnosis.

As a result of this ulceration of the alimentary canal, but sometimes even apart from it, we very commonly find tubercular disease of the *mesenteric glands*. These are seen to be enlarged, and on section are found to be in a condition of caseation. In rarer cases also irregular nodules of calcareous degeneration may be observed in them. *Peritonitis* again is another sequel which sometimes results

from the intestinal disease. In general it is of tubercular nature, and spreads from the peritoneal covering of the ulcers, which as already pointed out are the first portions of the serous membrane to be affected. As a result the intestines become adherent and matted together, while the omentum becomes rolled up and filled with tubercular deposits. Ascites is uncommon. Much more rarely the peritonitis is of the septic variety, and arises from perforation of one of the ulcers, or is due to the passage of micro-organisms through the greatly thinned floor without definite rupture having taken place.

Tubercular Meningitis is another but much less common complication of chronic pulmonary tuberculosis. According to Dr. Kingston Fowler's statistics only 3·3 per cent. of cases are terminated in this way. In even a smaller proportion of cases (2·7 per cent.) do we find tubercular disease of the male and female *generative organs*, while only very rarely indeed are tubercular *endo- or pericarditis* to be observed. The *spleen* is very often found softened, and occasionally shows tubercular deposits. The *kidneys* are commonly fatty, and it is not rare to find in them a few scattered miliary tubercles, the result of the entrance into the blood-stream of a very few micro-organisms. Occasionally also more advanced tubercular disease may be present. The liver is frequently in a condition of fatty infiltration, but beyond this is generally unaffected.

One other complication often met with in cases of phthisis of some considerable duration remains to be mentioned, namely, *amyloid degeneration*. This change occurs in about 11 per cent. of all cases of the disease. The exact proportion in which the various organs are affected is stated by Kingston Fowler, from the Brompton Hospital Records, to be as follows: spleen 11·1 per cent.; liver and kidneys each 6·1 per cent.; intestines 5·3 per cent.; and stomach 1·8 per cent.

CHANNELS OF INFECTION.—Now that we have studied the chief peculiarities of the tubercle-bacillus, and of the lesions produced by it, we are in a position to consider what are the channels by means of which it gains access to the human body, and thus originates the disease. Three methods of infection exist: (1) Inoculation; (2) Inhalation; (3) Ingestion; and of these the second is by far the most important.

1. Inoculation. — Only very rarely can tuberculosis in man be attributed to this cause. Laennec was himself, however, infected in this manner, and similar cases are recorded from time to time. At the Brompton Hospital the two following cases have quite recently occurred. The first was a nurse who wounded her left wrist with a spittoon containing virulent sputum. A local tuberculosis followed. This was excised four months later by Mr. Boyd, when complete recovery ensued. The second case occurred in the person of the museum-attendant (H. M. aged 62), who, while staining the sputa, ran a pen covered with virulent expectoration into the flexor tendon-sheath of the middle finger of the right hand. Tubercular teno-synovitis resulted, but the trouble was arrested, and the patient cured by the timely scraping out of the disease within two months of the primary infection. These cases, though very exceptional, prove that this method of infection does exist. They show also the happy effect of early operation, especially when we remember that unless so treated the disease spreads

from its primary seat to the glands and lymphatics, and then to the lungs and other organs of the body.

2. Inhalation. — We now pass to the great means whereby tuberculosis is spread, namely, the inhalation of dried sputum.

In considering this question we must first remember that the sputum, though by far the most important, is not the only means whereby the tubercle-bacilli may obtain exit from the human body. The breath and sweat of the consumptive patient never indeed contain the specific micro-organisms, and are consequently innocuous, but when the genito-urinary organs or the alimentary canal are diseased, the urine and faeces contain appreciable numbers of bacilli, and thus become possible sources of contagion. In view, however, of the high standard of modern sanitation the inhalation of dried particles of these excretions can only most rarely occur, and infection through these channels may therefore for practical purposes be neglected. Far otherwise is the case with the *sputum*. In the first place we must bear in mind the enormous numbers of bacilli which a consumptive patient may expectorate for weeks and months together. This has been computed by Nuttall as sometimes reaching the enormous total of four thousand millions a day or even higher. In the sputum, therefore, we have obviously a grave source of danger, even though a certain number of the micro-organisms may be really dead, as has been suggested. It can be, however, only rarely that inhalation of the liquid viscid sputum occurs, though occasionally in speaking or coughing minute portions may be scattered abroad and thus inhaled. The serious risk does not undoubtedly arise until the sputum has been allowed to dry, whether on handkerchiefs, on the floor, or elsewhere. Such desiccation, even when accompanied by some putrefaction, has been shown to have but little effect upon the bacillus, which retains its virulence under these conditions for many months, while its ability to pass into the air in the form of dust is at once rendered easy. Remembering the extreme frequency of primary tuberculosis of the lungs, and bearing in mind that a similar disease in animals has often been produced by causing them to inhale for a short time only dry and pulverised sputum, there can be no reasonable doubt that the disease in man originates, in the vast majority of cases at least, in a similar way.

It may be asked, however, if these facts are so, how it is, not that one-eleventh of our race die of phthisis, but that we do not all perish from it. Probably the chief explanation is to be found in the destructive action of sunlight, owing to which *tubercle-bacilli are not ubiquitous*, as might very reasonably be imagined after what has been said. This has been very clearly demonstrated by Cornet, who, using the animal test, examined for the presence of tubercle-bacilli 147 samples of dust from various sources. His observations proved that while virulent bacilli could be found in the dust from wards and rooms inhabited by phthisical patients, they could not be found in similar situations which had not been exposed to contamination. More important still bacilli were never discovered in dust taken from the streets, though 12 different specimens were examined.

Another very important fact to remember in this connection is that *those who actually harbour the*

bacilli do not by any means always acquire the disease. Thus virulent bacilli have been found by Strauss in the nasal cavities of people in perfect health, and who have shown no symptom of the disease even after this discovery. In truth, as with so many other infectious diseases, we must not lose sight of the fact that *the bacillus is but one factor in the causation of the disease*, and that to produce the malady other influences, often of a debilitating nature, are also required. In the case of pulmonary tuberculosis these *predisposing causes* may be briefly mentioned. Any cause, for example, which produces catarrh of the bronchi, such as measles, whooping cough, dusty occupations, dampness of the house and soil, will necessarily favour the onset of the disease. The effect of the bronchitis, however produced, will be to enfeeble, or even to annihilate for a time, the action of the ciliary epithelium in the respiratory tract. As a consequence, the bacillus, should it now gain admission, would not be expelled at once, but would acquire time and opportunity for development. Again alcoholism, insufficient food, prolonged lactation, and mental worry, all exercise a debilitating influence upon the patient, and by weakening the local and general protective forces of the body predispose towards the disease. In a similar way, too, act diabetes and influenza, though in many cases the local action of the latter upon the respiratory tract is also of importance. Lastly, heredity is without doubt a factor which cannot be neglected. *See below.*

Such then are the chief causes which favour the onset of the disease, and the important part which they play in giving rise to it should never be overlooked.

3. *Ingestion.*—That tuberculosis may be conveyed from animals to man has been accepted for many years by the scientific world. The opinion is based upon considerations already stated; and regulations have accordingly been made in all civilised countries to control in some measure at least the sale of meat and milk derived from infected animals.

These opinions have been, however, again placed upon their trial by the pronouncement of Dr. Koch at the recent British Congress of Tuberculosis (July 23, 1901). Dr. Koch, as already stated, has observed that though tuberculosis can be communicated to certain small animals (rabbits, guinea-pigs, &c.) by tubercle-bacilli derived from human sources, yet in the case of the higher mammals, such as cattle, pigs, asses, sheep, and goats, this is not possible, though the latter readily succumb if bacilli owning a bovine origin are used. He concludes therefore that 'human tuberculosis differs from bovine and cannot be transmitted to cattle.' Relying also upon certain German statistics which apparently show the rarity in children of primary intestinal tuberculosis, he accepts also the converse of this proposition, namely, that 'man is hardly if at all susceptible to the bovine disease, and that consequently infection of human beings through tuberculous meat or milk can only most rarely occur, and need not therefore be guarded against.'

In the present article it is not possible to criticise fully these important dicta. The following facts, however, may be noted. In the first place primary intestinal tuberculosis in children is not at all uncommon in England and Scotland, whatever may be the case in Germany. Thus recent statistics

dealing with tuberculosis in children (Still and Shennan) show that out of 547 cases in nearly 30 per cent. primary infection would appear to have taken place through the alimentary canal. Secondly, several cases are on record in which veterinary surgeons and others have accidentally inoculated themselves with bovine virus, and yet the disease has run its course in them, sometimes to a fatal termination, just as though the bacilli had been derived from the human subject. From these facts it is clear that the bovine organism is capable in some cases at least of producing tuberculosis in man. Hence it is possible that the primary tuberculosis of the alimentary canal so common in children in this country may really owe its origin to a bovine source. At the same time it may be pointed out that from their habit of crawling upon floors, dirtying their fingers, and immediately sucking them, young children in infected houses have ample opportunity of swallowing human tubercle-bacilli, and that their intestinal disease may conceivably originate in this way.

On the whole the provisional conclusion at which we must arrive is that though the danger of infection through food has no doubt been exaggerated, yet to some extent, for the present at least, it must be held to exist. Consequently, until it be definitely proved that precautions are unnecessary, we must continue to protect ourselves as heretofore.

Of the two articles of diet, namely, *meat* and *milk*, which must thus engage our attention, the latter is by far the more important. This arises from the fact that tubercular disease of the cow's udder, which is chiefly responsible for the presence of the bacilli in the milk, is by no means uncommon (according to MacFadyean probably 2 per cent. of all cows in this country are so affected), that the clinical symptoms of the disease are often most obscure during life, and lastly, that the milk itself may be for long quite unaffected to the naked eye, even though it be really swarming with tubercle-bacilli. The dangers therefore to be associated with cow's milk are subtle as well as real. They may, however, be entirely avoided by boiling the milk and thus destroying the bacilli, a precaution which under no circumstances should ever be omitted in any household.

With regard to *meat* the danger is less marked, even though perhaps 30 per cent. of all cows in this country be tuberculous (MacFadyean). The muscles, which constitute the 'meat' of the butcher, are but rarely affected with tubercular disease, and superficial contamination from other parts, acquired during the processes of 'flaying' and 'dressing,' is for practical purposes obviated in nearly all cases by the subsequent cooking.

Influence of Heredity.—We may now pass to consider the great question of heredity, which comes into play whatever be the exact means whereby the bacillus gains access to the organism. It is matter of common knowledge that tuberculosis is far more frequent in certain families than in others, and that consequently among those attacked by it a family history of the disease may very commonly be obtained. Quain, for example, found that among the patients attending the Brompton Hospital 25 per cent. gave a history of the disease in one or both parents (*First Report of the Brompton Hospital*). More important, however, are the observations of Theodore Williams, who, dealing entirely with the

upper classes, in whom, owing to their habits, the chances of infection would be somewhat less, was able to trace among 1,000 cases a history of the disease in one or both parents in 12 per cent. and in some near relative in 48 per cent. of the cases.

How are these facts to be explained? Before the discovery of the bacillus, and the acceptance of the infectious nature of the disease, they presented no difficulty; the tendency to the mysterious malady was hereditary, and that explained all. We now know, however, that many of the cases thought to be hereditary must have been in reality produced by infection, and that, in part at least, the reason why tuberculosis runs in families is that, when once introduced, the chance in favour of other members becoming infected is thereby greatly increased. At the present moment, indeed, among some there is a tendency to believe that this increased exposure to infection is sufficient to account for all the facts, and that tuberculosis is not hereditary at all. This, however, can hardly be maintained, for though it is true that many so-called 'hereditary' cases are really the result of 'family infection,' yet instances are not wanting in which the latter danger has been obviated, and in which, nevertheless, first one and then another member of the family has fallen a victim to the disease. Again, it is admitted that other infectious diseases, such as typhoid fever, are prone to attack certain families rather than others; hence there is no improbability in believing that the same may be true also of tuberculosis.

Accepting, then, that heredity is a factor of some importance in the ætiology of the disease, we must consider how it may be explained. Is it due, as Koch first suggested, to the inheritance of certain peculiarities in the tissues favourable to the growth of the bacillus; or is it due, as Baumgarten has so forcibly argued, to the direct infection of the ovum through the placenta, or more rarely by means of the spermatozoa, that is to say, to the direct inheritance of the germ itself? In favour of the latter view, which presupposes, be it noted, a latent period often of many years before the microbe takes on active growth—a sufficiently startling assumption—but little evidence can be brought. On the other hand, the extreme rarity of congenital tuberculosis, and the fact that tubercle-bacilli are in nearly all cases completely absent from the tissues of the fetus, originating from a tuberculous mother, militate most strongly against it.

Until, therefore, more definite proof is forthcoming we must believe that *the hereditary factor in the disease, which cannot be gainsaid, though it doubtless does not exist to the extent once imagined, is the result of a special idiosyncrasy of the tissues, whereby in certain families they become more than usually favourable to the development of the tubercle-bacillus.*

DIAGNOSIS.—The differential diagnosis of the various forms of tubercular disease need not be considered in this article. One or two points of a more general character may, however, be referred to. They may be considered under the following headings:—

1. *Pseudo-Tuberculosis.*—It has been shown by recent research that *the power of forming tubercles, quite indistinguishable to the naked eye from those produced by the bacillus of Koch, is by no means limited to the latter micro-organism or its allies.* On the contrary, it is now recognised that even in man typical tubercles may be also produced

by mechanical particles (seeds, fragments of oyster-shell, &c.), by various forms of fungi (*Aspergillus fumigatus*, &c.), and by various micro-organisms totally distinct from the tubercle-bacillus, and among which the 'Bacillus of Pfeiffer' may be especially mentioned. To these various granulomata, for the most part infective in nature, the inclusive name 'pseudo-tuberculosis' has by some been given. That such forms of disease are to be met with it is important to remember, for, apart from the fact that they are probably more common than is generally supposed, it follows from their existence that the mere development of the naked-eye appearances of tuberculosis in an animal after an inoculation made for diagnostic purposes is not *conclusive* evidence that the bacillus of Koch was present in the suspected matter. To be certain, the caseous material found must also be stained for tubercle-bacilli, and, if necessary, cultivations made from it, so that the presence of the specific micro-organism may be thereby conclusively demonstrated. Such a method of examination should therefore be made a routine procedure in all cases.

A further question now presents itself, namely:

2. *What diagnostic value should be placed upon the detection in tissues or in excretions of bacilli which stain like the tubercle-bacillus?*—Until quite recently the matter presented no difficulty. All such organisms were held to be without doubt true tubercle-bacilli, since in this country at least the possibility of leprosy needed only rarely to be considered, while the Smegma-bacillus could be differentiated by certain morphological differences, as well as by its decolouration by alcohol, subsequently to its treatment with acid, a routine method of procedure which should never be omitted in staining for the tubercle-bacillus. See 'Staining Properties,' p. 1743.

The discovery, however, already alluded to (see p. 1743) of acid-fast and tubercle-producing bacilli in nature (Timothy bacillus and Grass-bacillus), and of allied micro-organisms, nineteen in all, in urine, fæces, and nasal secretion of healthy people, in the dung of various animals (*Mistbacillus*), in butter, in milk, and finally in a case of non-tubercular gangrene of the lung, has made it evident that we can no longer rely implicitly upon staining properties for the diagnosis of the tubercle-bacillus. According to Moeller, however, to whom we owe most of our knowledge on this subject, the margin of error thus introduced into clinical work is really a very small one. Consequently, if acid-fast bacilli are found in the sputum, we must, for the present at least, continue to regard them as true tubercle-bacilli, though to obtain absolute proof of their identity resort must be had to *cultures*, the slow growth of Koch's bacillus differentiating it from all allied organisms.

3. *Tuberculin, value of, as a diagnostic agent.*—It was shown by Koch that if a minute dose ('001 grm.) of the original tuberculin (see pp. 1745 and 1754) be injected under the skin of a healthy man no result followed. If, however, the patient were the subject of tubercular disease, then, after about four hours, the temperature began to rise, reaching 102°–104° F., or even higher; the patient felt ill, suffered from cough and vomiting, and might even have a rigor. These symptoms lasted about twelve hours, and then gradually passed away.

Similar differences were also noticed in cattle, and

the method has consequently come into general use among veterinary surgeons for the early diagnosis in these animals of tubercular disease. So accurate indeed is the test that the errors in diagnosis connected with it are only estimated at about 5 per cent. of the total cases injected.

Is the test of equal value in the case of man? This has been doubted by some, who have stated that in cases of cancer and syphilis a similar reaction occurs, but it would seem that if the test be performed with care, the greatest reliance may be placed upon it. To quote a signal instance of its value, we may note the observations of Dr. France among the insane patients at the Claybury Asylum. France injected 75 patients. Of these 20 showed no clinical symptoms of the disease and gave no reaction. Of the 55 suspected cases 45 reacted. Of these 45, 34 subsequently died, and upon 29 of them *post-mortem* examinations were performed. Each of these 29 showed active tuberculosis. Of the 11 remaining patients, still alive at the time of writing, 6 now showed clinically very obvious signs of tubercular disease.

There can be little doubt, therefore, that the drug is a potent aid to diagnosis in difficult cases, and as such its employment may be encouraged. At the present time, indeed, it is in routine use in Osler's wards in the Johns Hopkins Hospital, Baltimore.

4. *The Agglutination-Test.*—In a very numerous series of papers it has recently been contended by Arloing and Courmont of Lyons that the serum of tuberculous patients will agglutinate the tubercle-bacillus, exactly in the same way as the corresponding typhoid serum agglutinates the typhoid bacillus, although as a rule in a far lower degree. In approximately 75 per cent. of cases of pulmonary tuberculosis, and in nearly the same percentage of cases of tubercular disease of bones and joints, they found that the serum of the patient would agglutinate their homogeneous culture of the tubercle-bacillus in a dilution of 1 in 10 or higher. Such a reaction they regard as specific, and almost certainly indicative of the presence in the patient of tubercular disease.

These results have, however, not been confirmed by Beck and Rabinowitsch, and a similar experience has befallen the writer and Mr. Armit ('Transactions of British Congress of Tuberculosis,' 1901). Thus, out of 31 cases of pulmonary tuberculosis examined by them at the Brompton Hospital 3 only were found to clump in a dilution of 1 in 10, or only about 10 per cent. of the cases, a figure which agrees well with the 12.5 per cent. obtained by Beck and Rabinowitsch. Further, it has been shown by the latter observers that, contrary to the statements of Arloing and Courmont, an exactly similar agglutination may occur in cattle, which have been proved by autopsy to be non-tuberculous.

There can be little doubt, therefore, that *the reaction occurs quite inconstantly in tuberculosis, and, further, that it is not specific. Consequently, as at present carried out, the test can be of no value as a means of diagnosis.*

PROPHYLAXIS.—The preventive measures necessary to check the spread of the disease have been sufficiently indicated in the paragraphs dealing with the methods of infection (see p. 1751). The following are the most important precautions necessary, and they may be thus summarised.

Concerning the *sputum*, the chief source of infection, the public must be educated to appreciate the

dangers arising from it. Spitting except into spittoons (containing where possible some 1 in 20 carbolic acid) must be strictly forbidden, and patients must learn that expectorating into a handkerchief is only less serious than indiscriminate spitting. The sputum should be collected at least once in every 24 hours, and preferably be placed upon the fire and burnt. Failing this, it must be covered with carbolic acid and cast down the drain. It should not be buried, as is sometimes done. The spittoon should be afterwards washed out with carbolic acid and then with boiling water. A phthisical patient must occupy a room by himself, and after his death or removal the room must be thoroughly disinfected, re-papered, and re-white-washed. If precautions such as these be taken, the direct risk of infection becomes but very slight.

As regards food, it is satisfactory to think that with care any possible risks may be entirely avoided. *Milk*, wherein lies the chief danger, should never on any account be drunk without being previously boiled, while if this be done even virulent milk is rendered innocuous since the bacilli are thereby destroyed. It may nevertheless be hoped that in the future the use of tuberculin may be greatly extended, so that a pure milk-supply may be thus obtained. Concerning *meat* the possible risk is less serious. Animals extensively diseased are now confiscated by the authorities, and for the reasons already given the meat of animals only slightly infected is rarely dangerous. Thorough cooking, however, as an additional safeguard should always be advised.

Lastly, to guard against the possibility of *inoculation*, those much associated with consumptives, or who are in the habit of performing autopsies on tuberculous subjects, should be careful to cover with collodion all cracks and abrasions on the hands and exposed parts. If this be done, the danger from this form of infection becomes extremely small.

TREATMENT.—The remedial measures generally adopted in cases of tuberculosis will be found described in other portions of this work. The specific treatment of the disease need alone be here briefly referred to. It may be discussed under the two following headings:—

1. *The tuberculin-treatment.*—Into the history of this treatment it is unnecessary to enter. It may suffice to state that, according to Koch, a cure may be effected in very many cases of *early* pulmonary disease by the continued use of the drug. To effect this it is essential that the cases be early ones, and that the tuberculin (either the original tuberculin of 1890, for further details of which see p. 1745, or the modified 'Tuberculin O,' suggested in 1897) be injected in minute doses, and only after the patient's temperature has remained normal for at least 24 hours previously. In later and rapidly advancing cases its use is contra-indicated or even harmful. It can be seen, therefore, that since the cases in which alone it is indicated are precisely those in which other forms of treatment offer the largest measure of success its use must always remain limited. Partly on this account, and partly also because, according to Virchow, the drug is sometimes not free from danger, a dissemination of the bacilli and a spread of the disease following its use, its employment as a therapeutic agent is now rare. Even in lupus, indeed, in which the results were at first so encouraging, further experience has shown that the benefit is only temporary, and that a permanent

ure, if it ever occurs, is most exceptional. The therapeutic use, therefore, of tuberculin, except, perhaps, as an adjunct to the open-air treatment in certain very early cases of pulmonary tuberculosis, can hardly be recommended.

2. *Serum-treatment*.—The striking value of the anti-diphtheritic serum led almost at once to attempts to manufacture a serum which should be equally effective in the case of tuberculosis. Very numerous experiments in this direction have been made, some using the natural serum of various animals, themselves more or less immune to the disease, others again employing the serum only after subjecting the animals to repeated injections of living and dead tubercular cultures or of their toxins. In some cases the results obtained have been encouraging, notably those of Maraghiano, but as yet no practical results have followed from them. No good purpose would accordingly be served by describing in this article the various experiments in greater detail.

So far, therefore, it must be confessed that the treatment of tuberculosis along specific lines has made but little progress. In the near future, indeed, it may be hoped that great developments in this direction may be attained, but until this time arrives we must continue to trust as heretofore to other remedies and in other measures. Meanwhile we must do all in our power to check the spread of the disease by careful attention to the preventive measures, which have been already described. P. HORTON-SMITH.

TUBULAR.—A term employed to denote (1) a peculiar quality of sound, indicated by the name, either elicited by percussion, or heard on auscultation, in certain conditions (see PHYSICAL EXAMINATION); or (2) that which pertains to the tubules of an organ, e.g. tubular nephritis.

TUMOURS.—SYNON.: FR. *Tumeurs*; Ger. *Teschwulste*.

DEFINITION.—In the broadest sense of the word, a tumour signifies a *swelling*, and must therefore include conditions so far apart as a phantom-tumour, hypertrophied muscle, an abscess, a hernia, or a cancer; but in its more restricted sense its application is confined to a *swelling caused by some form of new-growth*.

CLASSIFICATION.—The separation of new-growths into benign and malignant, though very useful as an approximate clinical distinction, is not admissible in a scientific discussion. Nor again is one that is founded upon the seat or shape of the tumour sufficiently accurate for the purpose. This arrangement would involve such antiquated terms as parenchymatous or superficial, nodules, infiltrations, fungus-growths, &c. The true classification must depend upon the actual structure, that is, the microscopical characters of the growth. Such a classification is the following:—

A. **Tumours composed of a normal tissue of the adult human body, or of such a tissue very slightly modified.**—(1) Fibroma; hard and soft, including Cheloid; (2) Lipoma; (3) Chondroma; (4) Osteoma; (5) Papilloma (warts and corns); (6) Adenoma; (7) Lymphadenoma; (8) True Myoma, including Myo-fibroma; (9) True Neuroma; (10) Angioma; and (11) Lymphangioma.

B. **Tumours consisting of some modification of embryonic connective tissue**, that is, the *Sarcomata*.—(1) Round-celled sarcoma, including Glioma; (2) Oval-celled sarcoma; (3) Spindle-celled sarcoma, large and small; (4) Alveolar sarcoma; (5) Mixed sarcoma; (6) Myeloid sarcoma; (7) Myxoma; (8) Osteo-sarcoma; (9) Chondro-sarcoma; (10) Melanotic sarcoma; and (11) Psammoma.

C. **Tumours consisting of a modification of epidermic, epithelial, and secreting-gland structures.**—These forms of new-growth are described in special articles. See CANCER; and RODENT ULCER.

D. **Tumours consisting of an inflammatory growth.**—(1) *Simple*.—Granulation-tumours, Osteophytes, &c. (2) *Specific*.—Depending on the presence of syphilis, tuberculosis, leprosy, glanders, actinomycosis, and conditions due to other parasitic organisms.

The inflammatory tumours included under this class do not come strictly within the scope of the present discussion; its various sub-divisions must be sought under the description of the diseases which give rise to them, in the several articles bearing their respective names.

E. **Cysts.**—This division is also dealt with in a separate article. See CYSTS.

A. **Tumours composed of a normal tissue of the adult human body.**—In this class are included representatives of each of the primary tissues of the adult body. The members of it, therefore, differ widely in structure and appearance; but they are distinguished from those of the second and third classes by one important feature, namely, that, though often multiple, they show little or no tendency to return after complete removal—that is, they are essentially *benignant*. To this may be added another less characteristic distinction, namely, that they have but little tendency to ulcerate; and that, as a result, if they interfere with life at all, it is by pressure on important organs, or in such an accidental way as by the bleeding which may result from a uterine fibroid, rather than by the production of direct constitutional disturbance.

1. **Fibromata.**—**DEFINITION.**—Tumours consisting simply of fibrous tissue or some modification of it.

VARIETIES, CLINICAL CHARACTERS, AND MICROSCOPICAL APPEARANCES.—Fibromata may be divided into *soft* and *hard fibromata*.

(a) *Soft fibrous tumours.*—The soft fibromata are simple masses of connective tissue, occurring in the submucous or subcutaneous structures, and generally, but not always, more or less pedunculated. In many cases there are overgrown papillae on the surface; and overgrown and distorted glands of the skin or mucous membrane are often entangled among the meshes of the tumour. The *subcutaneous* variety occurs in all parts of the body, but is perhaps most common in the labia majora and the lower limbs; and to it the name of *molluscum fibrosum* has been applied. These tumours often contain a considerable amount of fat, and thus approach the lipomata. They often appear oedematous; and may undergo calcareous or other forms of degeneration. The *submucous* variety includes the simple polypi of the nose. In these the fibrous tissue is somewhat modified; the ordinary connective-tissue cells, oval, oat-shaped, or branched, being embedded in a more or less copious gelatinous

(? mucous) matrix. Such tumours are nearly related, on the one hand, to the myxomata, and are covered by a mucous membrane corresponding to the region in which they occur—ciliated, for example, in the nose (Plate XIX.), and columnar in the intestine. On the other hand, they often contain in their interior the characteristic glands of the part they affect, and thus approximate to the adenomata. To the naked eye they have a gelatinous appearance.

(b) *Hard fibrous tumours*.—These tumours are made up of pure fibrous tissue, but it is very difficult to draw the line between them and some forms of sarcoma. They are firm, usually encapsuled, and often pedunculated. To the naked eye a section is white or pinkish, and presents an appearance as if its component parts were arranged concentrically round a number of points. This appearance is more marked on microscopical examination, which, while it shows this concentric arrangement in bundles that have been cut across, exhibits others which have been divided longitudinally (see Plate XIX.). Hard fibromata occur in many situations: in the subcutaneous tissue, including among others the cheloid tumours, the fibrous tumours of the pinna, which are sometimes caused by the piercing of the ears for earrings, or may result from the hæmatomata not infrequently met with in idiots, and some, at least, of that peculiar class of tumours called 'the painful subcutaneous tubercle'; in sub-mucous tissues, including many of the naso-pharyngeal polypi; in connection with the periosteum, including the fibrous epulis, which probably often starts as a myeloid, the so-called fibrous tumours of bone, and, according to some authorities, though this is doubtful, some kinds of subungual exostosis; in nerves, including the common neuromata, and bulbous nerves in a stump; and in the intermuscular planes. They are liable to various forms of degeneration; they often calcify; and those in connection with the periosteum may undergo ossification. Some fibrous tumours cause serious danger to life from the position they occupy; it will be enough to cite the cases of naso-pharyngeal polypi, and polypi of the uterus.

TREATMENT.—Fibromata can only be treated, if interference of any kind be necessary, by complete removal, the nature of the operation depending upon the position of the growth. If completely removed, except in the case of cheloid tumours, they have no tendency to recurrence.

2. **Lipoma.**—**DEFINITION.**—A tumour composed of normal adipose tissue.

VARIETIES AND CLINICAL CHARACTERS.—Occasionally more or less extensive local hypertrophies of the subcutaneous fatty layer occur. To these the name 'diffuse lipoma' is applied. They occur usually in those who are addicted to alcohol, and especially those who take freely of malt liquors. The circumscribed lipoma is a well defined tumour, made up of a larger or smaller number of overgrown fat-lobules. These are sometimes of enormous size, so that only two or three are found in a tumour of considerable dimensions. The skin presents a very characteristic dimpling, when moved to and fro over such a subcutaneous fatty tumour. The superficial parts of the mass may generally be easily separated from the surrounding structures during an operation for its removal; but the deeper parts, often consisting of smaller lobules, and generally containing a vessel of some magnitude,

require more careful enucleation. Fatty tumours are met with in all parts of the body in which adipose tissue is normally developed. The writer once met with a fatty tumour inside the spinal column. They may occur congenitally, but are more common in middle and advanced life. They are often multiple, and are apparently in some cases developed as the result of pressure; and sometimes they are remarkably symmetrical. They involve no danger to life, but are often very painful, as the result of pressure upon cutaneous nerves. Microscopically, the structure is that of ordinary adipose tissue.

TREATMENT.—Though fatty tumours are said to shift their position, and sometimes to diminish in size spontaneously, they are not to be dispersed by internal remedies or external applications. If necessary, they must be removed by the knife, an operation which, as already mentioned, is usually easy in the case of the circumscribed variety. The removal of diffuse lipomata is difficult, and hæmorrhage is free. It is said that if they result from beer-drinking they will diminish if the habit be discontinued. It is to be observed that recurrence may take place unless they be completely removed.

3. **Chondromata.**—**DEFINITION.**—Tumours made up altogether, or in great measure, of cartilage.

VARIETIES, COURSE, AND CLINICAL CHARACTERS.—Cartilage-tumours may be divided into those which grow in connection with a bone; and those which are developed in the soft parts.

Cartilaginous tumours growing in connection with bone.—These may be again subdivided into those which grow from the surface of the bone—*echondromata*; and those which grow from the interior—*enchondromata*. The latter are the simplest form of cartilage-tumours; they commence usually during the period of adolescence, and affect by preference the fingers and toes, but are occasionally found elsewhere; they are almost always multiple, but never show a malignant tendency; they may reach a very considerable size; and they are sometimes coated with a thin layer of bony tissue. The *echondromata* are developed, as a rule, during a later period of life; are found in connection with any of the bones of the body; and often attain an enormous size, as, for example, in the pelvis. Some of these tumours, to which Virchow has given the name of *osteoid chondroma*, such as are occasionally found forming elongated swellings in the shaft of a long bone, present a high degree of malignancy, recurring as such in distant parts of the body.

Cartilaginous tumours of the soft parts.—These tumours occur principally in connection with certain glands, and especially in the neighbourhood of the parotid, and in the testicle. It has been suggested that they may originate from some remains of foetal structures. Rarer situations for such tumours are the submaxillary gland, the breast, the ovary, the lachrymal gland, the kidney, and, it is said, the lung. These tumours are comparatively seldom pure, but are usually mixed with myxomatous, adenoid, or sarcomatous structure; the degree of such admixture determining in great part the benignity or malignancy of the growth.

An account of the so-called *ossifying chondromata* is given under heading 4.

NAKED-EYE APPEARANCES.—Cartilaginous tumours vary very much in density; the hardest

tain fibrous tissue, and are, in fact, fibro-cartilaginous growths; the softest are very soft, and are very closely related to the myxomata; indeed, it may be held that many myxomata are merely varieties of chondroma. Some chondromata soften, either in many parts or in the centre, giving rise to one or more cysts in the interior; the bursting of such may lead to a permanent sinus. Other forms of degeneration are not uncommon, and especially calcification. True ossification is not rare.

MICROSCOPICAL CHARACTERS.—Microscopically the structure often differs widely in different specimens of chondroma, and in different parts of the same tumour; the matrix may be hyaline or fibrous; and the cells round, irregular, stellate, or much-branched (Plate XIX.). It will easily be understood that with a soft hyaline matrix and much-branched cells, the appearance of myxoma is very easily simulated.

TREATMENT.—Bearing in mind the great variety of these tumours, it will be seen that it is impossible to sum up the treatment of them in a few words. The simple enchondromata of the fingers should only be removed to cure deformity or similar inconvenience. As a rule, other forms should be removed as early as possible; but many chondromata spring from regions which are altogether beyond the reach of the surgeon's knife.

4. Osteomata. — **DEFINITION.** — Tumours composed of bone.

VARIETIES.—If the inflammatory exostoses be excluded, such as those which are found round a joint affected with chronic rheumatoid arthritis, or those which depend upon the ossification of a node, or of inflammatory products in the external auditory meatus, we may divide this class of tumours as follows:—

(a) Osteomata developed as such on the exterior of a bone, including the ivory exostosis—*periosteal exostoses*.

(b) Osteomata developed as such in the interior of a bone—*enostoses*.

(c) *Pedunculated exostoses*.

(d) Osseous tumours of the *soft parts*.

(e) Osseous tumours produced by the *ossification of other kinds of new-growths*.

(f) And lastly (though not strictly under the same category) the *odontomata*.

(a) *Periosteal exostoses.*—These are irregular bony tumours, appearing usually in adult life; they are directly continuous with the bone from which they spring; and are composed sometimes of cancellous structure, with a thin coating of compact tissue, but much more frequently of denser material. They most often affect the bones of the face, where they produce horrible and distressing deformities; but are also found on the skull, in the meatus of the ear, or, more rarely, on the long bones. From the importance of the neighbouring structures it is, in most cases, impossible to remove them, but where it is possible and advisable, as for example in the ear, they should be removed with the gouge and hammer, or by means of a drill. Some of these tumours are of extreme density, and have hence been called *ivory exostoses*; these, when they affect the upper jaw, their commonest seat, must be distinguished from the *odontomata*, to be presently described.

(b) *Enostoses.*—Enostoses need only be mentioned in order to point out their extreme rarity; but it may be remarked that many of the last-

described series of tumours probably spring from the diploë of the cranial bones, and should thus, perhaps, more properly be included under this heading. Certain bony enlargements, the pathology of which is not understood, such as *Leontiasis Ossea*, must be mentioned here. These may result in great disfiguration, and from pressure on nerves cause great pain. Extensive surgical operations are sometimes undertaken for their removal.

(c) *Pedunculated exostoses.*—The pedunculated exostosis, or ossifying chondroma, is a subperiosteal chondroma, with a tendency to ossification, developed in young people, near the junction of an epiphysis with a diaphysis. They are common in the subjects of rickets.

Pedunculated exostoses approach the spherical shape, but are sometimes irregular or flattish, and often tuberculated. The peduncle varies in its relative size, the growth being often nearly sessile. On section the tumour shows a layer of periosteum superficially; beneath this is a layer of cartilage, sometimes thick, sometimes almost imperceptible. The deeper part of the cartilaginous layer is calcified, and looks like imperfectly formed bone. The centre of the tumour consists of true bone, with Haversian systems complete, and is directly continuous with the tissue of the bone itself. The cancelli are sometimes dilated so as to form actual cysts containing clear fluid. In adult life the layer of cartilage may disappear; the tumours always cease to grow.

The microscopical appearance answers exactly to the structure which is apparent to the naked eye (Plate XIX.).

These tumours occur most often near the ends of the long bones, but may be found elsewhere; on the scapula, for example. They are often multiple and symmetrical, and if multiple are frequently hereditary. In certain situations, as, for instance, on the inner side of the knees, they may cause much inconvenience, from the pain produced by pressure as in riding, or from the catching and sudden slipping over the tumour of tendons or other fibrous structures in the neighbourhood. For this reason, or from their size, they may require removal. This may be done freely if antiseptic precautions be adopted; otherwise the opening of the cancellous structure of the bone, and the danger of wounding the contiguous joint, may perhaps involve greater risk than the amount of inconvenience entailed by the tumour would justify. They have sometimes been either purposely or accidentally separated from their attachment by a blow, without inflicting a wound on the soft parts at all. Unless the whole cartilage-layer be removed, recurrence will probably happen, as growth of the tumour takes place by increase of this layer only, the process of calcification and subsequent ossification being secondary, and, so to speak, accidental.

(d) *Osseous tumours of the soft parts.*—These osteomata are also uncommon. They include such conditions as the following: tumours springing from the periosteum, but not actually united to the bone; ossifying chondromata not connected with the bone; detached exostoses; ossification taking place in muscles or tendons, such as that which is occasionally met with in the adductor longus; and perhaps some other varieties of greater rarity.

(e) *Osseous tumours produced by the ossification of other kinds of new-growths.*—These are only secondarily, and often only partially, worthy of the name

of osteomata; they are the result of a process of ossification taking place in tumours of a different nature originally, such as fibromata or sarcomata. It must be remembered that, while calcification of new-growths is a common form of degeneration, the occurrence of true ossification is very rare.

(f) *Odontomata*.—Odontomata are tumours composed of one or more of the constituents of the teeth, and they may be classified accordingly: 1. Epithelial odontomes, arising from the enamel-organ and forming encapsuled, multilocular cystic tumours, usually in the lower jaw. 2. Follicular odontomes or dentigerous cysts (*see* article CYSTS). 3. Fibrous odontomes, uncommon tumours developed from the tooth-sac. 4. Cæmentomata, including exostoses from the fangs, which are common, usually small, and often extend from one tooth to another; and also a rarer form of tumour, consisting of larger masses of cæmentum in which teeth are embedded. 5. Compound follicular odontomes, resulting from irregular ossification of the capsule and containing numerous small fragments of cæmentum, dentine, or small ill-shaped teeth, embedded in fibrous tissue. 6. Radicular odontomes composed of cæmentum and dentine, and growing from the root. 7. Composite odontomes, which are masses of cæmentum, dentine, and enamel indiscriminately arranged and forming tumours in the substance of the jaws, usually the lower, or occupying the antrum of Highmore. Many of these odontomata are of great rarity. This arrangement is borrowed from Mr. J. Bland-Sutton. They are only found in connection with the jaws. *See* TEETH, Diseases of.

5. *Papillomata*.—DEFINITION.—Papillary and villous over-growths, whether occurring on mucous membrane, skin, or serous membrane, which do not present malignant characters.

VARIETIES AND SYMPTOMS.—Mucous papillomata are found on the lips, tongue, and soft palate, and in the larynx; in the intestines, especially at the lower part; round the anus (condylomata); in the bladder (the simple villous tumour); on the conjunctiva; and at the orifice of the female meatus urinarius. Epidermic papillomata include warts and corns, and may occur on any part of the skin; those about the external genitals may reach an enormous size, and are frequently the result of gonorrhœa. The serous and synovial papillomata are more rare; under this class must be named the Pacchionian bodies, and the enlarged synovial fringes which are often the commencements of loose bodies in joints. Many papillomata are of syphilitic origin; others may be caused by local irritation, as, for instance, the cadaveric wart, in which the papillary growth is accompanied by inflammation and suppuration beneath the skin, due in most cases, if not in all, to the presence of the tubercle-bacillus.

NAKED-EYE APPEARANCES.—The naked-eye appearances vary very much with the locality in which the growths are developed; but they present this character in common, that they are obviously composed of the papillæ or villi of the part from which they grow, though these may be of much more than the natural size. Those springing from mucous and serous membranes are soft, and usually moist on the surface; while epidermic papillomata are dry and hard.

MICROSCOPICAL CHARACTERS.—Microscopically papillomata are made up of connective tissue containing numerous vessels, covered by the characteristic epithelium or epidermis of the part (Plate IV.

p. 244). The arrangement of the connective tissue and epithelial elements is a close imitation of that of the normal tissues from which they grow. The microscopical structure of the benign polypus of the intestine (fig. 4, Plate IV, p. 244) is hardly to be distinguished from that of many malignant growths in this situation. *See* CANCER.

TREATMENT.—If affecting the larynx or bladder, papillomata may give rise to distressing and dangerous symptoms, and may necessitate severe operations for their extirpation. Those which occur on accessible parts are generally removed without any risk, except such as arises from their great vascularity; and show, as a rule, but little tendency to recur after complete removal. The common wart, however, often gives great trouble. Various caustics may be used, such as the acid nitrate of mercury, fuming nitric acid, caustic potash, glacial acetic acid, or nitrate of silver; salicylic acid is also often extremely useful; but while these remedies are sometimes efficacious, the warts will often recur with the greatest possible obstinacy. At the same time it must be remembered that they frequently show a most capricious tendency to spontaneous cure; the surgeon will sometimes be mortified at finding that while his energies have been devoted with but partial success to the cure of one or two out of an extensive crop of these growths, the remainder have, in the meantime, spontaneously disappeared. The cadaveric or dissecting-room wart is best treated by excision, for it must be regarded as a local tubercular lesion which may lead to general infection. The best local treatment for condylomata and gonorrhœal warts is the application of some desiccating powder, such as dried alum. It is well to remember that warts which remain a long time uncured are apt to become epitheliomatous; and not only so, but that any chronic irritation, whether from the application of insufficient methods of cure or other causes, is likely to lead to the same result.

6. *Adenomata*.—DEFINITION.—An ill-defined group of tumours, a typical member of which is essentially non-malignant, and is made up of tissue exactly resembling that of the gland from which it springs; but the departures from the ordinary type are so many and so varied, and, at times, so indefinite, that it becomes impossible to draw a clear line between the adenomata and the carcinomata, or indeed between the adenomata and the sarcomata.

(a) *Adenoma of the Sweat-glands*.—This class is said to include some non-ulcerating cutaneous tumours (the tubular epitheliomata of some authors); and some ulcerating ones—the cancroids or rodent ulcers have been erroneously placed under this heading. *See* RODENT ULCER.

(b) *Adenoma of the Sebaceous glands*.—This is a rare tumour, growing on different parts of the skin. Though not strictly a tumour, that local hypertrophy of the skin of the nose, to which the popular name of 'grog-blossom' has been given, must be mentioned here. This forms a nodular purplish tumour, growing from the end of the nose, and often reaching an enormous size. When cut into, it bleeds freely, and exudes from innumerable cavities in its interior an inspissated sebaceous secretion. *Microscopically* it is seen that the connective tissue and the vessels are hypertrophied, as well as the sebaceous glands. The *treatment* consists in removal by the knife; and cicatrization generally

occurs with wonderful rapidity. Recurrence is not uncommon.

(c) *Adenoma of the Mucous Glands.*—Under this heading might be included some of the simple polypi of the nose (see FIBROMATA). The best representative, however, is the simple polypus of the rectum. This is a sessile or pedunculated roundish tumour, occurring mostly in children and young subjects. It bleeds freely from the surface, and is often the cause of painful and somewhat troublesome symptoms, among which prolapsus ani is the most common. *Microscopically* it consists of tissue closely resembling that of the mucous membrane of the rectum, but the hypertrophied follicles are often imbedded in a tissue very similar to that which forms the basis of the mucous polypus of the nose (Plate IV. p. 244). The treatment is by removal either with the knife or ligature, or some form of snare or écraseur. Recurrence does not, as a rule, take place.

As is stated in the article CANCER, and as is shown on Plate IV., it is often almost impossible to distinguish, by their microscopical appearances, the simple adenomata of the large intestine from the malignant growths affecting the same structures. The same observation applies to many tumours of the jaws, such as that in Plate IV., which, though classed among the adenomata, often exhibit a high degree of malignancy.

(d) *Adenoma of the Breast.*—The most typical adenoma of the breast is a rounded tumour of moderate size, occurring often at the margin of the gland and frequently near the axillary border, completely encapsuled, and consisting of tissue which hardly differs from ordinary mammary structure (Plate IV.). It occurs usually in young women, often during the child-bearing period. It shows no tendency to recur after removal. A large number of adenomata of the breast do not, however, agree with this description, either as regards position or structure. In structure departure may take place from the normal type in two directions: by an excessive or abnormal development either (1) of the epithelial or (2) of the connective-tissue elements. In the former case the tumour, in proportion to its abnormality, approaches the cancers; in the latter it assumes more and more closely the characters of the sarcoma. Thus we find some of the softer adenomata, as shown in Plate IV., exhibiting a tendency to recur after removal, in the same way as a carcinoma, and with an almost equal degree of malignancy; while others, presenting characters like those of Plate IV., may follow the same course as the sarcoma, both as regards the manner of involving surrounding tissues and the way in which they recur in the viscera. These latter are called *adeno-sarcomata*, and often attain an enormous size. If the stroma of one of these tumours be in large amount, and fibrous or myxomatous, the names of *fibro-adenoma* and *myxo-adenoma* may be applied. Adenomata often contain cysts, and these cysts not infrequently intracystic growths. They must be treated by removal of the growth.

The reader must be content with the foregoing approximate description of this important class of tumours, the varieties in the nomenclature of which are equal to the number of the authors who have written on the subject. The writer believes that such unnecessary confusion has been caused by his multiplication of names, for a detailed account of which special works must be consulted, as their

discussion would lead far beyond the limits of the present article.

(e) *Other forms of Adenoma.*—Among other rarer forms of adenoma, bearing a more or less close relationship to the glands from which they spring, may be enumerated the following: Adenomata of the testicle or ovary, of the salivary and lachrymal glands, and of the liver, and some tumours of the thyroid. Many of the symmetrical enlargements of the thyroid, however, are simply hypertrophies of the gland itself, and should therefore be classed with simple hypertrophy of the breast and ordinary enlarged prostate, rather than with the tumours now under discussion. It should be noted that many of the less typical adenomata, especially those of the salivary glands and of the testicle, frequently are found in combination with other heteroplastic growths such as chondroma, myxoma, or some form of sarcoma.

7. *Lymphadenoma.*—Under certain circumstances, for an account of which the reader is referred to the article LYMPHADENOMA, the lymphatic glands throughout the body become enlarged, forming tumours, often of enormous size.

8. *Myoma.*—DEFINITION.—A tumour composed of muscular tissue.

With certain very rare exceptions, the only form of muscle-tissue occurring as an integral part of a tumour is the *unstripped* variety; and almost the only position in which this is found is in the so-called 'fibroma' (myoma) of the uterus. This growth consists of a mixture of fibrous tissue with plain muscular fibres in varying amount, usually exhibiting the concentric arrangement of its elements, which was described as characteristic of fibromata generally. Fibromata of the uterus may form pedunculated tumours on the external or internal surface of the uterus, or they may not extend beyond the uterine wall. They give rise to a variety of special symptoms, and require special methods of treatment, which it is beyond the scope of this article to discuss. See UTERUS, Diseases of.

Striped muscular fibre has been found in a few cases of congenital tumour of the kidneys; and the writer has also seen it in a fatty tumour growing inside the spinal canal.

9. *Neuromata.*—DEFINITION. — Tumours composed essentially of any form of nerve-tissue.

The majority of neuromata are really fibromata, that is, fibrous tumours developed among and around the fibres of the nerve from which they spring. The idiopathic forms are sometimes single, but generally multiple, of small size, very hard, and affecting usually the branches of a particular cutaneous nerve. The amount of pain and tenderness caused by these growths varies very much, but is sometimes excessive. A clinical feature of some use in diagnosis is the fact that they usually move readily in the lateral, but very imperfectly in the vertical direction. What may be called traumatic neuromata are fibromata containing tortuous outgrowths of the nerve-fibres developed at the end of a divided nerve in a stump. These often cause excessive pain and peculiar reflex phenomena; while they show a remarkable tendency to recur after removal. Neuromata on the cranial nerves are rare; they may cause serious and characteristic symptoms. Still rarer are the true neuromata of the brain and spinal column, and those occasionally met with in connection with the nerves or ganglia of the sympathetic.

It must not be forgotten that less simple tumours not infrequently affect nerves, such as the various forms of sarcoma, or myxoma. No special description of these growths in this situation is, however, required.

10. **Angioma.**—SYNON.: Telangiectasis.

DEFINITION.—A tumour composed of blood-vessels.

Angiomata divide themselves naturally into those in which the *capillary* element predominates; and those which are chiefly made up of *cavernous* tissue.

(a) *Capillary angiomata.*—DESCRIPTION.—These are the *nævi*, which, while they sometimes form tumours of some magnitude, often, as in the case of so-called ‘claret-cheek,’ involve no increase in the size of the affected part. Nævi are nearly always congenital, hence the term ‘mother’s mark.’ They may be subdivided into *cutaneous* and *subcutaneous* nævi. The former are of a more or less bright red colour, and affect only the cutaneous structures or mucous membrane; the latter, as seen through the skin, in cases where this remains unaffected, have a purplish tint, and may involve any of the deeper structures of the body. They are usually as circumscribed as fatty tumours, and very commonly involve the skin. Nævi often grow with extreme rapidity, and though they involve no danger to life (except in such rare conditions as when serious or fatal hæmorrhage occurs from a nævus of the pelvis of the kidney or of the rectum), they may cause serious inconvenience and great disfigurement. Sometimes, however, they exhibit a tendency to spontaneous disappearance, and often they remain permanently stationary. They are liable to various forms of degeneration, notably the cystic, and the ulcerative or suppurative.

Microscopically a nævus is composed of large capillaries, among which are seen arterial and venous trunks of larger size. Between the vessels is found connective tissue or fat, and sometimes the special constituents of the skin, such as sweat-glands or sebaceous glands. The nævus-element enters rather largely into the composition of some other tumours, and notably of congenital moles (*benign melanoses*).

TREATMENT.—Inflammation of a nævus generally leads to spontaneous cure; nature thus suggesting one of the best methods of treatment at the disposal of the surgeon, namely, the injection of the tumour with some suitable irritant, such as carbolic acid. In adopting this line of treatment, it must be remembered that a danger exists of the irritating fluid entering a larger vessel, and by passing to the heart and setting up coagulation there causing instant death; this may be guarded against by the application of a temporary ligature. Other recognised and useful plans of treatment are the following: electrolysis, puncture with the actual cautery, and complete excision of the mass. The last in available situations affords the most speedy cure, and often leaves the least conspicuous scar. Resort is now seldom had to the ligature or treatment by pressure or the application of caustics.

(b) *Cavernous angiomata.*—DESCRIPTION.—Those angiomata which are made up of larger vessels, and which are hence called the cavernous angiomata, from their resemblance in structure to erectile tissue, consist of cavernous spaces, communicating by smaller or larger vessels, and separated by trabeculae of greater or less thickness and substance. These are the *pulsating nævi*, and

perhaps some of the so-called *aneurysms by anastomosis*. They are of a more dusky colour than simple nævi, and often present a distinct thrill or bruit, which is perceptible both to the patient and to the surgeon. They are sometimes encapsuled, sometimes diffused; and in the latter case show an almost malignant tendency to involve neighbouring structures. The pulsation is often a most distressing symptom to the patient, if the tumour be found occupying such positions as the pinna of the ear or the fat of the orbit, both of which situations are not at all uncommon for the occurrence of the disease. *Microscopically* a cavernous angioma presents fibrous trabeculae, lined with the characteristic vascular endothelium, and in parts perhaps separated by layers of areolar or any other tissue which the tumour may happen to involve.

TREATMENT.—The treatment must be pursued on the same lines as that for the simple forms of nævus. It should, however, be undertaken with caution; for injection is a much more dangerous proceeding on account of the large size of the vessels, and excision is apt to be accompanied with serious hæmorrhage, because of the enlargement of the vessels in the neighbourhood.

11. **Lymphangioma.**—DEFINITION.—A rare kind of tumour, which may briefly be described as a cavernous angioma made up of lymphatic vessels.

To this class belong some curious and uncommon flat pinkish elevations of the skin, characterised by the presence of minute vessels containing clear fluid, and particularly prone to erysipelatous inflammation. It also in all probability includes the *cystic hygromata* occasionally met with congenitally. See CYSTIC LYMPHANGIOMA.

B. **Sarcomata.**—DEFINITION.—It is to be regretted that the term ‘sarcoma’ has not been allowed to slip out of pathological terminology. From the days of Galen almost to our own time it has served, in the hands of different authors, to designate different classes of tumours, sometimes of the simplest, sometimes of the most malignant character. Virchow, however, has given a meaning to the word which is now generally recognised by pathologists. He includes under *sarcomata* those new-growths which, while they do not actually consist of any of the tissues of the adult body, are evidently built on the connective-tissue type, and consist of a modification of the connective tissue of the embryo. They are thus very closely related to some of the simple tumours, and indeed often include portions of some normal tissue, such as bone, cartilage, or fibrous tissue—a fact which necessitates the employment of complicated and confusing names, including *osteo-sarcoma*, *chondro-sarcoma*, *fibro-sarcoma*, and such-like.

Certain forms of sarcoma, especially of the rounded variety, are believed to originate in the endothelial lining of lymphatics or capillary blood-vessels. To these tumours the name *endothelioma* has been applied. The subject will be referred to later on.

MICROSCOPICAL CHARACTERS.—Histologically, then, a sarcoma is made up simply of cells of the connective-tissue type, which may assume very various shapes and sizes in different tumours, and which are surrounded by a varying amount of inter-cellular substance.

CLINICAL CHARACTERS.—Theoretically sarcomata should always be developed in one of the connective-tissue structures, and practically they are

not very often seen to originate in a secreting gland. But a glandular origin is not by any means very uncommon, as indeed might have been expected when it is remembered that every gland contains a considerable amount of connective tissue. Sarcomata present all degrees of malignancy; but, as a rough rule, it may be stated that the higher the degree of development of the tumour, the less likely is recurrence to take place after removal. In connection with this point it is interesting to note that each recurrence of a sarcoma often shows a more rudimentary structure, and at the same time a greater degree of malignancy.

Dissemination does not follow the same rule that has been observed in the case of cancer. The lymphatic glands often escape altogether, or are but slightly affected; while fresh tumours spring up in abundance in distant parts of the body.

Sarcomata increase in size in the same way as cancers, but in the less malignant forms are often surrounded by a more or less distinct capsule.

VARIETIES.—1. *Round-celled Sarcomata*.—These are the most rudimentary, and, as a rule, the most malignant of this class. They are usually soft—sometimes very soft—seldom encapsuled, and generally of a whitish colour. Formerly they were classed among the medullary cancers. They are made up of round cells, as the name implies, and have a tendency to group themselves into two classes, in one of which the cells are *small* and uniform in size (fig. 9), closely resembling those of granulation-tissue; and in the other large, sometimes very large, and often somewhat irregular (fig. 8). The intercellular substance may be copious and homogeneous, in which case the tumour approaches the myxomata; or smaller in amount and fibrous, when, if the cells are small, it may be difficult to separate such a sarcoma from the lymphomata. To some of these the term *lymphosarcoma* has been applied. Such tumours occur in the tonsil, or may start in the lymphatic glands.

Under this head must be placed the *Gliomata*—soft medullary tumours met with in the brain or in connection with nerves, frequently with the retina, and occurring commonly in children. They show microscopically a delicate stroma. See p. 196.

2. *Oval-celled Sarcomata*.—This variety of sarcoma represents the next stage in advance from the simplest towards a more complex structure. They differ, in fact, but slightly from the round-celled growth, either in clinical or in microscopical characters (fig. 10), but may be looked upon as intermediate between these and the spindle-celled sarcomata.

3. *Spindle-celled Sarcomata*.—This class must be subdivided into the *small spindle-celled*, and the *large spindle-celled* varieties.

The *small spindle-celled sarcomata* are firm, whitish, well-defined tumours, which approach the fibromata, sometimes very closely, and which after complete removal show a comparatively slight tendency to recur. These were the *recurrent fibroids* of older writers. *Microscopically* (fig. 12) they consist of broad interlacing bands of elongated cells, with but little intercellular material—a structure which does not differ widely from imperfectly formed fibrous tissue.

The *large spindle-celled sarcomata* (fig. 16) are softer growths, frequently supplied with a very imperfect capsule, generally pinkish on section, or stained in parts dark red from extravasated blood,

and often showing cysts. They may occur in any fibrous structure, but are rather common in connection with the periosteum. The malignancy of these growths is much greater than that of the small-celled class. *Microscopically* they consist of very large nucleated cells, with long tapering tails, and but little intercellular substance. These are the *fibro-plastic* tumours.

4. *Alveolar Sarcomata*.—Examined *microscopically* this rare form of tumour (fig. 13) bears a superficial resemblance to a cancer. There is, that is to say, a coarse stroma forming alveolar spaces, each of which contains a variable number of large, round, nucleated cells; each space is, however, again subdivided by a very delicate secondary intercellular stroma. This is only demonstrable on pencilling out the cells, which, unlike a similar process applied to a cancer, is a work of considerable difficulty. Alveolar sarcomata affect most commonly subcutaneous tissues primarily; they are apt to recur in other parts of the body, and ultimately in internal organs, but often run a very chronic course.

5. *Mixed Sarcomata*.—Tumours are often met with which present a mixture of the different structures just described. Such are conveniently called mixed sarcomata; and the term may with advantage be made to include those growths which contain, besides sarcoma-tissue, bone, cartilage, gland-tissue, &c. The latter growths will necessitate the employment of such names as osteosarcoma, chondro-sarcoma, adeno-sarcoma, &c.

6. *Myeloid*.—**SYNON.**: Giant-celled Sarcomata. — These tumours are best classed among the sarcomata. *Microscopically* (fig. 7) they present the following elements, one or other of which may greatly predominate: fibro-plastic or spindle-cells, oval or round cells, and very large nucleated cells, the so-called 'myeloid' or 'giant' cells. These last are irregular or rounded masses of granular protoplasm, in which occur numerous clear oval nuclei, each containing a well-marked nucleolus. The amount of intercellular substance is small. In a fresh scraping the clear oval nuclei are set free by the breaking up of the giant-cells. To the naked eye a section of a myeloid tumour is pink or yellowish, but almost always mottled with darker spots, the result of extravasations of blood. Very frequently, tumours of this class present points of ossification or calcification, and not infrequently cysts. They are very soft, and usually yield a thick juice on scraping. They generally originate in, or, more rarely, close to, the end of one of the long bones; probably most often in the medullary cavity or the cancellous structure. Another frequent seat is the alveolar border of the jaws, where they form the myeloid epulis. They occur most often in young people, and if the bone involved be removed completely or in great part, have no tendency to recur; but, on the other hand, they may exhibit a high degree of malignancy, recurring not only in other bones, but in internal organs. It is said that myeloid epulides may in time become completely fibrous.

7. *Myxoma*.—It is not easy to say whether myxomata should be classed among the sarcomata or among the simple tumours. On the one hand, the tissue of which a myxoma is composed finds no representative in the adult, unless that of the vitreous body be taken as such; but, on the other hand, they approach very closely some of the soft

fibromata, and are nearly related to fatty tumours. At the same time a large number of myxomata appear to be actual chondromata. It must be added that some modern pathologists assert that many myxomata are really endotheliomata.

Microscopically (fig. 3) a myxoma presents elongated or roundish much-branched cells, the prolongations of which intercommunicate freely. These cells are embedded in a copious, homogeneous, transparent matrix. The structure thus resembles that of foetal fat; but, in myxomata developed from cartilage, each cell is contained in a space similar to that enclosing a cartilage-cell.

Clinically these tumours are very soft and elastic, strictly encapsuled, gelatinous, semi-transparent on section, and exuding a peculiar mucous juice. Myxomata are not malignant; and as a rule, if completely removed, do not recur locally. They may be found in many parts of the body, but perhaps most frequently in the subcutaneous tissue, or in connection with some gland, particularly the parotid. Here, however, they are often mixed with adenoid and cartilaginous material. Not infrequently myxoma-tissue is combined with that of an undoubted sarcoma, which necessitates the term *myxo-sarcoma*. These tumours may occasionally be mistaken for colloid cancers. Histologically some of the soft enchondromata resemble them very closely.

8 and 9. *Osteo-Sarcoma*; and *Chondro-Sarcoma*.—These forms of sarcoma have just been referred to under the head of *Mixed Sarcomata*.

10. *Melanotic Sarcomata*.—These tumours are, in the experience of the writer, usually of the mixed round- and spindle-celled variety. Some, but not all, of the cells contain a brown pigment, but in very varying amount, and pigment is also found outside the cells (fig. 15). This gives the tumour a brown or blackish appearance. These tumours, though often completely encapsuled, show a high degree of malignancy; but are often succeeded by a mixture of white and black tumours, or sometimes by white tumours alone. They are not uncommon in connection with the choroid of the eye, and the papillæ of the skin (malignant mole), but have often been met with primarily in other parts of the body. The secondary growths are often found disseminated through every tissue of the body, forming tumours in such situations as the intestine, of peculiar and characteristic appearance. Secondary deposits in lymphatic glands are more common than is the case in other forms of sarcoma. It has been observed that in some cases of melanosis black pigment, accompanied by other morbid appearances, has been found in the blood, and also in the urine.

11. *Psammodoma*.—It is only necessary to mention this very rare tumour, which is found only in connection with the membranes of the brain. It is composed of flattened cells, and is characterised by the peculiarity of containing brain-sand in its interior. It seldom or never gives rise to symptoms. See p. 332.

Endothelioma.—It is difficult at the present time to write definitely on this class of tumours, which are supposed to arise from the lining membrane of the blood-vessels and lymphatics; for, while some observers describe them as rare, others consider that all the simple tumours of the parotid region and many cancers of the breast belong to this cate-

gory. Under the circumstances it seems impossible to attempt to describe them. The reader must be satisfied to know that this subject is under discussion, and to consult the most recent literature about it.

Teratomata.—Mention must be made, in conclusion, of a form of growth, which does not come within the classification here selected. This is a congenital tumour not infrequently met with in the region of the sacrum (*congenital sacral tumour*), but occasionally seen elsewhere; often reaching a size almost equal to that of the infant itself. In structure these tumours consist of various imperfectly developed foetal or mature elements of the body, mixed together in apparently great confusion. Various theories as to their causation have been propounded; such, for example, as that they consist of an imperfect attached foetus, or that they originate from Luschka's gland; but we have not sufficient data at present to express an opinion on this point. Attempts at their cure by removal are attended with great danger (see p. 1518).

R. J. GODLEE.

TUNBRIDGE WELLS, in Kent.—Iron waters. See MINERAL WATERS.

TUNNEL-WORM.—A synonym for the Ankylostoma duodenale. See ENTOZOA.

TURGESCE (*turgesco*, I swell).—A term applied to a swollen condition of a part, generally associated with fulness of the blood-vessels, as in the mucous membrane of the conjunctiva, the fauces, or the rectum.

TUSSIVE (*tussis*, a cough).—This word is applied to certain physical signs which are elicited by the act of coughing, such as *tussive fremitus* and *tussive resonance*. See PHYSICAL EXAMINATION.

TYLOSIS (τύλος, callus).—SYNON. : Callosity.—This name originally signified any hardening of the skin, the result of pressure, or any other cause. It has, however, become customary to apply the term to certain fairly well-defined conditions. In its clinical significance it may be regarded as a thickening of the horny layer of the skin, accompanied by appreciable inflammatory reaction. In this category is included the condition known as *tylosis palma et planta*. This disease, which appears to be in many cases congenital, consists in the thickening of the epithelium of the palms and soles, so that a firm parchment-like or horny layer is produced. This is usually of a yellowish or brownish tint, and semi-translucent in appearance. On account of the stiffening produced, and the movements of the hand, cracks are liable to occur, and this may be the cause of much pain; the surface also may lose its yellowish, horny appearance, and become greyish or black as the result of the discolouration of epithelium, and the adhesion of dirt and foreign matter. The condition is usually limited to the palmar and plantar surfaces.

Several of the cases reported have occurred in family groups, and may be regarded as congenital. In other cases the disease appears in adult life, and is often associated with hyperidrosis. Arsenical keratosis in bad cases may simulate this affection, but its papular appearance in the early stage, and the increase of pigmentation, which is frequent, as

well as other symptoms of arsenical poisoning, serve to distinguish the one condition from the other.

In addition, one or two rare affections of the palms and soles produce thickening of the epithelium to a very marked extent. These are, however, associated with a greater or less degree of erythema, which may be especially distinguished at the margins of the horny areas. In this category come the Erythema keratodes of Brooke, and the Keratoderma erythematosa symmetrica, described by Besnier.

The term 'tylosis' is loosely applied to the thickening of the palms and soles secondary to conditions such as eczema, psoriasis, and lichen planus. The inflammatory reaction in these conditions is usually recognisable, and the darkened, cracked, and crusty surface serves to distinguish them from the congenital diseases, to which the name is perhaps more appropriately limited.

In many of these pathological states the peculiar thickening which is given rise to may be the result of imperfect development of the epithelium as the result of abnormal conditions of the epitrachium. This condition would especially account for congenital cases of the disease unassociated with inflammation.

TREATMENT.—Even in congenital tylosis, and more especially in the irregular varieties of other types, much can be done by softening the epithelium by means of baths, or even by alkaline applications of soft soap or borax, and the subsequent application of salicylic acid. This drug may be applied in the form of solutions, as ointments, or plasters. The strength of these ranges from 5 to 50 per cent. The horny epithelium is thus removed from time to time, and in those cases which cannot be cured the skin is rendered more supple, while in certain cases actual cure can be brought about.

JAMES GALLOWAY.

TYMPANITES (τύμπανον, a drum).—SYNON.: Fr. *Tympanite*; Ger. *Windsucht*.—This word signifies the distension of the abdomen that results from excessive accumulation of gas within its cavity. As a rule, the gas collects in the interior of the alimentary canal, especially the intestines; but in exceptional cases it occupies the peritoneal cavity.

ÆTIOLOGY.—Tympanites is chiefly met with under the following circumstances: 1. In connection with certain diseases which, from their local effects, tend to paralyse the intestines, especially acute peritonitis, typhoid fever, and dysentery. 2. In cases of intestinal obstruction from any cause, but particularly when this condition is acute, and situated low down. 3. In certain low febrile diseases, accompanied by the 'typhoid state,' and tending towards a fatal issue, such as typhus fever, small-pox, erysipelas, and pneumonia. 4. As a result of perforation of the stomach or intestine. 5. In certain cases of chronic disease of the spinal cord. 6. In connection with hysteria sometimes. In all these conditions, except where the gas escapes into the peritoneal cavity, the immediate cause of the tympanites is a more or less paralysed state of the walls of the intestines; but there is often, at the same time, an excessive formation of gas in their interior, which distends them.

SYMPTOMS.—The symptoms of tympanites are due to the mechanical effects of the gaseous accumulation. The patient is usually conscious of the distension of the abdomen, and the sensation may

amount to extreme discomfort or actual suffering and great distress, there being a feeling in some instances as if the abdomen must burst if the condition is not relieved. The mental state of the patient may, however, be such that he is unconscious of, or indifferent to, any unusual sensations. Breathing is often interfered with in various degrees, and the act may be very hurried, with a feeling of urgent dyspnoea. The heart is also liable to be affected, and its action more or less disturbed. The secretion of urine may be interfered with, even almost to actual suppression.

PHYSICAL SIGNS.—These are usually very characteristic. 1. The abdomen is uniformly enlarged, often to an extreme degree; being of a rounded shape; equal and symmetrical in every part, unless there happen to be a portion of bowel specially distended, and without any tendency to undue prominence in dependent parts. The skin is stretched more or less, but there is no protrusion of the umbilicus. 2. The sensations on palpation are those of perfect smoothness and regularity, with great tension or a drum-like feel. 3. Percussion gives a general tympanitic sound over the abdomen, and also brings out the drum-like sensation. If, however, the distension is extreme, the sound becomes more or less muffled and toneless. Generally the dullness of the solid organs in the abdomen is partially or entirely obscured, or is displaced upwards. 4. Change of posture produces no alteration in the physical signs. 5. There may be indications of displacement of the thoracic organs. It must be mentioned that tympanites may be associated with some fluid in the peritoneal cavity, or with other conditions, and the physical signs will be modified accordingly.

TREATMENT.—In the first instance, any obvious and immediate cause of tympanites must be removed, if practicable, such as intestinal obstruction, or an accumulation of fæces. If the symptom calls for direct treatment, relief may be afforded in some cases by applying heat or cold, sinapisms, or turpentine stupes over the abdomen; and administering internally such remedies as brandy, aromatic spirit of ammonia, the various ethers, the volatile oils, camphor, musk, valerian, sumpul, galbanum, asa-fetida, or other gum-resins. Should these fail, enemata containing asafetida or turpentine may not uncommonly be used with advantage. The passage of a long tube, such as an oesophagus-tube, through the anus into the bowel, reaching as high up as possible, is often very serviceable. In extreme cases it has been recommended to open the abdomen and make a longitudinal incision in the bowel, thus establishing an artificial anus for the time being. When gas accumulates in the peritoneal cavity, it can only be got rid of by surgical interference, should such interference be otherwise indicated.

FREDERICK T. ROBERTS.

TYMPANITIC (*tympanum*, a drum).—A peculiar drum-like quality of sound elicited by percussion (see PHYSICAL EXAMINATION). The term is also applied to the abdomen, when it is distended with gas. See TYMPANITES.

TYMPANUM, Diseases of.—See EAR, Diseases of.

TYPE-WRITER'S CRAMP.—See WRITER'S CRAMP; and OCCUPATION-DISEASES.

TYPHLITIS (τυφλόν, the cæcum).—Inflammation of the cæcum. See APPENDIX VERMIFORMIS, Inflammation of; and INTESTINES, Diseases of.

TYPHOID FEVER (τύφος, stupor).—SYNON.: Enteric Fever; Pythogenic Fever; Gastric Fever; Infantile Remittent Fever; Fr. *Fièvre Typhoïde*; *Fièvre Gastrique*; *Dothiëntérie*; Ger. *Typhus Abdominalis*.

DEFINITION.—A continued fever of long duration; usually attended by diarrhoea; and characterised by peculiar intestinal lesions, an eruption of small rose spots, and enlargement of the spleen.

ÆTIOLOGY.—Typhoid fever is now known to be due to a specific *typhoid-bacillus* which is reproduced in the system during the fever. Its chief outlet is in the intestinal discharges. There is no evidence that it is conveyed by the breath or perspiration; the bacilli, however, have been abundantly found in the urine. While the contagium is present in the fæces and urine, it has not apparently always at the moment of their passage its full virulence, but requires for its complete development a certain period of time, and this is forwarded by some conditions, retarded or prevented by others. Exposure to sunlight and open air, as in flowing rivers, is inimical to the development of the typhoid-microbe, and probably indeed destroys it. On the other hand, warmth, stagnation, seclusion from open air and light, accumulation and concentration of the infected discharges intensify the poison, and it would seem that a small amount of typhoid-evacuations may give rise to a large development of the contagium in excretory matters with which they become mingled, and even in milk to which they may obtain access. This multiplication of the bacilli outside the body explains the autumnal prevalence of typhoid fever observed in large towns, and the association pointed out by Murchison between a hot and dry summer and a high fever-rate in London. The drains not being flushed by abundant rainfall, sewage accumulates and stagnates in them, and typhoid stools never being wanting, the specific fermentation goes on rapidly under the influence of the high temperature, and produces the poison in quantity and intensity. See p. 1191.

The modes in which typhoid fever is disseminated are various. It is not commonly transmitted directly from person to person. Medical men, clergymen, and others visiting those who are suffering are not attacked, nurses very rarely, when proper precautions are observed. If, however, bedclothes or carpets soiled by the evacuations are not removed and disinfected, and still more where gross neglect of cleanliness and decency is permitted, attendants will contract the disease.

Flies may carry the bacilli from urine or fæces or perhaps from the mouth of the patient to food or drink in the sick-room, and thus be the means of communicating the disease from person to person.

The most common vehicle of the poison is drinking-water, which may be contaminated in various ways, mostly through sewage. The water-supply of a town may be thus poisoned at its source, as in the case of a river into which drains empty themselves, or a reservoir or well accidentally contaminated; or the pipes of distribution, when the supply is intermittent, may while empty become charged

with sewer-gases, or may even receive sewage; or excessive rainfall may, in villages and small towns, wash the contents of cesspools into wells. This same rainfall, by flushing the sewers of well-drained towns, and washing away the specific poison, has often a contrary effect in towns and country. In some places the subsoil water, permeating a bed of gravel, is at the same time the well-water of a village and a reservoir of its sewage. An imported case of fever will under these conditions poison almost the entire community. With these examples of wholesale dissemination of typhoid fever must be mentioned the so-called 'milk epidemics' already alluded to. A case of fever occurs at a farm, or among the employés of a dairy; from defective sanitary arrangements the water used at the farm or dairy becomes contaminated by the excreta; this is added to the milk as an adulteration, or, as is usually said, is used in washing out the cans, and in this way the poison obtains access to the milk, where apparently it must increase very rapidly. Hundreds of cases have been traced to a single dairy.

The poison may lurk in various articles of food and drink. The cheap ices sold on barrows in the streets have been shown to be frequently contaminated with typhoid bacilli, and even the cream given with strawberries at a fashionable dinner-party has been known to convey the poison. Oysters and other molluscs, again, have been proved by conclusive evidence to have been the means of disseminating typhoid fever, and an investigation instituted by the Public Health Department of the Local Government Board showed that certain oyster-beds were open to contamination by typhoid excreta. The bacilli, moreover, have been found in oysters.

More commonly, perhaps, the occurrence of typhoid fever is traceable to the absence of proper sanitary arrangements in individual houses. Not to speak of cesspools and leaking drain-pipes allowing the basement to be sodden with sewage, sinks or water-closets may be imperfectly trapped, and sewer-gas diffuses through the apartments or is drawn into the living-rooms by fires, or is forced into the house by pressure in the main drains, or the waste-pipe of the cistern is in direct communication with the drains, and sewer-gases conveyed by it are confined in the space under the cistern-lid, and absorbed by the water used for drinking purposes, which conveys the poison. In connection with these modes of dissemination it should be borne in mind that well-made and close-fitting doors and windows may aid in compelling foul air to enter from the drains or subsoil, and that houses in elevated situations, and thus apparently well placed for drainage, are in greater danger from pressure of gases in the main drains. It is said, however, that the bacilli do not leave the sewage and the moist walls of drain-pipes, and sewer-gas has on examination always been found free from bacilli. This would seem to invalidate the explanation just given, but the fact remains that in some way or other defective drains and leaking soil-pipes give rise to enteric fever.

It is again possible that emanations from a newly opened drain, or cesspool, or foul privy, may communicate the disease by atmospheric contagion—though this is comparatively rare—it being understood always that typhoid excreta form part of the contents. But a drain open to the air throughout

its course, however offensive, is not so likely to give rise to the disease as closed and unventilated sewers; and sewage-farms, if at all well managed, are quite harmless.

It should be added that while, in this country and in Europe generally, all the evidence tends increasingly to confirm the dependence of typhoid fever on dissemination by drinking-water as its chief mode of propagation, observations in India show that the part played by water here is in India played by dust, which conveys the poison in the dry state to articles of food and drink. Contaminated dust has apparently been one of the agencies in the spread of enteric fever in the recent campaigns in South Africa.

It is unnecessary here to discuss Pettenkofer's hypothesis that the varying prevalence of typhoid fever is connected with the varying level of the subsoil water, which as it rises displaces gases which have become saturated with poison from the soil into the atmosphere. It certainly does not apply to the facts as observed in this country.

One word must be said with regard to individual susceptibility to the disease, and with regard to predisposing causes acting on the individual. It is a matter of almost daily observation that some persons never contract typhoid fever, however much they may be exposed to the poison, while others take it readily; and it is almost equally obvious that certain families are extremely susceptible, and liable to have the disease in a severe form. It is always a reason to apprehend a formidable attack if a parent have died of the fever. Typhoid fever may occur at any age, but it is very rare in advanced life. It is probably more common in infancy than is generally supposed, as it is easily overlooked or confounded with common infantile ailments. The period of life at which the disease is most common is during adolescence and the first decade of adult age. Among the predisposing causes are mental depression or shock, over-work, and debility, however induced. A person habitually imbibing the poison may not be attacked until his power of resistance is impaired by some depressing influence. In this way a chill may appear to bring on the disease. It is natural to suppose that unfavourable hygienic conditions would generate a predisposition, but doubt is thrown on this by the fact that typhoid fever does not by any means predominantly affect the poor. The influence of habitual consumption of impure water, again, is not very clear. In some instances it has appeared to make an epidemic severe, but, on the other hand, it would almost seem that the inhabitants of some towns, the water of which is constantly contaminated, acquire an immunity from the disease.

Influenza undoubtedly acts as a predisposing cause of enteric fever, and apparently in a more direct way than simply as a debilitating influence. Beginning with the characteristic symptoms of influenza, the sudden onset, the severe general pains, the rapid rise of temperature, and the prostration, there may be a gradual development of symptoms belonging to typhoid fever without any marked fall of the temperature. In other cases there is a distinct remission of the initial influenza temperature to be followed by the gradual rise commonly seen in enteric fever. In others again there is a brief period of convalescence before the typhoid fever sets in. Influenza opens the door to enteric fever so frequently that there would seem to

be some such relation between these two diseases as between measles and pertussis.

BACTERIOLOGY (by DR. EYRE).—The *Bacillus typhosus* or *Bacillus typhi abdominalis* was first detected by Eberth in 1880, in sections of spleen, Peyer's patches and lymphatic glands of cases of typhoid fever; but was isolated, cultivated and described by Gaffky. During life the organism may be isolated from the faeces (from the sixth day onwards) and urine (from about the twenty-first day) of patients suffering from enterica; but although one observer claims to have obtained it from the blood of the 'rose spots,' the bacillus is not present in the blood of the general circulation. *Post mortem*, the typhoid-bacillus can be demonstrated constantly in the spleen, mesenteric glands and Peyer's patches; and frequently in the liver, heart, muscle and lungs.

Morphology.—The typhoid-bacillus is a short rod with rounded ends, 2μ to 4μ in length, by 0.4μ to 0.8μ in breadth. In artificial cultures, the bacillus is pleomorphic, and long thread forms of 10μ to 20μ

FIG. 1.—Typhoid-Bacilli in section of a swollen Peyer's patch. Showing the usual appearance in stained sections. $\times 950$.

are common. The bacillus is extremely motile (although in old cultivations this character may be almost lost), and possesses from 12 to 20 flagella, arranged at the poles and also laterally. Spore-formation does not take place, but central or ter-

minal vacuoles may be noted in the bacilli derived from certain media, e.g. potato. The bacillus stains with the ordinary anilin dyes, usually evenly throughout but occasionally showing polar or irregular distribution of the colour; it is decolourised when treated by Gram's method.

Biological.—The typhoid-bacillus multiplies rapidly under either aerobic or anaerobic conditions, and is readily cultivated upon artificial nutrient media, even those containing a fair amount of free acid. The temperature-limits within which growth takes place are 10° C. and 46° C.; the most luxuriant growth occurs between 35° C. and 42° C.; the thermal death-point is reached at 58° C. The vitality of the organism is maintained for many months upon artificial media. It is killed by exposure to direct sunlight for from four to eight hours, but resists desiccation and freezing for considerable periods. The typhoid-bacillus remains alive in sterilised water for about one month, but dies in about fourteen days in aerated water; and in about the same time in ordinary unsterilised water. It has been recovered after eighteen days in dry garden-earth, and after forty-two days in moist garden-earth, but disappears after seven days in artificially dried soil. In sterilised sewage it also disappears within a few days. The admixture of highly diluted serum from an animal immunised against the *Bacillus typhosus*, or a patient suffering from typhoid fever, with a suspension of the bacilli in some indifferent fluid, causes the organism to become aggregated into masses or clumps, and affords a valuable means of differentiating the typhoid-bacillus from the colon-bacillus. See SERUM-REACTIONS.

Cultural Characters.—On gelatine plate-cultivations incubated at 20° C. the superficial colonies appear at 48 to 72 hours as flat, thin, bluish, translucent plaques, 1 to 3 mm. in diameter, with irregular crenated edges. They increase somewhat in size during the next few days, the central portion of each colony becomes slightly elevated, the surface granular and covered with lines and grooves, resembling the veining on a vine-leaf, the margin sloped and irregular in outline. The bluish translucent tint is retained. The deep colonies are not characteristic, being simply small spherical points, with sharp regular contour, finely granular surface, and yellowish in colour. The gelatine is not liquefied.

A gelatine streak-cultivation shows as a delicate bluish translucent film, with a granular surface and irregular sinuous margins, spreading a little at the bottom of the tube, where the medium is most abundant, but closely restricted to the needle-track at the upper parts. In old cultivations the growth may become more opaque, and iridescent; and deposits of phosphate-crystals make their appearance in the gelatine around and below the growth.

In gelatine stab-culture, small lenticular colonies, which sometimes coalesce, appear along the needle-track, while a semi-transparent filmy disc with scalloped edges develops on the surface.

Shake-cultivations in sugar-gelatine show abundant growth throughout the medium, but no gas-formation occurs.

Bouillon-cultivations incubated at 37° C. show a uniform turbidity within 24 hours, and when shaken present a peculiar shot-silk appearance. After a time some of the growth is precipitated to the bottom of the tube, but the supernatant fluid never becomes quite clear. The nitroso-indol reaction cannot be obtained from cultivations of the typhoid-bacillus.

In agar and glycerine-agar streak-cultivations the growth is rapid and luxuriant, and forms a raised, moist, shining, greyish-white layer, which, how-

ever, does not extend to any great distance from the needle-track.

On inspissated blood-serum, the growth resembles that upon agar; the medium is not liquefied.

In litmus-milk free growth takes place resulting in the production of a faint though distinct acid reaction, but not accompanied by any clotting of the medium.

Upon potatoes of acid reaction, the growth of the typhoid-bacillus is apparent only as a moist patch, but if the reaction of the medium chances to be alkaline, a moist yellowish or buff-coloured layer is formed.

PATHOGENESIS.—The *Bacillus typhosus* is pathogenic for the ordinary laboratory animals, though extreme variations in virulence are observed in 'strains' obtained from different sources, and in nearly every case a series of passages through the serous cavities of a number of animals, assisted perhaps at first by the simultaneous injection of 'killed' cultures of the colon-bacillus or some other indol-producing organism, is essential for the production of a fixed virus. The typhoid-bacillus is pathogenic for the guinea-pig, the mouse, and the rabbit, in the order named, death from general septicæmia resulting after subcutaneous, intrapleural, intraperitoneal or intravenous inoculation of a virulent culture, in from twelve hours to two or three days, according to the dose employed. A very small dose of a highly virulent culture or the inoculation with an attenuated virus results in purulent infiltration of the infected tissues, which either spreads extensively and leads to general infection and death, or is limited in area, producing an eschar, after which recovery ensues. In fatal cases, identical lesions are produced by all forms of inoculation, and consist in sero-fibrinous or sero-purulent exudation into the serous cavities, varying in amount from a few drops to 8 or 10 c.c., and teeming with typhoid-bacilli; hæmorrhagic enlargement of the spleen, which may be almost black in colour; injection of the intestinal vessels, with increased mucous secretion; and tumefaction of Peyer's patches; and hæmorrhagic infiltration of the adrenals and, to a less extent, of the kidneys. The bacilli can be demonstrated in these organs, though in progressively smaller numbers, in the order named. The heart-blood also contains the bacilli, but in very small numbers. Similar anatomical lesions are noted when death follows the subcutaneous injection of virulent toxins obtained from bouillon-cultivations of the *Bacillus typhosus*.

ANATOMICAL CHARACTERS AND PATHOLOGY.—Special interest attaches to the structural lesions which take place in typhoid fever, as they are closely associated with the symptoms, and are accountable for many of the complications which occur. The relation of the intestinal lesions to the febrile process has been differently interpreted. They have been considered, on the one hand, as the focus in which the morbid germs multiply, and from which the blood is infected; and, on the other, the primary change has been supposed to take place in the blood, the lesions being secondary to this, like the pustules in small-pox. In fatal cases local congestions and inflammations are met with in the lungs and other organs, but the special and characteristic lesions are those taking place in the intestines and mesenteric glands. The intestinal mucous membrane of the ileum generally presents the appearances of acute catarrh; but the

chief seat of the morbid changes is Peyer's patches, and the changes consist in a gradual infiltration of the glands here crowded together, followed by ulceration. The process is divisible into three stages—of *infiltration*, *ulceration*, and *separation* or *resolution*, each of which may be said, speaking roughly, to occupy a week. In the first, that of infiltration, the glands of Peyer's patches are swollen and distended by a leucocytic exudation. The entire patch is thickened and raised above the level of the surrounding mucous membrane; has a reddish, or fawn, or grey colour, according to the intensity and stage of the inflammation, and an irregular surface; is firm to the touch; and opaque when the intestine is held up to the light, often showing through the peritoneal covering.

The patches are attacked successively from below upwards; and as they are largest and most numerous at the lower end of the ileum near the ileo-cæcal valve, it is here that the lesions are most extensive and most advanced.

In about a week the follicles begin to ulcerate, or, as it is sometimes said, burst. This marks the beginning of the second stage. As it progresses, the minute ulcerations extend and coalesce, the patch having first a worm-eaten appearance, and later becoming one large ulcer, which may be superficial or deep; in very severe cases the patches slough and fall off as a whole, a deep line of demarcation forming round them. At this period they are stained with bile, or when gangrenous are almost black.

During the third week in mild cases a sort of resolution may occur, the infiltrated material being broken down and absorbed; and this change probably takes place in patches high up in the ileum when in those lower down there is ulcerative destruction. For the most part this stage is occupied by the separation by ulceration or sloughing of the affected patches, and an ulcer is left of corresponding size and shape. Of course, as the patches run longitudinally, along the aspect of the bowel away from the mesenteric attachment, the ulcers also have their long diameter in the same direction. The superficial layer only of the mucous membrane may be ulcerated, or its entire thickness may be destroyed; and where there has been necrosis of a patch as a whole, the muscular coat may be implicated, and even in some cases the peritoneal covering. When the muscular fibres are laid bare, and especially when they are partially destroyed, the base of the ulcer will have a shreddy appearance. Large vessels may be opened, giving rise to hæmorrhage; or perforation of the intestine may take place from necrosis of the serous coat, near the centre of the ulcer, and a perforation formed in this way will usually be large.

At the end of the third week the separation of the diseased patches will be completed, and the ulcerations left begin to granulate. There is for some time a liability to hæmorrhage from erosion of vessels, and perforation may still occur, the apertures now, however, being as a rule minute. Unless perforation has been preceded by adhesion to some neighbouring coil of intestine, which may possibly be the case at this period, the escape of gas and extravasation of liquid fecal matter will set up general peritonitis, which is almost always fatal. The time required for complete healing of the ulcers varies.

Besides the large ulcers formed in the patches of

Peyer, it is not uncommon to find small circular ulcerations scattered over the mucous membrane, and at times minute disseminated ulcers constitute the predominant lesion, Peyer's patches being absent, or, if present, little affected. The large intestine is usually healthy or nearly so, the ileo-cæcal valve forming a sharp demarcation between healthy and diseased mucous membrane, but in some cases there are numerous small ulcerations in the cæcum and colon.

The changes in the mesenteric glands are secondary to those in the intestinal mucous membrane. The glands are enlarged, firm, pink or fawn-coloured, and present on section a corporcular infiltration like that affecting the agminated glands. Later, they become paler and softer, and may gradually return to a normal condition, or may undergo caseation. Ulcerations, superficial or deep, are not uncommonly present in the larynx.

The spleen is almost always much enlarged, dark in colour, and soft.

Granular degeneration of the gland-cells of the liver and kidneys, of the muscular fibres of the heart, and of the voluntary muscles generally, is a constant morbid change. It is due to the prolonged high temperature and the associated toxæmia, and is proportionate to the severity and duration of the fever; when it reaches an advanced stage, it may be the cause of fatal syncope from failure of the heart.

SYMPTOMS.—The period of *incubation* of typhoid fever is not definitely known. There is great difficulty in fixing it, as the date of exposure to the poison can rarely be exactly ascertained, and the onset of the attack is usually insidious. It is certain, however, that the incubation-period is long, probably in most cases from fourteen to twenty-one days. Cases are met with from time to time which suggest that the poison may reside in the system for an indefinite period until the resistance is lowered by a chill, or an attack of influenza, or by great fatigue. On the other hand, instances are on record in which the disease appears to have come on immediately after exposure to powerful emanations from sewers which have burst, or have been opened on account of obstruction, but they are quite exceptional. The incubation is not attended by any marked symptoms; sometimes the appetite falls off, the tongue becomes furred, and there is headache or depression; but, as a rule, the patient is not debarred from his avocation, and there may be no complaint of any kind.

Invasion.—The invasion is almost always insidious. Occasionally severe headache sets in suddenly, with depression, muscular weakness, general pains, and chilliness almost amounting to rigor; but, as a rule, the patient at first feels simply out of sorts, loses appetite, and is indisposed for his usual work or for exertion of any kind. Epistaxis is not uncommon. The headache increases; the prostration becomes greater; sensations of cold down the back, alternating with heat and slight flushing, come on at intervals. At this point medical advice is usually sought, when the patient, giving the above history, will be found to present the ordinary indications of the febrile state—the pulse will be increased in frequency, the temperature raised, and the tongue will have a whitish or yellow coat, thick or thin in different cases. The bowels may be confined or relaxed; the urine high-coloured and diminished in quantity, or so far apparently normal.

In endeavouring at this early period to decide whether the case is one of enteric fever, the first thing to be done is to exclude local inflammation as a cause of the pyrexia. Among the positive indications the appearance of the patient is often a guide; he may look more heavy and oppressed than is accounted for by the temperature or the duration of the illness, and may be more prostrate. The tongue, as a rule, is not thickly coated, and the fur does not extend quite to the margins or tip, which even now may be unduly red. The abdomen may be tumid, and there may be some tenderness over the right iliac fossa, but the absence of these symptoms does not exclude enteric fever. The recurrence two or three times of slight epistaxis during the first few days of a febrile attack would increase the presumption of the disease being typhoid fever. The temperature, however, if it is watched from the first, affords the most conclusive early evidence of the disease; it rises with remarkable regularity from day to day, and is from one to two degrees higher in the evening than in the morning; the appearance of the temperature-chart recording morning and evening observations is highly characteristic, and may, indeed, almost be called diagnostic. The opportunity of watching this gradual rise, however, is often wanting; but if, on the third or fourth day of an illness, without obvious local cause we find a temperature of 103° or 104° F., and especially if the evening rise and morning fall are marked, the probabilities are that the case is one of enteric fever.

As has been stated, the fever is of long duration, lasting from twenty-one to thirty days on an average, and probably the clearest idea of the course and progress of the disease will be conveyed by a brief description of the condition of the patient week by week, during a fairly severe attack.

At the end of the first week the temperature will have reached the level, whatever that may be, which will be maintained, in the absence of complications, throughout the dominant stage of the disease— 103° , 104° , or 105° F. in the evening, 1° or $1\frac{1}{2}^{\circ}$ F. lower in the morning; in mild cases it may not be more than 102° F. when highest. The fever is now well-established, and all its characteristic features will be more or less pronounced. The initial headache will in most cases have disappeared; the patient lies on the back or on either side; the face is flushed, often presenting a bright patch on the cheeks, rarely dusky; the expression is good, though usually suggestive of the disease; the eyes are bright and observant; the skin is more or less hot, usually dry, but often moist at some period of the day. The pulse is frequent, 80, 100, or 120—short, large, and very often dicrotic. A short cough is common; and a scattered sibilus, heard on auscultating the lungs, is so frequent as to constitute a feature of the disease. The tongue will be moist, with a white or yellowish fur thinning off towards the edges and tip; the margins are red, and a red triangle invades the dorsum at the tip. The abdomen will be more or less tumid; and on pressure tenderness may be elicited in the right iliac fossa, and gurgling of liquid and gas may be felt in the intestine. It is to be understood that the gurgling is an incident attendant on diarrhoea, and is absent in cases where there is constipation. The spleen may sometimes be felt below the ribs, and when not palpable in the left hypochondrium may give an

enlarged area of dullness on percussion, but it will not yet have reached its full size. The characteristic spots may occasionally be found, but though they have been seen as early as the fourth or fifth day, they do not usually come out till after a week or more of fever. The bowels will mostly act loosely, and sometimes frequently, so that there is diarrhoea. The urine will be high-coloured and generally turbid; it not infrequently shows a trace of albumin and may contain an appreciable amount. It will not respond to Ehrlich's test. The motions will have a powerful and offensive peculiar odour; they will be copious, liquid, rather pale, yellowish or drab in colour, with flocculi. A familiar descriptive comparison is to 'pea-soup.' The blood should be periodically examined for the Widal reaction. See SERUM-REACTIONS.

A week later—that is, on the fourteenth or fifteenth day—the disease will have told obviously upon the patient. He will lie mostly on his back, and little on his side. The face, still flushed, and presenting often the red patches on the cheeks, will begin to look worn and thin; the eyes, still bright, will be less observant. The aspect and expression of the countenance are so characteristic as to be at once recognised by an experienced observer. The hand may be unsteady when held out, and there may be slight twitchings of the lips. There may be restlessness or even sleeplessness, and very often delirium. It has been stated that delirium mostly sets in about the twelfth day, but the time varies greatly. At first the patient is confused on waking from sleep, does not quite know where he is, and appears to have been dreaming, but soon collects himself; later he fails to shake off the confusion of thought, and he may talk incoherently,—may ramble, in fact, as it is said. At this period the delirium does not go beyond slight rambling, and it is rarely violent at any stage. In severe cases there may be retention of urine.

The pulse will be more frequent, still less full, weaker; dicrotism is rarely well-marked. The lungs will not have undergone much change; the sibilant sounds may be more numerous.

The tongue will be more characteristic; the fur will be represented by a thin yellow or brownish streak down the centre, while the tip and edges will be red and angry. There will be a tendency to dryness, and generally the entire tongue looks shrunken and pointed. See p. 1723.

The abdomen will be larger and more tense, and the tenderness and gurgling in the right iliac fossa more marked; the spleen will be larger. Now the eruption may be expected to present itself, if at all; but it must be remembered that it is absent in a considerable proportion of cases—a proportion estimated by some observers at 30 per cent. The eruption consists of small pink spots, about the size of a pin's head, slightly raised and pointed, well-defined, and disappearing on pressure, or when the skin is stretched, to reappear when the pressure is withdrawn. They are usually few in number, and are distributed irregularly over the abdomen and chest; but sometimes they are very profuse, the number having no relation whatever to the severity or character of the attack. The spots do not all come out at once, but in successive crops till the end of the fever; the duration of individual spots, as observed by surrounding them with a ring of ink and dating them, being about four days. It has been recommended that the back should be searched

for spots, but conclusions from eruption found here only would be untrustworthy, as the back is seldom free from spots, and there is nothing very peculiar in the spots of typhoid fever to distinguish them from others.

If the case is characterised by diarrhoea, it is usually at this period that it begins to be most troublesome; the stools have the appearances already described.

The temperature will be maintained at about the same height as at the end of the first week, but not uncommonly there is about this time a deceptive remission of fever, and it is perhaps worthy of remark that the active ulceration is now coming to an end. The fever which persists after this period has indeed been attributed to septic absorption from the intestinal ulcers—with doubtful justice, however.

It is from the latter part of the second week onward that complications, both local, such as hæmorrhage or perforation from ulceration and separation of sloughs, and general, such as pneumonia, are to be apprehended.

The end of the third week finds the sufferer at his worst. If he is now able to turn in bed and to lie on either side, and if other symptoms correspond with this indication of power, the case is favourable. In a severe attack he will lie on his back, and probably tend to slip down in bed. The face may be either pale or dusky; its look will be that of prostration. The patient is mostly very deaf, often dull of apprehension, so that he is with difficulty made to put out his tongue, and when it is protruded he may keep it in this position when told to withdraw it; he may be half unconscious, or in the condition of coma-vigil, a stuporous sleep with the eyes half open; or he may be restless, with muttering delirium, picking at imaginary objects in the air, or at the bedclothes. Sometimes the slightest pressure on any part of the body appears to give pain, or the patient may start in great alarm when spoken to. The body will be emaciated; the skin thin, pale, dry, and harsh; the muscles wasted; the tendons starting up, from sudden irregular muscular contractions (*subsultus tendinum*) when the limbs are at rest, while attempted movements are attended by jactitation and tremors; the lips tremble when the patient speaks, and the tongue twitches when protruded. A tap with the end of the finger on the pectoral muscle will cause a small swelling to rise on the spot—the so-called ‘myoidema,’ due to contraction of the degenerated fibres; it lasts for twenty or thirty seconds. The tongue is shrivelled, brown or even black, destitute of true epithelium, or dry and shiny, or coated with sticky slime or with black sordes. Sometimes it cannot be protruded at all. The roof of the mouth will be similarly coated; and there will be sordes on the teeth, and perhaps on the lips.

The pulse will be small, soft, extremely weak, often very frequent—130 or upwards per minute in bad cases; the beats run into each other, and are not distinct, giving an undulatory sphygmographic trace. The heart is extremely weak: the impulse absent, or a mere tap; the first sound short and feeble, or altogether extinguished. The lungs exhibit evidence of hypostatic congestion, impairment of resonance, and imperfect entry of air all over the posterior aspect of one or both sides of the chest.

The abdomen will usually be distended; spots may be present and continue to come out. There may or may not be diarrhoea. The stools may be

passed unconsciously; and there may be retention, or incontinence, of urine. Bedsores often form rapidly, unless the nursing is both careful and skilful.

A tendency to recovery is usually indicated by improvement in the temperature, pulse, tongue, and abdomen. The temperature gradually falls, but at first this is shown chiefly by the increasing morning remissions, giving a greater difference between the morning and evening temperatures, and showing on the chart greater zigzags; the evening temperature then begins to fall day by day. The pulse becomes less frequent, and more full and distinct; the tongue gradually cleans, beginning at the margins; the abdomen subsides, the diarrhoea ceases; and strength returns little by little. In fatal cases the mode of death, when not due to some complication, may be by asthenia, or more frequently by coma and asthenia combined; hyperpyrexia is not uncommon as a phenomenon of the moribund condition; and, as the heart fails, hypostatic congestion of the lungs is usually very marked.

Relapses.—Relapse is very common in enteric fever. It usually occurs about ten days after the subsidence of the temperature in the primary attack, and is sometimes attributed to premature administration of solid food, but more commonly has no such cause. A true relapse is not merely a recurrence of pyrexia, but a return of all the phenomena of the fever. Fresh Peyer's patches are attacked, and there is frequently a fresh outbreak of the spots at about the same period after the initial symptoms, or often earlier. The relapse, however, is rarely as long as the original fever; very commonly, indeed, the third stage, that of so-called infective or pyæmic fever, is wanting; and when this is so, it is probable that there is no ulceration of the intestinal glands. Fortunately, also, it is not so often fatal as might be expected, seeing that the patient is reduced by the first attack. A second or a third relapse may take place; the writer has even indeed seen a fourth, the patient recovering and surviving five distinct attacks of fever, each of which was severe. No satisfactory explanation of the relapse of typhoid fever has been given. It has been said that there is a re-infection of the subject by poison lodged in the mesenteric glands; but it is not easy to understand why he should be susceptible to the influence of the poison from this source, when for the most part the susceptibility to the disease is exhausted by an attack.

Special Symptoms and Complications.—These are so numerous and varied that it has been thought better to describe them separately, rather than to interrupt the account of the fever.

Hæmorrhage.—This occurs in about 6 or 8 per cent. of the cases. It may come on as early as the tenth day, but more commonly it is between the fourteenth and twenty-fourth days, and in the later rather than the earlier part of this period; bleeding may be provoked by imprudence in diet, or by exertion later still. The hæmorrhage is due to the erosion of some vessel during the ulceration of Peyer's patches, without protective plugging by fibrin, or to vessels being laid open by the detachment of a slough. The quantity of blood lost, and the rate at which it is poured out, vary greatly. Sometimes the fact of hæmorrhage having taken place is only known by the stools being black, sticky, and offensive. At other times the blood is

discharged in large clots, or it may be extravasated so rapidly that it is liquid and red, not having had time to become blackened and coagulated by the intestinal contents or secretions. When the hæmorrhage is considerable, the patient is rendered pale and pulseless. The temperature always falls, and not infrequently the loss of blood can be recognised before it appears in the stools by this fall of temperature, and by the pulse and general appearance of the patient. Confirmatory evidence may be obtained by careful examination of the cæcum and ascending colon: there will be diminished resonance and the colon will feel heavy when lifted from the loin. It is said that severe and persistent headache early in the attack is often followed by hæmorrhage in a later stage.

This complication is always a source of anxiety, and often exhausts the strength of the sufferer; but it is not by any means necessarily fatal. In many cases, indeed, the occurrence of considerable hæmorrhage marks the setting in of improvement; the temperature which falls on account of the loss of blood does not rise again; the patient becomes clearer and less heavy and oppressed; the tongue cleans; and all unfavourable symptoms gradually subside.

Perforation.—This, like hæmorrhage, may occur early, or at a late period; when early it is due to the entire thickness of the intestinal wall being implicated in the necrosis of the Peyer's patch, and the perforation may then be large. Later, at the end of the third week or afterwards, the perforation results from ulceration, and is often very minute. Unless adhesive inflammation at once glues the affected point to a neighbouring coil of intestine or to the abdominal wall, there is extravasation of intestinal gases and liquid into the peritoneal cavity, producing general and usually fatal peritonitis.

It might be expected that this occurrence would give rise to severe pain, but very often there is neither pain nor tenderness. The abdomen, however, rapidly becomes distended, often to an extreme degree; its walls are absolutely motionless in respiration; and on the application of the hand and making pressure, there is not only tension but resistance of a peculiar kind, which is highly characteristic. With the local symptoms there are evidences of shock: great anxiety of countenance, which may be flushed and beaded with perspiration, or pallid and livid; extreme frequency of pulse, often 140, 160, or 200, which is small and weak; and very great frequency of respiration. The respiratory distress is so marked that, in some instances which the writer has been called to see, the perforation had been overlooked, and the condition attributed to some lung-complication.

Peritonitis.—Peritonitis, without antecedent perforation, is an occasional complication of typhoid fever. It differs from the peritonitis caused by perforation in the more gradual onset, and in the less urgent character both of local signs and general symptoms—of the latter especially.

Tympanites.—Great distension of the abdomen by flatus is not uncommon in the course of typhoid fever, coming on independently of peritonitis or perforation. Most frequently it gradually appears late in the disease, together with other symptoms of prostration of the nervous system, but it may set in abruptly within the first week, and it is then prognostic of an early fatal issue. Simple tympanites is distinguished from peritonitic distension by the

difference in the feel to the hand; but chiefly by the fact that the respiratory movements of the abdomen are not suppressed, though, of course, impeded. Absence of pain is so common in the peritonitis of typhoid fever, that it is no criterion by which to distinguish inflammation from tympanitic distension. See p. 1763.

Diarrhœa.—As has been stated, the bowels are usually loose in typhoid fever. Not infrequently this looseness becomes excessive, and is thus a cause of exhaustion and a source of danger. Unless there is blood in them, the stools are more liquid, frequent, and copious, but not otherwise different from the usual typhoid motions. They may contain curds of undigested milk.

Albuminuria.—Albuminuria is not uncommon as a complication of typhoid fever, and it may be accompanied by convulsions, though it is by no means so dangerous as in typhus. The albuminuria may be the effect of the poison or of the fever-processes on the blood, or it may indicate nephritis. In the former case, which is much more common, the urine does not differ in appearance from this secretion as usually seen at the stage of the disease at which it is present, and the albumen is only detected by examination; in the latter, the urine will be scanty and dark-coloured, as in desquamative nephritis when it is not a complication of typhoid fever.

Pneumonia.—Inflammation of the lung may come on early or late in the course of typhoid fever. When early, it is usually a lobar croupous pneumonia, not differing greatly from ordinary pneumonia; in the later stages it is often a combination of lobular catarrh with hypostatic consolidation. The symptoms are not marked. The temperature rises or is more sustained; there is increased frequency of the pulse and respiration, and perhaps obvious respiratory distress; the face may be flushed or anxious. As a rule, there is little or no cough or expectoration. Examination, when practicable, reveals the ordinary physical signs.

Pulmonary Gangrene.—Gangrene of the lung may occur from obstruction of branches of the pulmonary artery by fibrinous coagula carried from the heart.

Pleurisy.—Pleurisy is occasionally met with as a complication of typhoid fever. It does not give rise to much pain, and may easily be overlooked, the condition of the patient precluding careful examination.

Venous Thrombosis.—Thrombosis may be either a complication or a sequel of typhoid fever. It arises from the languid state of the circulation, and from the condition of the blood, which is liable to coagulate. The femoral vein and its branches are the vessels most commonly obstructed, the thrombosis usually beginning in the small deep-seated branches and extending to the larger trunks, so that there may be deep-seated pain and tenderness in the calf or in the gluteal region for a day or two before the large vein is affected. Thrombosis gives rise to pain and swelling of the limb, with some oedema, and the vein can usually be felt as a solid cord; there is a new access of pyrexia, especially if convalescence has already set in.

Embolism.—Embolism by plugs of fibrin deposited in the heart, and subsequently launched into the arteries, may occur in any part of the body. Hemiplegia may happen from this cause in the

course of typhoid fever; or occasionally, but very rarely, gangrene of part of a limb.

Parotitis.—Parotid abscess is less common in typhoid than in typhus fever, and when present is usually due to secondary infection of the gland by the ordinary pyogenic cocci, although occasionally the organism responsible for the pus-formation is undoubtedly the typhoid-bacillus; but it may occur in very severe cases, and is then an additional source of danger.

Baldness, neuritis, epididymitis, cystitis, perioritis, and perichondritis may occasionally accompany or follow typhoid fever. These conditions are described elsewhere.

Sequelæ.—Enteric fever always leaves the patient weak, and the debility lasts long. This is due not merely to the waste of tissue by the protracted fever, but to the fact that the intestinal and mesenteric lesions interfere with absorption of nutrient material. In some cases the patient never recovers strength, but gradually becomes emaciated, and dies from asthenia or from some intercurrent attack. Occasionally the ulcerations do not heal, and they may prove fatal after the lapse of a considerable time. Phthisis, again, may be started by an attack of typhoid fever, usually, but not invariably, in an individual predisposed to the disease. Insanity is another occasional sequel; the most common form of mental derangement is melancholia, but there may be acute mania. It may come on almost immediately, the patient never appearing quite to recover his faculties after the stupor of a severe attack; or it may develop itself at an early or late stage of convalescence, or not till a still later period.

VARIETIES.—Typhoid fever runs a very varied course, and different epidemics may be characterised by special features as well as by differences in the degree of severity. The state of health or general condition of the individual or of the community may have an important influence in respect of this, but just as the virulence of the bacillus may be intensified or moderated in the laboratory, so it may be modified by climatic and other influences. The typhoid fever of this country, of the continent of India, and of Africa, may thus come to present important clinical diversities. To complete the account of typhoid fever, some of the principal deviations from the ordinary course and type of the disease must be enumerated; and in the first place it must be understood that, both in individual cases and in entire epidemics, typhoid fever may run its course without rise of temperature, the characteristic lesions being found after death. Again, there is sometimes so little general depression of strength that the sufferer may walk about, and carry on his usual avocations up to a late period of the attack. The term *typhus ambulans*, or *ambulatorius*, has been applied to such cases. The writer has known several instances in which patients have *walked* into the London Fever Hospital with perforation.

Infantile Remittent Fever.—Infantile remittent fever is so called from the remissions often observed in typhoid fever affecting young children. No special description is necessary, the disease pursuing much the same course in children as in adults, only with greater fluctuations. Spots are less frequently seen.

Typhoid Fever with Constipation.—This really constitutes a distinct variety, the constipation persisting throughout, and not merely lasting for a

few days and then giving place to diarrhœa. It is a difficult form of the disease to deal with, and is often followed by relapse.

Bilious Fever (*Fièvre bilieuse*).—This is recognised as a special form of typhoid fever by French observers, and deservedly so. The characteristic feature is frequent, sometimes almost incessant, vomiting of liquid containing bile, both after food and when no food has been taken. Severe headache often persists throughout the attack. The temperature does not, as a rule, rise high, and it fluctuates much; the face is pale and anxious; the pulse is frequent and very weak; the tongue is usually coated, and may be white or yellow. It is a very dangerous form of the disease, and may end fatally in ten or fourteen days by simple asthenia, without delirium or comatose symptoms.

Typhoid Fever with Meningitis.—True meningitis sometimes, though rarely, occurs at an early period of typhoid fever, and is attended by pain in the head, excitement, which may be maniacal in character, or violent delirium.

Abortive Typhoid.—This is sometimes described as ‘fourteen-day fever.’ After well-marked symptoms of the attack, the temperature is not maintained, but gradually subsides. Such cases are mostly set down as common continued fever, or febricula. See *FEBRICULA*.

DIAGNOSIS.—A well-marked case of enteric fever at the height of the disease is easily recognised by the aspect of the patient, and by the symptoms already described: the red tip and edges of the tongue, the tumid abdomen, the enlarged spleen, the rose spots, and the character of the stools. In the early stage, however, it is often necessary to suspend the judgment for a day or two, and there may be difficulty in forming a definite opinion for a much longer period. The diseases which have most frequently been taken for typhoid fever are tubercular meningitis, acute pulmonary tuberculosis, and gastro-intestinal catarrh; typhlitis, catarrhal pneumonia and other acute affections of the lungs, glands, pyæmia, and ulcerative endocarditis, have also from time to time been confounded with it. On the other hand, typhoid fever may possibly be taken for one of these affections, or may more easily be masked by some complication, such as pneumonia or peritonitis. What is most liable to happen is, that it may be entirely overlooked.

The insidious onset of typhoid fever is very characteristic; and, as has been said before, the thermometric chart of the first four days, showing a rise day by day with the morning remissions, might of itself suggest the diagnosis. But occasionally the invasion is abrupt, or there is some pulmonary complication at the outset, which raises the initial temperature, so that it would be unsafe to rely too implicitly on the temperature. The first thing to be done in establishing a diagnosis of enteric fever is to exclude local inflammation as a cause of the febrile condition, which will be effected by physical examination and other means. It must not be forgotten during this investigation that in pneumonia the consolidation may not occur for three or four days. When there is doubt, epistaxis will be evidence in favour of, herpes labialis against, such a diagnosis, though herpes may break out when there has been a rigor. The presumption of typhoid fever arrived at by excluding local

inflammation and other acute diseases will soon be strengthened by the appearance of corroborative indications which we need not again specify, or be overthrown by their continued absence.

As regards the particular diseases enumerated as those with which it is specially liable to be confounded—in tubercular meningitis the temperature is not usually so high as in typhoid fever, the pulse is at first not very frequent, and is often hesitating, while it almost always presents the condition of tension in the early stage when the confusion is liable to occur, thus contrasting with the soft short pulse of fever. There are usually, but not constantly, headache and vomiting early in the attack, the bowels are mostly confined, and the abdominal wall is retracted. Squint, inequality of the pupils, or double optic neuritis, would be unmistakable indications of meningitis. In acute pulmonary tuberculosis there is more cough; and although at first there may be only scattered sibilant sounds, such as are heard in typhoid fever, these soon become more abundant, and other physical signs of the infiltration of the lungs are added, such as impairment of resonance, and imperfect entry of air. The temperature also is usually more sustained. Gastro-intestinal catarrh in children is sometimes attended by so much febrile disturbance as to give rise to a suspicion, or even a diagnosis, of typhoid fever, especially as the abdomen is tumid, and there may be diarrhoea; overfeeding with milk may keep up the appearance of fever for some time. There are, however, intermissions and variations which, when carefully noted, are found to be inconsistent with continued fever; the tongue is more thickly and coarsely coated; and the stools, though they may be pale from undigested milk, have not the typhoid character. In typhlitis there is more local pain and tenderness, and a lower temperature; and the symptoms set in more abruptly, vomiting being common. It is unnecessary to enter upon the distinction between typhoid fever and the other diseases mentioned; for the most part a few days will clear up any uncertainty or confusion.

As a matter of fact, errors rarely arise, when it is deliberately considered whether a given case is or is not one of typhoid fever. The danger is that the idea of fever may not be entertained at all, its symptoms being attributed to some slight local ailment. Or there is pneumonia or peritonitis as a complication, when the patient first comes under observation, which is not very uncommon among the poor or in hospital practice. The possibility, therefore, that typhoid fever may underlie an acute local affection should always be borne in mind, and when the desired crisis does not come on in pneumonia, or if in peritonitis the general symptoms are not altogether those of inflammation of the peritoneum, indications of enteric fever should be carefully looked for. When, again, a patient complaining only of some functional derangement, or of weakness and loss of appetite, has a look of illness and prostration which is disproportionate to the assigned cause, enteric fever should be suspected.

There is often great difficulty in distinguishing *infantile* remittent fever from tubercular meningitis on the one hand, and from gastric catarrh on the other. In gastric catarrh the tongue is more loaded; the temperature is less sustained and more irregular; constipation is more common than diarrhoea; and the evacuations, whether solid or liquid, have not

the specific characters, but consist more or undigested food. In meningitis there will usually be purposeless vomiting, but not always; the temperature is not so high; the pulse is often slow or irregular, and the respiration shallow and sighing; the abdomen is not distended, and may be retracted; the bowels are confined. A squint would at once confirm suspicions of meningitis. Ehrlich's urinary test¹ and the Widal reaction in the blood will often aid in the formation of a definite diagnosis, and these examinations should never be omitted, although the responses are not absolutely conclusive. Clumping of the bacilli may take place as the result of an antecedent attack, and the writer has seen a characteristic Ehrlich reaction in a case of septicæmia with abscesses.

PROGNOSIS.—It is never safe to speak confidently of the recovery of a case of typhoid fever, in view of the complications which may arise; but the prognosis is favourable or unfavourable, according to the antecedent condition of the patient, and to the severity of the attack, as estimated chiefly by the temperature. The mortality varies from 15 to 25 per cent., but there may be epidemics in which it may be throughout lower or higher than the average here stated.

Children seldom die of typhoid fever, and in the young the attack is less likely to be severe, and there is a better chance of recovery even when it is. In debilitated subjects, and especially in persons addicted to alcohol, typhoid fever is always attended by danger; even in a mild attack there may be failure of the heart, and pulmonary complications or thrombosis, which may prove fatal. Pregnancy also renders an attack dangerous (*see* p. 1313). Apart from causes of anxiety in the general condition of the patient, and exception being made of cases in which the fever assumes the bilious type, attended by frequent vomiting of bile, headache, and prostration, and of the rare instances of meningitis as an early complication, the prognosis turns mainly on the temperature. If this is not more than 102·5° F. in the evening at the end of the first week, there is very little danger; on the other hand, if the evening temperature reaches 105° F., nearly half the cases prove fatal. When the temperature ranges high, it is of great importance to ascertain whether it is so for many consecutive hours, or only for a short period; a heat of 104° F. sustained for a great part of the day is a more serious matter than a brief rise to 105° F. On this account, and also because the maximum may be attained at different periods of the day, it is desirable that the temperature should

¹ Ehrlich's reaction or the diazo-reaction depends upon the temporary presence (between the 5th and 22nd days), in the urine of typhoid patients, of a chromogen, which when treated with diazo-benzene-sulphonic acid and ammonia gives a characteristic colour-reaction.

In applying this test, the sulphonie-acid reagent is prepared by mixing the two following stock solutions:

1. Hydrochloric acid 5 c.cm., diluted with distilled water to 100 c.cm., and saturated with sulphanilic acid.
2. Sodium nitrite, 0·5 per cent. aqueous solution, in the proportion of 40 parts of the first to one part of the second.

Two or three cubic centimetres of the suspected urine are added to an equal quantity of the sulphonie-acid reagent, in a narrow test-tube. Ammonia is then carefully run in so as to form a colourless zone above the mixture of urine and acid: this results in the formation of a more or less deeply coloured ring at the junction of the two liquids. If now the contents of the tube are poured into a porcelain basin containing some water, the production of a salmon-red colour will indicate a positive reaction; a yellow or orange colour only being obtained when the result is negative.

be taken in serious cases every two or three hours, or even more frequently. In typhoid fever, as in other acute diseases, a contrast between the surface-temperature and the temperature of the blood, as revealed by the thermometer, is of unfavourable significance. If with high temperature there are indications of failure either in the nervous system or in the heart, the prognosis becomes serious; a tendency to stupor or retention of urine early in the disease is a bad sign; and acute tympanites at this period, indicating, as it does, paralysis of the muscular walls of the intestine, and presumably of the sympathetic nervous system, almost invariably points to a speedily fatal termination; the later gradual distension of the abdomen ranks with the unfavourable signs, but is often met with in cases which recover.

Unusual frequency of the pulse, marked diastole early, and extreme weakness of the beat and compressibility of the vessel later, intimate danger, as does also an increasing frequency day by day towards the end of the third week. When the beats run into each other, and the pulse is a mere flutter, the danger is immediate and extreme. The sounds of the heart should be noted throughout the disease; the first sound, as heard at the apex, tends to become, first, short and sharp, then weak, and at last may altogether cease to be audible; a good or bad first sound is of good or bad augury respectively. A systolic apex-murmur is not uncommon, and occasionally a distinct presystolic murmur is heard; these murmurs have no great significance, and usually disappear as the patient recovers.

TREATMENT.—The principles on which the treatment of typhoid fever should be conducted are generally accepted and well understood. Success depends greatly on their intelligent application to individual cases, and on careful attention to details at every stage of the disease.

The patient should, if possible, be placed in a large, airy, and well-ventilated room, the windows and door of which should be more or less continually open, according to the season and weather. The bed should not be too wide, and it should be approachable on both sides, so that the patient can be easily reached from either side; it should be firm, but comfortable. A feather- or flock-bed is very objectionable, on account of the hollow into which the patient sinks in it. When practicable, it is a great comfort to have two beds—one for day, the other for night. The covering should be light, but sufficient to protect the patient from changes in the external temperature; eider-down quilting, or any material impervious to the insensible perspiration, should be forbidden; the under-surface of such coverings will often be found quite damp, and exhaling an offensive odour. Conscientious, skilful, and efficient nursing is of the utmost consequence; and that nothing may be overlooked, a record should be kept of the condition of the patient, of the food, stimulants, and medicines administered, and of the evacuations passed.

The patient should be sponged night and morning with tepid water, to which a little vinegar, or eau-de-Cologne, or permanganate of potassium may be added. The temperature of the water may vary, the feelings of the patient being consulted, and the effects in producing sleep and quiet noted. The hands and face may be washed or bathed frequently, and the general sponging may be repeated

at any time when it seems to be required owing to heat or restlessness.

It is useful to habituate the patient to the use of the bed-pan from the first. It is true that very often the chair or utensil is used throughout; but in severe cases, or on the occurrence of hæmorrhage, the sitting posture is dangerous, and indeed impossible, and it may be most distressing to have to pass the excretions into the bed-pan for the first time under circumstances of extreme prostration; this may, indeed, destroy the patient's chance of recovery. A disinfectant solution should be placed in the pan or other vessel into which the stools are received, and more should be added and left in contact with them before they are thrown away. The urine should also be carefully disinfected in a similar manner. *See* DISINFECTION.

Perhaps the most important element in the treatment of typhoid fever is the regulation of the diet. This should be exclusively liquid, and the staple constituents will be milk, and beef-tea or broths of one kind or another. It should be borne in mind that these liquids are food, and not mere drinks, and they should be given with strict regularity. Two or three pints of milk, and a pint or pint and a-half of beef-tea or the equivalent of broth of some kind will be about the quantity required for twenty-four hours' consumption in the first instance; and it should be so divided that milk and beef-tea are given alternately about every three hours, judgment being exercised in waking up the patient if he is sleeping when food is due, or allowing him to sleep beyond the hour. The great tendency now, on the part of the public, is to overfeed cases of fever. When the patient asks for drink, milk is offered, and if it is iced or diluted with soda- or seltzer-water it is sufficiently grateful in quenching thirst to be accepted in quantity altogether beyond the digestive powers; it then coagulates in masses, escapes solution by the gastric and pancreatic juices, and passes down the intestine in heavy curds, which irritate the ulcerated surfaces, besides producing other disturbances. It is in this way that milk has been discredited as an article of diet. The writer's experience is in accord with that of Parkes, who looked upon milk as the typical diet for enteric fever. In later stages of the disease it may be necessary to give nourishment more frequently, but the attention of the medical attendant will in most cases be required rather to moderate the amount of food given than to urge its administration; it may, however, be found necessary to take precautions against neglect in this respect during the night. In emergencies, concentrated meat-extracts may have to be given in teaspoonfuls every few minutes. The patient should, of course, be allowed to drink freely of cold water, toast-water, or any simple drink. The key to the regulation of the diet—it may almost be said to the management of the patient—is to be found in the careful inspection of the stools; the medical attendant ought to see every evacuation, or, at any rate, one motion every day, supplementing his own information by the report of a trustworthy nurse. When curds appear in the dejections, either too much milk is taken, or too much at a time, or its digestion is interfered with. If the passage of undigested milk is not remedied, there will certainly be flatulence, discomfort, and restlessness, elevation of the temperature, and in most cases diarrhoea. When, without error in the administration of the

milk, curds appear in the stools, dilution with soda- or seltzer-water, or the addition of lime-water or bicarbonate of sodium, may prevent premature and unduly firm coagulation; or the admixture of arrowroot, barley-water, or gelatine may cause the curds to be subdivided, and thus ensure their digestion. A more efficacious method, however, is to peptonise the milk (*see* PEPTONISED FOOD). In some cases beef-tea excites diarrhoea, and, given in excess, it will almost always have this effect. Chicken-broth should be substituted when beef-tea disagrees, and it is often more grateful to the patient.

As the fever subsides, eggs beaten up, or lightly boiled or poached, may be added to the dietary. In all cases the return to ordinary diet must be made with great caution, bearing in mind the fact that there may be intestinal ulcerations unhealed, and it should be a rule that no really solid food be given till the temperature has been normal for a week; even at the end of this time it is not uncommon for the temperature to rise one or two degrees, after a moderate amount of fish or meat with bread has been taken. These rules have been pronounced to be antiquated and the precautions unnecessary, and it is said that food of a semi-solid character may be given throughout the fever, and that the returning appetite may be at once gratified. The advantage claimed for this departure from the cautious administration of nourishment so long recommended is that the period of convalescence is shortened. It has yet to be seen how far any such advantage is real, and whether it may not be too dearly purchased.

It is an unfortunate aggravation of the sufferings in typhoid fever that fruit, which is so grateful when the mouth is dry and parched, cannot be given freely, on account of its liability to excite diarrhoea; but a few grapes may be permitted, care being taken that the skins and seeds are not swallowed, and the effects being carefully watched.

The question of stimulants is an important one. Here, again, the prepossession in the public mind is in the direction of almost indiscriminate administration of alcohol, and the importunities of friends may have to be resisted. The amount of brandy or wine given must therefore be carefully checked and controlled. In a large proportion of cases no alcohol is necessary from first to last; it is scarcely ever required in the early stages of the disease, except perhaps in drunkards; and at no period should it be given as a matter of routine, or merely because the case is one of fever, but only to meet certain definite indications. These are mainly evidences of weakness of the heart, frequent, weak, and fluttering pulse, and weakness or absence of the first sound of the heart. When, as is usually the case, the tongue is also dry, and the teeth and lips are covered and the mouth lined with sordes, the indications for the use of stimulants are unmistakable. The effects should be watched; when alcohol does good the pulse becomes less frequent, and of better strength and volume, and the temperature is usually lowered; an important indication also is that the odour of spirit is not detected in the breath. When very high temperature and other unfavourable prognostic symptoms set in very early, stimulants may be given without waiting for the conditions above-mentioned. Alcohol is again often required as an adjunct to the treatment of fever by the cold bath. The safest form of stimulant is

brandy or whisky; the quantity needed will vary greatly in different cases; in most two or three ounces in the twenty-four hours will be sufficient, in some ten or twelve ounces may be required. It is scarcely ever necessary or useful to go beyond this amount, and the administration of alcohol should always be checked when it can be smelt in the breath. It should be given in divided doses in, or immediately after, the milk or beef-tea.

It will be convenient to say here a word on the use of opium. Its employment in certain complications—tympanites, peritonitis with or without perforation, hæmorrhage, and excessive diarrhoea—will be described later; the question now is whether it is well to give it for the relief of sleeplessness and restlessness. In the writer's opinion, when the restlessness is not so far allayed by cold or tepid sponging as to permit of sleep, it is of great advantage to the patient to give ten or fifteen minims of laudanum at night, or its equivalent in some other form. The writer has not found it to interfere with the digestion.

In a large proportion of cases no medicine need be given from first to last, but effervescent salines are usually grateful; the mineral acids, at one time very largely employed, often seem in small doses to do good; and one or two grains of quinine may frequently be given with advantage. It should be understood that medicines are of less importance than food, and that they are not to be allowed to interfere with its regular administration. A gentle aperient, calomel or grey powder followed by a mild saline draught, at the outset, is often useful, but it may be blamed for subsequent diarrhoea. In Germany and America the treatment is often begun by administering six or eight grains of calomel in two doses, and at an early period of the disease this is more likely to do good than harm, though the dose is unnecessarily large.

Daily washing out of the large intestine by copious enemata of some weak antiseptic solution—permanganate of potassium, boric acid, carbolic acid, or sulphocarbonate of sodium—apparently exercises a favourable influence on the course of the disease. The temperature of the enema may be varied so as to have some effect on the temperature of the body.

When treatment, other than the careful watching, nursing, and feeding which are sufficient in mild cases, is required, this should not be a mere matter of routine; and it may conduce to precision in meeting the various indications presented from time to time if an attempt is made to classify and distinguish them.

We can recognise, then, in the course of typhoid fever, effects attributable (1) to the action of the poison; (2) to the intestinal lesions; (3) to protracted high temperature.

1. The entire fever-process, with all its concomitants, is of course due to the action of the specific microbe, but certain effects appear to have a more direct relation with the poison than others. The immediate agents in the production of nearly all, whether direct or indirect, is a ptomaine secreted or formed out of disintegrated proteids by the typhoid-bacillus; and an important question bearing on treatment is whether the toxic material is formed entirely in the intestinal canal or also in the blood and tissues. It is apparently on the first of these two suppositions that the employment of mercury, iodine, carbolic acid, sulpho-carbolates,

alol, salicylates, and other intestinal disinfectants suggested by the theory of the bacterial origin of typhoid fever, has been based. Good results have undoubtedly been obtained, but not such as to invalidate the long-established conclusion that it is not within the power of medicinal agencies to cut short an attack of typhoid fever, or even effectually to modify its course. Undoubtedly ptomaines are formed in the small intestine, and this not only by the typhoid-bacillus, but by other bacteria which find a congenial soil in the albuminoid exudations poured out by the irritated mucous membrane. It has seemed to the writer that this is the explanation of the dark and peculiarly offensive stools sometimes met with in the early stage of typhoid fever accompanied by a high temperature, and of the extraordinary oppression of the nervous system and depression of the circulation occasionally seen without high temperature, or distension or tenderness of the abdomen, or diarrhœa, or other indication of a severe attack.

These are, therefore, the cases in which intestinal antiseptics are indicated; and, according to the writer's experience, mercurial preparations are the most trustworthy. When the motions are specially offensive and accompanied by much gas, the abdomen being tumid and the temperature high, from a half to one fluid drachm of the solution of perchloride of mercury, with perhaps one or two grains of quinine, may be given every four hours for two or three days with excellent effects, or calomel in small doses of one-sixth to one-third may be given every three or four hours. When the nervous system is evidently overwhelmed by poison, while the abdominal symptoms are slight, the local lesions may be disregarded, and two or three grains of calomel may be administered once or on two successive days. The entire aspect of a case threatening to prove fatal may sometimes be changed by thus clearing out and disinfecting the intestinal canal. It will be remembered that two or three grains of grey powder were formerly given three times a day throughout the early part of the attack.

The formation of ptomaines in the blood and tissues is little, if at all, influenced by remedies. The chief and most characteristic effect is the rise of temperature; and this, when not aggravated by adventitious causes, is not controlled by antiseptics of any kind.

2. Severity of the intestinal lesions, as indicated by marked tenderness in the right iliac region, tumidity and tension of the abdomen, and diarrhœa, may call for opiate fomentations, and, when the motions are unduly frequent, for starch-and-opium enemata. Careful examination of all the stools is specially necessary in case of irritation by undigested milk, and for the early detection of sloughs and blood-clots which may give warning of hæmorrhage.

3. The great source of danger in typhoid fever is the prolonged high temperature; and it is to this, together with the fever-poison or process, that are due the prostration of the nervous system and the weakness of the heart which are the most frequent causes of death. To keep down, therefore, the febrile heat of the body is to diminish very greatly the danger attending this disease. It was natural and inevitable that the remarkable class of drugs which have been found to have the power of lowering the temperature—acetanilide, phenazone, phenacetin, and the like—should be eagerly employed for

this purpose in typhoid fever; but while an immediate effect can be obtained, it is only fugitive, and a continued administration is usually disastrous. The most trustworthy means of controlling the temperature is cold bathing. The cold-water treatment of fever was, as is well known, originated by James Currie, and practised with marked success by him and many other distinguished and trustworthy physicians. Notwithstanding results obviously good, it fell into disuse, till revived by Brand of Stettin. Brand's method is to place the patient in water at a temperature of 65° or 70° F. whenever the temperature of the body, as taken in the rectum, reaches 102·2°, and to keep him there for ten, fifteen, or twenty-five minutes, until the heat is reduced 2°, or at any rate until he has been shivering for some minutes. Liebermeister takes 103° as the temperature which requires the bath, and this he does not make quite so cold, that is, 75° F., while he recommends ten minutes only as the period of immersion. The bath has to be repeated three, six, or eight times a day—as often indeed as the heat of the body rises to the point named; and it must be persevered with for two or three weeks or more, as may be required. A little brandy is given before or during the bath; and when the patient is taken out of the water he is placed in bed, dried, covered up, but not too warmly, and kept at rest (*see* HYDROTHERAPEUTICS). In order that the full benefit may be obtained from this treatment, it must be begun early, in which case the temperature need never be allowed to reach an injurious height; and it is claimed that the intestinal lesions are also held in check. When thus carried out, it must be taken as established that the mortality of enteric fever is very greatly reduced by the bathing. Jürgensen's statistics show a reduction from 15·4 per cent. to 3·1; Liebermeister's from 27·3 to 8·2 (this observer, however, employing quinine largely); others show a still larger fall; and it may be safely estimated that in France and Germany the deaths have been diminished by at least one-half. Cayley has shown that like results are to be expected in this country, and the writer's own experience is corroborative of his conclusions. If, however, the remarkable success obtained by Barr of Liverpool by the continuous bath—the patient being kept in water at a regulated temperature throughout the attack—is confirmed by general experience, this method ought to supersede all other treatment. Against the advantages of cold bathing are to be set off the difficulty of carrying it out, and the labour it involves; the prejudices of the public, and the dislike and dread of some patients; the facts that some cases may be protracted (which, by the way, might otherwise end fatally); and that relapse is certainly more frequent. These are good reasons for trying whether the same end may not be attained by other means; but unless we are successful in this, the duty of the medical attendant is to insist on the uncompromising employment of the cold bath. The graduated bath, in which the initial temperature of the water is 90° F., or, as the writer has found to answer the purpose equally well, 80°, is often more acceptable to patients, the water being cooled down rapidly to 70° or 65°. The good effects of bathing are not due simply to the abstraction of heat, a favourable influence is exerted on the nervous system; and if the fever be high, and the nervous prostration great—conditions in which the shock of sudden cold is of great service—the

cold water added to bring down the temperature may be poured over the patient's head. The cold wet pack and Thornton's ice-cap have been tried as alternatives to the bath, but without effects adequate to the requirements of the case. A valuable expedient is to apply over the entire abdomen wet lint or thin flannel, upon which small pieces of ice are distributed. A cage will be necessary over the body, and the water from the melting ice must not be allowed to saturate the bed. It has been hoped to prolong the effects of the bath, and so render frequent repetition unnecessary, by the administration of large doses of quinine or salicylic acid. Quinine, to keep down the temperature for any considerable time, must be given in large doses—thirty or forty grains; and even this amount will, as a rule, produce no decided impression unless the way has been cleared by a bath. It is to be given, then, shortly after a bath in two or three equal portions within the space of about half an hour, and a little laudanum may be given with, or just before the quinine, to prevent vomiting. Very frequently the temperature remains depressed for twenty-four hours afterwards, sometimes even for a longer period. The patient often suffers from severe symptoms of cinchonism, but in view of the advantage obtained this need not be seriously regarded. Sometimes, however, violent and protracted vomiting is set up, which is an absolute bar to the further employment of quinine, except hypodermically. The neutral sulphate is the most convenient form for this purpose, and it is sufficiently soluble to be given in adequate doses, that is, of five or six grains. The writer's own experience tends to the conclusion that the frequent bathing has advantages over the combination of quinine with the bath, both as regards the safety and the comfort of the patient; though he has also seen cases in which the bath alone seemed inadequate, while with the aid of quinine the fever was kept down. He has twice seen severe tetanus produced by the bath and quinine, both cases, however, recovering. Salicylic acid and the salicylates have appeared to him to have a dangerously depressing effect. Of digitalis, employed in large doses as an antipyretic, he has had no experience.

Without going so far as to say that the cold or graduated bath should be employed in all cases, the writer is of opinion that many lives would be saved were cold-bathing at once put in practice, whenever a temperature of 103.5° or 104° F. in the first few days shows that the attack is of more than average severity; and it is of the greatest importance that this should be done early, so that the pyrexia may never get the upper hand, and that the intestinal lesions may, if such a thing is possible, be modified. And no patient should be deprived of the chance which is afforded by the bath when, at any stage of the disease, life is threatened by hyperpyrexia or by consequences of high temperature, such as violent excitement, sleeplessness, restlessness, or nervous prostration. In such emergencies it may be necessary to plunge the patient into ice-cold water. The only complications which render the bath inadmissible are hæmorrhage, peritonitis, and the advanced cardiac weakness and degeneration sometimes found late in the disease. Albuminuria or pulmonary affections do not constitute a bar to cold bathing. The writer has known albumen to disappear from the urine at once, and pulmonary congestion to clear up after a single bath.

Treatment of Complications.—In severe and protracted cases a state of extreme prostration ensues which must be combated by special therapeutic measures. A feature of this condition is great frequency and weakness of the pulse, with loss of tension, so that the beats run into each other. Here digitalis may be of very great service, not only by diminishing the frequency and increasing the strength of the heart's action, but by giving tone to the vessels. Probably, however, the most valuable resource is the hypodermic injection of strychnine, which may undoubtedly save life. One-sixtieth to one-thirtieth of a grain may be given every three or four hours as long as necessary, the effect being carefully watched. Digitalin or ether, or both, may be combined with strychnine. Strychnine hypodermically is again the best remedy in the sudden intercurrent attacks of prostration which sometimes occur in the course of fever. The most careful watch should be kept for complications at all stages of the fever, but especially after the end of the second week. A rise of temperature must always be taken to have some definite significance requiring explanation. With increased frequency of respiration, it may be the sole indication of the accession of pneumonia or pleurisy. A fall of temperature may give warning of hæmorrhage. Retention of urine, though uncommon in typhoid as compared with typhus fever, should always be borne in mind; and unusual restlessness should at once suggest an examination of the hypogastrium. The passage of a catheter has often put an end to sleeplessness and excitement. Bed-sores ought never to occur, and it will conduce to their prevention for the medical attendant to inspect the sacral region and other parts where they are liable to be produced.

Hæmorrhage.—In the treatment of hæmorrhage the first thing to be done is to arrest the peristaltic action of the bowels by a full dose of opium; and as an immediate effect is required, one of the liquid preparations should be given—the tincture or liquid extract, and the dose may be from twenty minims to a drachm. The bleeding vessel has to be closed by a clot, and peristaltic movements will tend to disturb this, while it must be remembered that the blood poured out is a continued provocative of movements on the part of the intestine. Direct astringents which depend on local action are useless; before they could travel the whole length of the small intestine, and reach the bleeding point, they would be neutralised by combining with the intestinal contents. Physiological hæmostatics may be of more service. Ergotine hypodermically, or alternate doses every hour or every two hours of the liquid extract of ergot, ʒss to ʒi, and of turpentine m℥x-xv, have seemed to the writer to have most effect. Acetate of lead and opium or morphine, sulphuric acid and decoction of logwood, tannic acid, and all the known styptics have been recommended. An important adjunct—probably more effectual than any internal remedy except opium—is an ice-bag over the region of the cæcum: this at the same time quiets peristalsis and contracts the vessels.

Stimulants must be given if the patient is in danger of dying from syncope, but it must be borne in mind that fainting gives time for the vessels to close; and until the bleeding has stopped, this condition must not be too diligently averted. We must, in fact, sail as close to the wind as is consistent with safety. The same considerations apply

to the administration of food: very little, if any, should be given by the mouth for twenty-four hours, nourishment being supplied by small nutrient enemata.

Perforation.—The only medicinal treatment likely to be of service is the administration of large doses (ʒj or more) of laudanum or the liquid extract of opium or an equivalent of morphine, hypodermically or by the mouth. This has saved life in a few cases, but in the immense majority of cases a fatal termination speedily ensues. Laparotomy may also be proposed. Many cases are now on record in which it has been successful.

Peritonitis.—Here, again, opium in repeated moderate doses is the most useful remedy; with poultices applied over the abdomen.

Tympanites.—Once more the remedy is opium, which should be given in pill three or four times a day when the distension is late and gradual; in very large doses of some liquid preparation when it is sudden, and especially if early in the disease. Charcoal has been recommended, but in the writer's experience it has rarely been other than hurtful.

Diarrhœa.—As long as the stools do not exceed three a day, or while they do not appear to distress or exhaust the patient, nothing special need be done to check the diarrhœa. It must always be borne in mind that beef-tea or other strong flesh-juices may excite diarrhœa: undigested curds of milk may have the same effect. As soon as undue frequency in the action of the bowels is observed, any possible cause in the diet should be eliminated; this failing, the best remedy is an opiate enema, twenty or thirty drops of laudanum in two ounces of thin starch. In most cases two or three enemata will arrest the diarrhœa; should this not happen, astringents must be given by the mouth—acetate of lead and opium or morphine, sulphuric acid, laudanum, logwood, or tannic acid.

Constipation.—This, whether intercurrent when there has been diarrhœa, or present throughout the fever, is a perplexing symptom. It is best relieved by enemata given every other day, but sometimes these are insufficient: a teaspoonful of castor oil may then be given, care being taken that any accumulation in the rectum which might give rise to difficulty of defæcation is previously removed by enema.

Bilious Vomiting.—When this is present from an early period of the attack, attended as it usually is by great prostration, it has seemed to the writer that life is endangered by the formation and absorption of some poisonous ptomaine, and that the intestinal lesions are then of secondary consequence. Acting on this idea, calomel has been given in doses of two or three grains, in order to carry off the poison and disinfect the intestinal tract, with excellent results.

Albuminuria.—Nephritis must be treated by poultices and dry cupping over the kidneys. Albuminuria due to alteration of the blood requires no special treatment, and it is not a bar to cold bathing, but on the contrary may be among the symptoms calling for it. The disappearance of albumen from the urine, which is sometimes observed when the temperature has been reduced by bathing, seems to show that the blood-change is due to the pyrexia, and not to the poison. If the typhoid-bacilli are found to persist in the urine during convalescence, as occasionally happens, some urinary disinfectant, such as urotropine, should be admin-

istered, and the disinfection of the urine carefully attended to.

Pneumonia.—When pneumonia sets in, stimulants are generally required, and the patient will derive benefit from quinine, which may be given in the form of the ammoniated tincture. Turpentine in small doses, or the stimulant balsams, will often be found useful. Turpentine stupes are generally better than poultices.

Thrombosis.—Elevation of the leg on soft cushions, warmth, and gentle support by means of a flannel bandage, will be the treatment required.

W. H. BROADBENT.

TYPHOID STATE (τύφος, stupor).—SYNON.: Fr. *Etat Typhoïde*; *Etat Adynamique*; Ger. *Typhose Erscheinungen*.

DEFINITION.—A condition which may arise in the course of any febrile disorder, when the approach of death is gradual, and the rise of temperature either excessive or long-continued. The typhoid state was so named because of its similarity to the condition usually seen in severe cases of typhus fever. It is most frequent in enteric fever, yellow fever, and pernicious malarial fevers; and in such cases the tendency is often evident from the very beginning of the attack.

DESCRIPTION.—The symptoms of the typhoid state comprise extreme prostration, low muttering delirium, passing into stupor, with little or no true sleep (*coma-vigil*); the 'chaff-collecting' movements of the hands (*carphology*); derangement of the senses, and hallucinations of sight and hearing. The urine and fæces are passed unconsciously, or there may be retention of urine. The sensibility of the skin is greatly impaired; flies creep unnoticed even over the eyelids. General muscular weakness is shown, the patient lying on his back, sunk down in the bed. The lips and gums are covered with sordes, and the tongue is dry and black. *Subsultus tendinum* is present. The pulse is frequently small, weak, and even running in character, sometimes irregular, and easily affected by slight causes—for instance, failing distinctly during inspiration. The heart's impulse is greatly weakened; the first sound almost or quite lost at the apex. The skin is dry, if, as is often the case, the temperature is high, 104–5° F. or upwards; or it is bathed in clammy sweats, which rarely prevail at one time over the entire surface. There is lividity of, or even ecchymoses on, the under-aspect of the trunk and limbs; and in the exanthematous fevers the eruption becomes petechial. The breathing is hurried and shallow, and towards the close frequently assumes the type known as Cheyne-Stokes respiration.

PATHOLOGY.—It is unwise to attempt to attribute all these different symptoms to one single cause. The disorder of the nervous centres which are principally affected is probably due to the presence of toxins in the blood, and to the enfeebled circulation.

PROGNOSIS.—The prognosis of the typhoid state is always grave, but in fevers which run a definite course recovery may take place, even when the condition is fully developed, if it be so only at or towards the end of the febrile period.

TREATMENT.—The treatment consists in the free use of stimulants. Of these brandy is the best, and may be given in doses of half an ounce every half-hour or hour; but the quantity must be determined not by measure, but by the effects upon the patient.

If no improvement follows its exhibition by the mouth, frequently repeated rectal injections of brandy with egg or strong beef-tea ought to be tried. The subcutaneous injection of five to fifteen minims of ether is often so successful in increasing the vigour of the heart's action, that it well deserves a trial here, too, if other means prove ineffectual. If the temperature is excessive, the cold or tepid bath, or the cold pack, should be used; but immediately before or during the application of external cold, half an ounce of brandy at least should always be given. The salutary effects of cold are maintained and increased by full doses of quinine, such as five or ten grains of the sulphate every hour, until twenty or thirty grains have been taken. Hypodermic injections of strychnine (gr. $\frac{30}{100}$) and the inhalation of oxygen are occasionally of service. External stimulating applications are not without value, for example, vesication by blistering fluid, or by strong solution of ammonia to the shaven scalp, when nervous symptoms predominate, or a flying blister to the præcordial region when the heart's action is seriously impaired. Throughout the typhoid state the patient's strength must be husbanded as carefully as possible; and the great object of the nursing should be to save him from the necessity of any mental or muscular effort whatever.

JAMES ANDREW.

H. MONTAGUE MURRAY.

TYPHUS FEVER (τῦφος, stupor).—SYNON. : Malignant Fever; Petechial Fever; Gaol-Fever; *Typhus Exanthematicus*; Fr. *Typhus*; Ger. *Flecktyphus*; *Kriegspest*; *Lazarethfieber*.

DEFINITION.—Perhaps no better definition has been given in modern times than that which Hilderbrand formerly assigned to typhus: 'Morbus acutus, febrilis, contagiosus, exanthemate proprio ac eminenti systematis nervosi passione stipatus.'

Within the past decade or two typhus has remarkably decreased in prevalence, and there is good reason to suppose that the time is not far distant when it will have entirely disappeared, its poison being readily neutralised by fresh air and possibly by exposure to sunlight.

ÆTIOLOGY.—All experience goes to prove that food, bad in quality and deficient in quantity, is the most potent predisposing cause of typhus. All the great epidemics of fever in Ireland and elsewhere have followed times of famine, owing to bad seasons and failure of the crops. It has been assumed on high authority that typhus is a hunger-fever, but against this view a protest must be entered. That want and misery, and consequent mental depression, overcrowding, and dirt, render the person susceptible and a ready recipient of the poison must be admitted. But that there is a something in the air—'a contagium vivum,' a typhus-miasma, which, taken into the system, produces fever—must also be admitted. Up to the present, the most ardent and able investigators have failed to discover the presence of a fever-producing parasite in typhus, such as has been found in some infective diseases.

BACTERIOLOGY.—Hlava (1891), Lewaschew (1892), Calmette (1893), Dubief and Bruhl (1893), are among the most recent writers on the bacteriology of typhus. Nothing definite, however, has as yet resulted from their researches or those of other investigators. In 1898 E. J. McWeeney, of Dublin, made an unsuccessful attempt to isolate micro-organisms from the blood of two typical

cases of spotted typhus. In both cases the blood proved to be absolutely sterile, tubes of glycerine-agar and faintly alkaline peptone-broth failing to show any signs of growth when put away at 37° C. to incubate. In both cases also the blood-serum, tested by the Gruber-Widal method, gave a negative reaction, so excluding a diagnosis of enteric fever. McWeeney, as a result of his experiments, concludes that our present methods of investigation are not capable of solving the question as to the nature of the *materies morbi* in typhus.

The poison, whatever it may be, is present in certain localities, causing endemic disease, and under favourable conditions assuming the epidemic form.

ORIGIN OF TYPHUS.—The doctrine of the *de novo* or spontaneous generation of typhus is opposed to all analogy, so far as the specific fevers are concerned. Indeed it is beset with greater difficulties than those which it is designed to explain. The theory would become untenable, were the microbic origin of the disease once proved. It is unnecessary, if we assume that in cases of obscure origin we have to deal with a sudden increase of virulence in the infecting agent on the one hand and an acutely developed susceptibility by the patient on the other hand. It must, however, be admitted that now and again a case of typhus occurs in which it is impossible to trace the infection. There is no disease, with the exception of smallpox and scarlatina, which is admittedly more infectious than typhus fever.

In Ireland the question of infectiousness was many years since set at rest by Marsh. Cheyne's reports of the Hardwicke Hospital are also replete with facts pointing to the same conclusions. The greater number are not conscious when they are poisoned by the typhus miasm, but the exceptions are not rare. Marsh perceived, on suddenly turning down the clothes of a patient, a highly disagreeable odour; he was oppressed, and at once overwhelmed *uno ictu*, being conscious at the time of having absorbed the poison.

PRODROMAL OR LATENT PERIOD: PERIOD OF INCUBATION.—The time intervening between exposure to infection and the advent of the series of phenomena constituting fever is generally from three to seven days; but it may be shorter or more protracted. There may be no incubation—*typhus siderans*; the overt symptoms appearing simultaneously with the reception of the poison. The incubation-period is not generally a time of health: sleep is disturbed, there is often a malaise, an undefined sense of illness, a depression, and often a fear of some impending calamity. The patient may struggle against it, and follow his ordinary occupations, until it becomes impossible to further resist.

SYMPTOMS.—The symptom which ushers in the disease is generally a rigor, a sensation as if cold water were trickling down the back. There may, however, be no distinct rigor, merely a *frisson*, a chilliness; and even this may not be noticed. There may be one distinct severe rigor, or a number of slight shiverings. After the rigor a rapid rise of temperature takes place; and now, if not before, the patient is in most cases compelled to take to bed. The symptoms then are headache, giddiness, heaviness, languor, dulness, pain in back and limbs—especially the thighs—sleeplessness or disturbed sleep, thirst, anorexia; perhaps nausea or even

vomiting; the tongue may be loaded, white or yellowish.

The early symptoms are at times so slight that the affected person may be able to walk about; and in three, four, or seven days defervescence takes place, and restoration to health follows. This is termed 'febricula'—*Febris ambulatoria* of the Germans. In by far the majority, however, the symptoms become aggravated day by day; sometimes catarrhal symptoms supervene—often they are the earliest manifestations. Headache is complained of, with intense flashes of light before the eyes, or intolerance of light; the skin, at first red, assumes a dusky hue; the tongue becomes brownish and dry. On the fourth or fifth day of the fever the rash (the exanthem to which the disease *typhus exanthematicus* owes its name) appears. This rash is generally first observed on the trunk, then spreads to the extremities; it rarely appears first on the backs of the hands and face. The spots vary in size from a slight speck to three or four lines; sparse at first, they soon extend; isolated or grouped together, they have been compared to pieces of marquetry; they may be of an intense red, but generally they are pale; little papules are seen in some few cases. The typhus-exanthem bears a close resemblance at its commencement to the rash of measles; hence it is often termed 'measly eruption.' The spots disappear on pressure. In the space of two or three days the eruption is complete; the colour gradually assumes a more or less dark hue, livid or mulberry, no longer disappearing on pressure. The usual duration of the rash is from a few days to fourteen or fifteen days. Its colour is often deeper on the back than elsewhere; and when a doubt exists as to its having appeared, it should be looked for there.

The rash does not seem to have any influence on the fever, and it may continue after the defervescence; but the more copious it is, and the deeper its colour, the more severe is the disease. This is the opinion which is held by most observers. The change of the eruption from a measly rash to true petechiæ or cutaneous hæmorrhages is the rule. The skin in the course of the disease may be the seat of various epiphenomena—erysipelas, furuncles, sudamina, œdema, abscesses or gangrene of the parts most exposed to pressure; and sometimes even the nose and the genitals are affected. In some epidemics icterus occurs, and its appearance has in some cases been remarkably sudden. The febrile phenomena are not mitigated with the development of the rash.

It sometimes happens that towards the end of the first week there is an amelioration of the symptoms; but this is but a lull in the storm in the greater number of cases. The temperature, which had fallen, rises again, and often exceeds the former record. The pulse attains a frequency of 100 in the morning, and 112 to 120 in the evening, and in the severest cases far exceeds this. In the early stages it is fairly full, but it may become weak, compressible, and fluttering; or, which is perhaps a more evil omen than great frequency, slowness is observed, owing to the diminished power of the ventricle to make every contraction felt at the wrist. The patient lies on his back in a state of great prostration; there is a tendency to slip downwards in the bed; the headache of the early days has been succeeded by delirium, the character of which varies much. At first, chiefly at night or on awaking from

disturbed sleep, he is confused and unable to answer questions correctly; at the end of the first or beginning of the second week the delirium becomes more pronounced—noisy, restless, or apathetic—and often the strangest phantasies arise. A fixed idea may take possession of the mind; there may be muttering delirium, coma vigil, sopor, sudden furious mania alternating with sopor; often there is difficulty of restraining the patient in bed; hence the necessity of closest watching, especially at night. The tongue is dry, contracted, and black, covered with fuliginous deposit—'parrot tongue'—as are also the gums. Retention occurs from paralysis of the detrusor vesicæ, or involuntary discharge of urine; and the bladder should be examined frequently, as the discharge is sometimes merely an overflow; for days it may be necessary to employ the catheter. The urine is high-coloured, scanty, and often albuminous. Such are the symptoms of typhus in its severe form.

Towards the end of the second week, in, fortunately, the great majority of cases, a favourable change takes place. There is no disease in which the change may be so sudden from a state of extreme danger. The patient, who had been violently delirious, or lying in a torpid state of low muttering delirium with subsultus tendinum, falls into a tranquil and profound sleep which may last for many hours—so long that it is necessary to awaken him for nourishment; and on awakening the temperature may be normal or below it, the tongue moist, the pulse—which had been rapid, thready, and tremulous—firm and moderate in frequency, and intelligence to a great extent restored, with returning desire for food and drink. This change—crisis by sleep—is the most favourable event. The skin, which was burning hot—*calor mordax*—may become moist, bedewed with a gentle sweat; and this seems in some instances critical, altogether different from the copious sweat which, occurring at an earlier stage, is almost always indicative of danger. A change, too, occurs in the urine which has been considered critical: it has been high-coloured and albuminous, or even bloody, and now the secretion is abundant, of normal colour, or even paler than natural, with a copious deposit of the lithates and phosphates. To this change in the urine the term 'crisis by urine' has been given.

COMPLICATIONS.—Many are the dangers and difficulties from complications which threaten the patient in the course of typhus, and prolong the disease; one of the most common is implication of the respiratory organs. In some epidemics so frequent is bronchitis, that the disease has received the name of 'broncho-typhus.' From the onset there may be a bronchial affection unmarked by the ordinary symptoms, even in advanced stages—no expectoration, perhaps not much acceleration of breathing; it may involve the whole extent of the bronchi (bronchiolitis), even producing collapse; its presence being discoverable only by auscultation. It is noteworthy that secondary affections in typhus are more or less latent. Broncho-pneumonia, hypostatic congestion, diffuse pneumonia, are among the most formidable complications in fever, and often indicate a lethal termination. Multiple abscesses, or gangrene in various situations, not confined to the parts exposed to pressure, may occur. Convulsions may usher in a fatal termination. Sudden death has occurred when all seemed to progress favourably.

DIAGNOSIS.—There are cases of typhus the course of which is normal, and which present no difficulties to the experienced physician in arriving at the diagnosis, and hence it is said the disease is easy of diagnosis; but he will meet with others, though few in number, in which it is occasionally impossible.

The fevers with which it is most likely to be confounded are enteric and relapsing fever, both of which are found to exist in company with typhus in many epidemics of the latter. Cases of enteric fever may be wanting in the characteristic changes in the intestinal canal and the glands; and, again, typhus may exhibit changes resembling those of enteric fever, and so the two may, as it were, shade into each other. The knowledge of the exposure to either disease will assist very much, for typhus never gives rise to enteric, nor enteric to typhus. Important aid also in the diagnosis may be obtained by observation of the temperature: marked elevation of temperature is noted in typhus from the onset, and the rapidity of the rise and the shortness of its duration exclude the idea of enteric. The course of typhus resembles that of relapsing fever in the first days. In both of these diseases the temperature is high; but it is higher in relapsing fever, and on the fifth or seventh day defervescence takes place, and the patient is for the time fever-free, to be attacked later by a new access of fever. Other febrile diseases seldom maintain so high a temperature as typhus for so long a period. The return of the temperature to the normal from fever-height in typhus is often very rapid, the defervescence, as before mentioned, taking place in one night.

Comparing typhus with enteric fever, the defervescence is extremely rare at so early a period in the latter, or at so late a date in an acute exanthem or in relapsing fever. The rapid fall of the temperature in typhus, as compared with the gradually decreasing fever in enteric, is also a distinguishing feature. The profuse petechial rash contrasts strongly with the sparse rosy spots of enteric fever, which usually come out in successive crops, and are slightly elevated. The absence of epistaxis and intestinal lesion, also of hæmorrhage and of marked splenic enlargement; as a rule, absence of the diarrhoea characteristic of enteric fever, and of ileo-cæcal tenderness and gurgling; and the comparative rarity of meteorism,—all are to be taken into consideration. In both, the respiratory and circulatory organs are liable to be implicated, and so are the kidneys.

It has been affirmed that no single symptom proclaims the presence of typhus; but the order in which the symptoms are presented, the grouping of symptoms—what German writers call ‘symptom-complex’—and the disturbance of the nervous system, powerfully aid in arriving at the diagnosis.

PROGNOSIS.—In forming a prognosis of typhus fever, the character of the epidemic, and the rate of mortality, may first be taken into account. Some epidemics are peculiarly mild and benign, others are malignant in the extreme. The period of the epidemic is also important, as the earliest cases are generally most fatal. Then the condition of the patient, if previously in broken-down health, ill fed, ill clothed, ill housed—such fall ready victims to the pestilence; perhaps nothing renders the prognosis more unfavourable than habits of intemperance. In the upper ranks of life, occupations

involving anxiety and mental stress predispose to bad attacks, in which the nervous symptoms are prominent at an early stage; such cases have received the popular name of ‘brain-fever.’ Sex-mortality is also to be noted, being greater in adult men than in women. The symptoms indicative of danger are the early existence of delirium alternating with stupor, the peculiar affection denominated ‘coma vigil,’ subultus tendinum, and other low nervous phenomena. See COMA VIGIL.

Very high or very low temperatures, and extreme rapidity of pulse, always proclaim the severity of the disease and consequent danger. It has been observed, however, that in no disease is high temperature so well borne as in typhus. The character of the pulse is one of the most reliable indications of danger. To rapidity may be added irregularity, feebleness, compressibility. The opposite state however (slowness) is also of evil augury; for the first sound of the heart may be absent, and the impulse diminished in force or absent—conditions of the heart indicating the need of wine and other stimulants, as first pointed out by Stokes. Great tympanic distension is another indication of danger; and the presence of rash of the deepest hue.

Other conditions which add to the danger in typhus fever are weakness or paralysis of various parts; hypostatic congestion, which may end in gangrene of the lung; strabismus; and contraction of the pupil; spasm, convulsions, stiffness of neck, utter unconsciousness, automatic movements; and, above all, advanced age.

The prognosis in uncomplicated typhus is favourable; in early life the mortality is moderate. It is not so great in women, except when they are pregnant. Danger increases after passing the meridian of life; a quarter and even half of the cases between fifty and sixty years of age succumb. In some epidemics the enormous mortality of 40 or 50 per cent. has been reached, contrasting remarkably with the low rate of others—only 5, 6, or 7 per cent.

ANATOMICAL CHARACTERS.—It is admitted by all who have had the most extensive opportunities of investigating the disease, that there are no anatomical changes which can be considered pathognomonic of typhus.

If death takes place early the body is little emaciated; the petechiæ which are caused by blood-extravasations are visible, and, as in life, most marked on the back. Almost all the organs of the body are the seat of change in structure, congestions and hyaline, granular, or fatty degeneration. The mucous membrane of the intestinal tract is infiltrated, and shows traces of catarrh, and in exceptional cases even superficial ulceration, but there is nothing constant. The brain and membranes in the early stages are hyperæmic; if death occurs late in the disease they may be anæmic, with serous effusions. The heart-walls are softened, and the seat of granular and fatty change; there is fluid blood in the ventricles. The lungs are the seat of hypostatic congestion, the blood being almost black. The veins and arteries have been found to be the seats of thromboses and emboli.

TREATMENT.—Impressed with the communicability of typhus, it is the duty of the physician to insist on the isolation of the sick from the healthy. On the first access of fever the patient should be ordered to bed. Every exertion, mental or bodily,

should be forbidden. The transport of those sick of typhus in war has been known to intensify the symptoms; so it is, too, in civil life. Therefore removal from the locality where first attacked should be avoided, except under the stress of absolute necessity.

In the management of typhus-cases, an abundant supply of air should be afforded. From the chamber all unnecessary furniture should be removed; the covering of the bed should be light. The temperature of the apartment should not be under 59° F. or over 65° F. During the height of the fever, when the temperature is high, exposure to cold does not act injuriously; but it is harmful when once defervescence has taken place. The patient should not be permitted to change from the prone position or any purpose—an order often difficult to enforce during the early period of the illness. The strictest injunction should be issued against noise, or even whispering, in the room. Light should be modified, but not excluded. The patient will sleep better if the room is not darkened during the day. No one should be admitted to the room except the necessary attendants.

The disease in uncomplicated cases, when of moderate severity, runs a certain course, tending towards a favourable termination, and then the treatment is absolutely expectant. The idea of arresting typhus fever is now altogether abandoned. The regulation of the diet is of paramount importance. Thirst is constantly felt, and the craving should be satisfied, and the fancies of the sick, when possible, be indulged. Cold water or some mineral water will generally be found to be most acceptable; when the tongue is dry, iced water or ice may be permitted. If the patient's sensibilities are so blunted that he cannot give expression to his wants and wishes, care must be taken that at regular intervals drink and nourishment be given; no more suitable drink than milk and water or soda-water can be given, thus supplying nourishment at the same time that the thirst is assuaged. Broths of different kinds are freely allowed, and, when there is great debility and manifest failure of strength, more concentrated nourishment, as essence of meat, or eggs. The administration of wine and stronger alcohols is one of the points in the treatment of fever demanding the most careful consideration on the part of the physician. In most cases, except in those stamped by malignancy from the commencement, it may be postponed to the end of the first or beginning or even the middle of the second week, and alcohol may then be cautiously, tentatively given, marking its effects. The selection of the stimulant should depend on the age and previous habits of the patient: the young or previously temperate require wine in only small quantities, and diluted; the aged or intemperate a liberal allowance of strong wine or even brandy. Without reference to the day of the fever, if there be prostration, a tendency to sinking of the vital powers, stimulants must be freely given; and thus the threatened paralysis of the heart may be ward off. Medicinal agents, such as ammonia and ether, are often advisable. See STIMULANTS.

The cerebral symptoms—headache and delirium—are frequently relieved by the application of ice or, what is sometimes more effectual, cold or tepid affusion. Care should be taken, when the ice-bladder is employed, that it should not remain too long on the head, as it seems to have a depressing

effect. When insomnia is present, and the temperature is high, tepid affusion often has the effect of inducing sleep; so has the abstraction of a small quantity of blood from the temples (two or three leeches on each temple), sleep often coming on while the blood is flowing. In conditions of a comatose nature blisters should be employed—strips of blisters on the vertex, and not to the nucha, the part usually selected, but which should be avoided. If insomnia continues, the use of the bromides may be resorted to, and often with advantage; but when they fail, as they may, then opium or morphine must be administered. Hall has found sulphonal a remedy of much value, but it often has a depressing effect.

The application of water to the head has been spoken of, but in all cases it is also essential for the whole body. The most scrupulous cleanliness is to be observed, and sponging with cool or tepid water may be used when the antipyretic treatment by cold baths has not been fully carried out. This treatment is now being adopted in typhus also, in which, as in other cognate diseases, the danger of high temperature is universally admitted. At the same time our object must be to control temperature, not recklessly to reduce it too much or too fast. The nature of the fever-process is now far better understood than it was even a few years ago, and we have learned that 'fever,' or elevation of bodily temperature above the standard of health, or 'normal,' serves a useful purpose, provided that it is properly controlled.

Quinine has been looked on by some as a specific. Liebermeister recommended it in colossal doses, and said he treated no serious case of typhus without it. It is used as an adjunct to the cold bath in the antipyretic treatment of fever; it may be the sole antipyretic when the cold bath is contraindicated. Mosler, who had the experience of two epidemics of typhus, attributes the low mortality of the second to the fact of the antipyretic treatment having been by him more energetically carried out in that epidemic than in the first.

The best means of removing constipation is by warm- or cold-water enemata, which never cause over-action, which even mild aperients by the mouth often do. One of the most dangerous complications in fever is meteorism, and the best means of combating it is by the internal and external use of turpentine. Another is bed-sore, which in low forms of fever, despite all efforts to guard against it, will sometimes appear. The back should be examined daily, and the surface, which has become red, should be bathed with brandy or camphorated spirit; the position of the patient should be changed, and air- or water-cushions placed under the back, or a water-bed employed. In all cases it is most desirable to have two beds; a change can be effected without difficulty or danger, and the comfort and advantage of separate day- and night-beds are incalculable. It is most difficult at times to limit the ravages of bed-sores; the nates have in some instances literally sloughed away, but even in such a case recovery has taken place. For the treatment of GANGRENE, see p. 571.

The danger of hypostasis has been alluded to, and this may be averted by altering the position of the patient, and also by the free administration of wine or brandy to stimulate the heart's action.

In pneumonia occurring as a complication,

quinine is a most useful remedy; and in cardiac failure it seems to have almost a specific influence on the muscular tissue of the heart, for it has been often found that under its influence the weak, irregular, and fluttering heart has become regular.

The physician must be always on the watch for complications, for their approach is generally insidious, and wanting in the symptoms which in ordinary cases appertain to them; they may be truly termed latent. The restoration to health after ordinary typhus is rapid; but typhus protracted beyond its ordinary duration leaves the patient's bodily strength at a very low ebb, and sometimes the brain does not speedily recover from the shock it has received. Mania may be a sequel, but the form of cerebral disturbance is more frequently characterised by mental weakness, with inability to fix the attention and follow any train of thought. The prognosis is generally favourable, for usually in time the mind recovers its wonted vigour.

JOHN BANKS.
J. W. MOORE.

TYROSINE (τυρός, cheese).—SYNON.: Fr.

Tyrosine.—Tyrosine, or para-oxyphenyl- α -amido-propionic acid, is, like leucine, with which it is generally associated, a decomposition-product resulting from the prolonged action of the pancreatic secretion on the complex proteid molecules. Its chemical composition is represented by the formula $(C_6H_4(OH)CH_2CH(NH_2)COOH)$. Tyrosine is never a constituent of *fresh* tissues. It is normally a constituent of the intestinal contents, being one of the products of the action of trypsin on the hemipeptone resulting from proteolysis by the gastric and pancreatic ferments. See ALKAPTONURIA.

CHARACTERS.—Tyrosine-crystals are soluble in acids and alkalis, but very sparingly soluble in cold water, much more soluble in hot water, and practically may be considered insoluble in ether and strong alcohol. It cannot be sublimed without decomposition.

Microscopically, tyrosine-crystals are usually seen in the form of very fine needles, either

separate, or occurring in feathery or 'wheatsheaf' bundles or rosettes (*see* p. 1798).

Chemically, tyrosine may be separated from the urine, by the method described under LEUCINE, but the residue obtained, insoluble in boiling alcohol, is treated with boiling water, and allowed to crystallise. The most reliable and delicate reactions for tyrosine are the following:—

Piria's Reaction.—Warm on a water-bath for about five minutes a watch-glass containing tyrosine moistened with concentrated sulphuric acid; a pink colour is produced. Dilute with water, warm, neutralise with calcium carbonate; filter while hot. Add to the filtrate a few drops, carefully avoiding an excess, of a weak solution of the perchloride of iron. A violet colouration is indicative of the presence of tyrosine. Leucine interferes with Piria's reaction.

Hoffmann's Reaction.—If to a heated solution of tyrosine a little Millon's reagent be added, the fluid assumes a rose-red or crimson colour; and if tyrosine be present in quantity, a precipitate of a similar colour will be thrown down.

Scherer's Reaction.—Apply a mixture of strong nitric acid and water to a solution of tyrosine, evaporate to dryness, a yellow residue is obtained; moisten and warm with liquor sodæ—a yellow turning to a deep reddish-yellow colour is produced.

PATHOLOGICAL SIGNIFICANCE.—Tyrosine is never present in healthy livers; it, however, is probably normally present in very small amount in the pancreas and the secretion of this gland, and in the spleen. It is not considered a normal constituent of the urine (Ulrich regards leucine and tyrosine as normally present in minute quantity), but its presence in this excretion along with leucine is of value diagnostically in certain morbid states of the liver, especially acute yellow atrophy, in which the secreting cells are quickly disintegrated. It has also been detected in the urine in cases of acute poisoning by phosphorus. See LEUCINE; LIVER, Atrophy of, Acute Yellow; XANTHOMA; and URINARY DEPOSITS, Plate XX. JOHN HAROLD.

U

ULCER AND ULCERATION (*ulcus*, a sore).

SYNON.: Fr. *Ulçère*; Ger. *Geschwür*.

DEFINITION.—An ulcer is a solution of continuity of an epithelial or endothelial surface, resulting from the destructive changes associated with inflammation. *Surgically* the term 'ulcer' signifies an open sore.

ÆTIOLOGY.—The inflammatory process to which ulceration is due results in almost all instances from the action of micro-organisms. In a few cases continued mechanical irritation may cause an ulcer, but even in such instances extension of the process is due to the invasion of the wound by bacteria. The poisons formed in the growth of these cause the phenomena of inflammation, with death and disintegration of the tissues. In the majority of ulcers the organisms at work are the common pyogenic cocci (*see* PYOGENIC BACTERIA). Ulcers may also be due to the tubercle-bacillus, the

B. typhosus, the organism of dysentery, and others. In syphilitic (tertiary) ulceration, a breach of surface results from the breaking down of a gummatous deposit, and secondary invasion by pyogenic organisms takes place: this secondary invasion may occur in other 'specific' ulcers, such as the tubercular, or in those arising from necrosis of new-growths.

'Predisposing' causes of ulceration are seen in any conditions which diminish the resistance of the tissues to bacterial attack. Thus the defective nutrition of the skin due to varicose veins causes slight injury (scratching, blows) to result in the formation of an ulcer. In diabetes mellitus small abrasions or wounds may give rise to ulcers, which show little tendency to heal, the factors at work in this disease being not only the presence of sugar in the tissues, but also special changes in the vessels and nerves. Owing to their poor vitality the cells

of tumours rapidly undergo fatty degeneration and necrosis, which result in the early appearance of ulceration in superficial malignant growths. Ulcerative endocarditis is generally secondary to old rheumatic lesions, which become the seat of fresh bacterial invasion.

It is not yet certain whether the nervous system exerts a direct trophic influence upon the tissues, but the evidence appears to favour this view. Perforating ulcer of the foot is met with in cases of tabes dorsalis, and less commonly along with other nervous lesions. If it be not due to direct nervous action it must be supposed that the resistance of the tissues is weakened by disturbance of their vascular supply, and that organisms are thus enabled to gain a footing as a result of insignificant injuries. The same alternative explanations may be offered in the case of bed-sores; or the combined causes may be at work in both instances.

A breach of surface by which bacteria may enter and set up the process of ulceration may arise from external causes, such as mechanical violence, chemical irritation, heat and cold, continued pressure, &c. So-called constitutional causes are in reality only 'predisposing' conditions, in the sense given above.

PATHOLOGY AND MORBID ANATOMY.—The process of ulceration consists in a gradually extending molecular death of inflamed tissues, and is exactly the same as that by which an abscess-cavity is formed and extends (*see* ABSCESS). The wall of an ulcer is in structure the same as that of an abscess, and varies according as the destructive process is still spreading or has been arrested. If the ulcer is spreading the surface will be formed of a layer of leucocytes, and these cells also infiltrate the underlying tissues; the elements of the latter are granular, and in process of destruction, and the blood-vessels dilated for some distance around the lesion. Sloughs of tissue killed *en masse* may here and there remain adherent to the surface of the ulcer. If arrest of the ulceration have taken place, the ulcer is practically a healing wound, and its floor is covered with 'granulations,' the deeper layers showing all stages in the gradual conversion of granulation-tissue into fibrous cicatrix (*see* WOUNDS, Healing of). The naked-eye appearances of the different varieties of ulcers are given below, the essential parts for study in any ulcer being—the surface or floor; the edges and surrounding parts; the base or underlying tissues; and the discharge secreted.

The discharge from an ulcer consists of serous exudation from the vessels, with a varying amount of leucocytes, which die and constitute pus. Occasionally blood is present either from intensity of inflammation or from rupture of capillary loops in the granulations. If the discharge is retained beneath a crust or dressing, it may accumulate and putrefy.

CLASSIFICATION AND VARIETIES.—Ulcers may be classified according to their most obvious causes, predisposing and exciting; thus there are tubercular, typhoid, syphilitic, paralytic or perforating, varicose, malignant and other kinds. For clinical purposes the following varieties may be distinguished:

1. *Healing or healthy ulcer.*—This is practically a granulating wound. The surface is covered by granulations, which are small and bleed when smartly touched. There is a thin, blue epidermic pellicle, consisting of the epidermis advancing from

the edges over the surface. The edges are on a level with the surface, of a pink tint, and free from induration. The surroundings are free from induration, and normal in appearance. The discharge is small or moderate in quantity, and, unless free from pyogenic bacteria, consists of so-called 'laudable pus.' The pain is inconsiderable.

2. *Weak ulcer.*—The cause of one form of weak ulcer is the prolonged use of emollient applications. The characters are: flabby, watery, gelatinous granulations, rising above the level of the surroundings as so-called 'proud flesh.' The edges are overlapped by the granulations. The surroundings may be fairly normal. The discharge is thin and watery. There is little or no pain.

Another cause of 'weak' ulcers is where, owing to some local or constitutional cause affecting the circulation, there is a defective blood-supply to the ulcerating surface. The granulations under these circumstances become smooth and yellowish, the edges look pale and flat, the secretion is thin and small in quantity, and a dry crust or scab is apt to form. In yet a third variety the ulcer becomes oedematous, a condition frequently associated with Bright's disease, and any local or constitutional trouble in which the circulation in the larger vessels is defective.

3. *Indolent, callous, or 'chronic' ulcer.*—This sub-variety occurs when, from chronic irritation in a part devoid of sufficient blood-supply, the fibrous induration is excessive, and the blood-vessels reach the surface of the ulcer in too minute quantities to build up healthy granulations.

The surface is sunk below the level of its surroundings, is destitute of granulations, and looks glazed. The edges are raised, hard, and irregular. The surroundings are indurated and raised, and the veins in them frequently become varicose. The discharge is thin, serous, and small in quantity. The pain at times is very great, especially at night.

4. *Irritable ulcers.*—These are met with on the legs of neurotic and anæmic women, and in women suffering from menstrual disturbances. The surface is uneven, often covered partially with a grey slough. The edges are thin and irregular. The surroundings are red and glazed, but not raised or thickened. The discharge is a thin sanious pus. The pain is excessive, of an aching or neuralgic kind.

5. *Inflamed ulcers.*—Any form of ulcer may become inflamed, owing to fresh bacterial invasion. This sub-variety may arise during the course of an indolent ulcer, from derangement of the patient's health or local irritation.

The surface is covered with a greenish-grey exudation. The edges are swollen, everted, red, and angry. The surroundings are red, swollen, and hot. The discharge is ichorous, offensive, and often bloody, causing irritation wherever it touches. The pain is of a throbbing kind.

6. *Phagedænic and sloughing ulcers.*—When an inflamed ulcer commences to spread, the edges liquefy and rapidly break down. The process may take place with extraordinary rapidity, as in chancre, when it is called phagedæna; or as in hospital gangrene, when it spreads chiefly by sloughing. The patient in either case is usually in a cachectic state; the ulcerated part is dusky red, angry-looking, hot, and painful. The surface is covered by a grey or black slough, and the edges are sharply cut and undermined. *See* BUBO; CANCRUM ORIS; GANGRENE; and VENEREAL SORE.

7. *Varicose ulcers*.—These are small at first, and gradually enlarge with œdema of the edges, soft prominent granulations, and eczematous surroundings. They seldom bleed except at the moment of the bursting of a periphlebitic ulcer, from which they sometimes originate. The chronic ulcer, induced by varicose veins, develops a widespread induration, which, by interfering with the venous circulation, tends to increase the tendency to varicosity.

8. *Hæmorrhagic ulcers*.—Hæmorrhagic ulcers occur in persons suffering from amenorrhœa, scurvy, chronic jaundice, or hæmophilia. They possess many of the characters of irritable ulcers, but in addition have a special tendency to bleed. The blood is of a capillary-venous character, and flows fairly freely at times.

9. *Atonic (paralytic) ulcers*.—In the feet of paralytic patients ulcers may develop with extraordinary rapidity. They are painless, frequently multiple, and present uneven, often scooped-out, surfaces covered by granulations of irregular size. *Perforating ulcer of the foot* is an affection of this nature. The ball of the great toe or the under surface of any of the metatarsal bones may become the seat of this ailment. There is first seen a callosity on the sole of the foot; pus develops beneath this, and when the abscess bursts a long sinus will be found leading down to bone. The bone may in turn become involved and undergo absorption. The peculiarity of this form of ulcer is that it is funnel-shaped, the granulations are protuberant, the discharge profuse and foul, and the surfaces of the sinus become lined by an epithelial coating. The ulcer may heal under rest and antiseptic treatment, but generally reappears when the patient once more walks about.

Syphilitic, lupoid, rodent, scorbutic, endothelial, mucous, tubercular, and cancerous ulcerations, as well as those occurring in *mycetoma, leprosy, cancerum oris*, &c., are described under the diseases of which they form part.

TREATMENT.—To treat an ulcer on a rational basis it is necessary to ascertain as exactly as possible the cause of the ailment, both as regards its genesis and its continuance. When a constitutional factor plays a part in the ætiology, suitable treatment for the condition should be adopted. When, on the other hand, the cause is of local origin merely, attention must be devoted to allaying or removing the source of trouble. Some ulcers from their very nature may be incurable, such as those of a malignant or leprosy nature; others, such as diabetic, syphilitic, or scorbutic ulcers, heal only when suitable drugs or diet are exhibited; while a third group, including all those ulcers caused more essentially by local disturbances, such as varicose ulcers, pressure-ulcers (bed-sores), senile ulcers, inflamed, weak, septic, and phagedænic ulcers, require local treatment for the most part.

The removal of the constitutional causes is dealt with under the several diseases with which the ulcer may be associated, so that only the local treatment need be commented upon here.

Rest.—Of all the aids to cure this is perhaps the most important. When the lower extremity is the seat of the trouble a splint or stiffened bandage may be applied at times with advantage; the upper limb may require to be supported by a splint or sling. The joints immediately above and below the section of the limb on which the ulcer exists should be kept at rest.

Position.—Elevation of the limb while the patient is recumbent is a primary consideration, especially in ulcers of the lower extremity.

Massage is an excellent accessory when extensive induration of the tissues around an ulcer is marked.

Removal of sepsis.—To render the parts around a chronic ulcer aseptic proceed as follows: wash the parts around the wound with soap and water, and shave off the hairs if necessary. Dry the part and apply turpentine to get rid of the sebaceous materials in the skin. The skin is again washed with soap and water, using a large nail-brush for the purpose. Carbolic-acid lotion (1–20), corrosive-sublimate solution (1–5000), or other reliable antiseptic lotion is applied to the skin thoroughly by a nail-brush. The process should be repeated several times on successive days, to ensure complete surgical cleanliness.

To render the surface of the ulcer itself aseptic, it is to be converted into a healthy wound at once by scraping it with a sharp spoon while the patient is anæsthetised, and then thoroughly mopping the part over with pure carbolic acid or some other corrosive. The surface of the wound and the surroundings are then enveloped in antiseptic dressings, of which, perhaps, cyanide-gauze dipped in corrosive-sublimate solution (1–2000) is the best.

When, for any reason, this radical method of treatment is inexpedient, the ulcer, after the surroundings have been dealt with as recommended above, may be dressed with lint soaked in carbolic oil (1–5), the lint being firmly pressed into the surface of the sore at all points. When the oil is used, daily dressing will be required, but when the wound has been scraped and covered by gauze, the dressing may be left in place for two, three, or more days.

To promote healing after the ulcer has been rendered aseptic, and when it appears fairly healthy, proceed as follows: Cut a piece of protective oiled silk to the size of the ulcer; wash it clean in carbolic lotion (5 per cent.), and afterwards in a saturated solution of boric acid; apply the oiled silk thus prepared directly upon the wound. Cover the 'protective' by layers of boric-acid lint, wetted in a saturated solution of boric acid and cut somewhat larger than the protective. Maintain the whole in position by a firmly applied bandage, commencing at the foot (or hand) and carried upwards to a considerable distance above the dressing.

In place of the dressing, protective ointments or dusting powders may be employed. An excellent ointment is one consisting of the unguentum acidi borici, B.P., 1 part, and vaseline 3 parts. The ointment is best spread on butter-cloth, not on lint. The part is then covered over with a dry antiseptic lint or gauze, and bandaged. Iodoform, boric acid, or a mixture of the two, are efficient dusting-powders.

When ulcers are *inflamed* it is necessary to allay the pain and inflammation by rest and by boric-acid fomentations. A boric fomentation is made by soaking boric-acid lint in boric-acid lotion or warm (boiled) water, laying it on the ulcer and for some distance beyond, then covering the whole with a piece of mackintosh and bandaging. This dressing is changed two, three, or more times daily until inflammatory signs and symptoms disappear, when the ulcer may be treated in the ordinary way by protective, &c.

Should boric fomentations fail to allay pain it may be necessary to *incise the margins and surface* of the ulcer by a few strokes of a scalpel carried parallel to each other and to the long axis of the sore. After incising, fomentations may be applied until inflammatory signs have gone, when the ulcer to be treated as the granulations indicate.

An *irritable* ulcer may require to have the surface destroyed by blistering with liquor epispasticus, or by rubbing nitrate of silver, nitric acid, or other corrosive, upon it, before a healthy action can be induced. As the irritable ulcer is a frequent concomitant of menstrual abnormality, this condition has to be tended to as an essential element in treatment.

When *weak* or *callous* ulcers become quite *chronic* it is necessary to stimulate activity in their condition by every available means. Rest and elevation of the limb, with attention to the general health, may alone serve to attain an alteration in the nutrition of the part. The ulcerated surface may be stimulated by the application of a fly-blister to the surface, or still better to the thickened parts around the edges of the ulcer.

Pressure, when equably applied, proves at times a reliable method of stimulating a callous ulcer. Pressure by *strapping* is applied as follows : Cut strips of plaster one-third longer than the circumference of the part of the limb to be covered. For the leg the strips should be one inch in breadth. Apply the centre of the strips on the opposite side of the limb, commencing two or three inches below the ulcer. Each succeeding strip should overlap its predecessor by two-thirds of its breadth. The ends are crossed over the ulcerated surface and pulled fairly tight. The strapping is continued for two or three inches above the ulcer, and holes cut in it if the discharge is very free.

Martin's elastic bandage, perforated, with or without a suitable dressing on the ulcer, may be applied to the whole limb, commencing, in the case of the leg, at the foot, and carrying the bandage to just below or above the knee. The bandage ought to be removed at night, cleaned and dried, and applied on the following morning before the patient gets out of bed.

Unna's bandage consists of a double-headed roller of porous material applied to the limb, commencing at the ulcer ; over the bandage a mixture, consisting of gelatine 10 parts, glycerine 40 parts, a little oxide of zinc, and 40 parts water, is melted and rubbed on the bandage ; over the mixture, and before it has set, a second covering bandage is applied. In this way the parts are kept at rest and pressure kept up. To remove the bandage, place the limb in warm water, when the hardened mixture is melted and the bandage can be unwound. The application may be renewed every second or third day, or less frequently, as occasion requires. The ulcers and parts around must be first thoroughly disinfected and then dusted with iodoform before applying the bandage.

Varicose ulcers should be treated by rest, pressure, stimulation, or blistering, before any attempt at removing the varicose veins by operation is made.

Phagedenic ulcers demand the thorough scraping away of the foul surface by a sharp spoon and the chopping over of the exposed tissues with a corrosive such as nitric acid or caustic potash ; or the tissues may be touched lightly by the actual cautery. Carbolic oil (1 to 5) is the best dressing after the ulcer is scraped and cauterised. The ulcers occur-

ring in *paralytic* patients are treated for the most part after the manner of bed-sores.

Perforating ulcer of the foot requires to be completely eradicated ; the fistulous opening, the sinus leading down to the bone, and the carious surface of the bone itself must be cut or scraped away and the cavity packed with gauze.

The treatment of *syphilitic, lupoid, rodent, scorbutic, endothelial, and mucous* ulcerations is described in the articles devoted to these special subjects.

Bed-sore.—SYNON. : Fr. *Décubitus* ; Ger. *Decubitus* ; *Wundliegen*.

DEFINITION.—A form of ulcer caused by continued pressure, consequent on maintenance of the recumbent position.

ETIOLOGY.—Bed-sores are dependent either on a low condition of the nutrition of the tissues of the patient, on bad nursing, or on a combination of the two. In patients suffering from fractured spine, especially if the spinal cord be torn ; in those paralysed from other causes ; in cases of fractures of the lower extremity ; in angular curvature of the spine ; in patients suffering from hip-joint diseases ; in the acute specific fevers ; and in the aged—in fact, in any disease or condition necessitating long confinement to bed and rest in one position—bed-sores may be developed. When, in addition to the illness, the nursing is badly conducted, as shown by urine, pus, blood, or any discharge whatever being allowed to remain on the bedding on which the patient lies, a strong determining cause is set up, which will in all probability originate a bed-sore. Other strongly predisposing causes are the use of a feather-bed, and the presence of a blanket between the mattress and the under-sheet, into which the perspiration from the patient's body soaks, causing the blanket to act like a poultice. Hence it will be seen that paralysis and an enfeebled state of the circulation, combined with pressure and inattention to strict rules of cleanliness, are the main elements in the production of a bed-sore.

The various sites on which bed-sores form are arranged here in the order of frequency with which they are met—the sacrum, the heel, the buttocks, over the trochanters, between the shoulders, on the middle of the back from the shoulders to the sacrum, on the malleoli, on the elbows, and on the calf of the leg. On the heel, the usual cause is the pressure of a splint ; on the elbow, bed-sores frequently supervene in such cases as hip-joint disease, owing to the tendency patients have to support themselves on one or both elbows.

PATHOLOGY.—A bed-sore is only one of the many forms of the evil results of pressure. The passage of blood through a part where pressure is great becomes mechanically difficult. Exudation from the blood-vessels takes place, causing the cuticle to be first raised, and then to peel off ; finally a moist catarrhal surface results. Complete stagnation of the blood in the blood-vessels may occur, and as a consequence part of the skin may become practically dead. In the surrounding parts the blood-vessels become engorged ; and, the presence of the slough acting as a foreign body, the irritation causes inflammation, and an exudation of inflammatory products occurs between the living and dead parts. This takes place all around and beneath the slough, but is first apparent as a furrow in the skin. This furrow gets gradually deeper and deeper, and, the process of separation extending

beneath the slough, it becomes detached and finally thrown off. An ulcerating surface now results, the further history of which will vary with the patient's health, and according as the illness, which renders confinement to bed necessary, is of a curable or an incurable nature.

SYMPTOMS.—The premonitory symptoms of bed-sore may be either subjective or objective. Subjectively the patient complains that the bed feels hard, that there is a crease in the sheet, that there are crumbs of bread or salt in the bed; along with these generally imaginary troubles, a pricking, numbing sensation is felt at the point of pressure; but, on examination of the part complained of, no change may be apparent. Or, again, the complaints may be *nil*, as in the paralysed, and yet the effects of pressure may be far advanced. The objective symptoms may here be the first indications of the effects of pressure. These are—alteration in the colour of the skin, a roughening of the cuticle, and a variable amount of pain on pressure with the finger. Any of these is sufficient indication that preventive measures must be immediately undertaken, otherwise a bed-sore will develop. As the symptoms advance, the discolouration becomes deeper, passing from red to livid red, from purple to black. The pain, except in the paralysed, becomes for a time severe, and then finally disappears, as all nervous connections are severed. The circulation through the part being completely stayed, a dark slough is formed, and a line of demarcation between the living and dead tissue is set up. A foul discharge runs from the part, the tissues around become red and congested, the edges are undermined, and a feeble attempt is made to throw off the central slough. Should the slough be thrown off, the muscles, fasciæ, and even the bone of the damaged part may be exposed. The general symptoms associated with bed-sores are chiefly those of the disease in the course of which this complication has supervened. In some instances a form of pyrexia may, however, be induced by the discharging ulcer itself—a condition which constitutes one form of 'bed-fever.'

PROGRESS AND PROGNOSIS.—Should the patient recover from the illness for which confinement to bed had become necessary, the bed-sore will in all probability heal. Bed-sores, however, can scarcely be healed in those patients whose maladies do not subside, or in whom recovery does not take place. At times pyæmia supervenes; or the exhaustion, consequent on a long-continued and profuse discharge from the sore, proves too great a drain on the patient; or ulceration into the spinal canal may rarely occur and set up meningitis. The prognosis in regard to bed-sores developing in any individual case will depend on the disease, the age of the patient, and the care taken in nursing. The patients in whom a bad prognosis might be given, in regard to the appearance of a bed-sore, would be the old and the partially paralysed, especially when bad nursing is superadded.

TREATMENT.—It is necessary to consider this subject under the heads of (1) the *preventive measures*; (2) the treatment *when abrasions have taken place*; and (3) the treatment or cure of the *sore when formed*.

1. The *preventive measures* have, in paralysed patients and in patients suffering from chronic illness or incontinence of urine, to be commenced at the beginning of the illness, and signs of changes in

the skin are not to be waited for. The part must be thoroughly cleaned, the circulation stimulated, the skin hardened, and pressure removed from the parts where it is greatest. The best means by which to gain these ends are as follows: First, the part is to be washed with soap and water, and then thoroughly dried. Secondly, a piece of cotton wool dipped in spirits of wine, eau-de-Cologne, or brandy, must be applied to the part with gentle rubbing, until it has become thoroughly dry; and this process must be repeated three or four times at each dressing. Thirdly, to keep the skin supple, a very small quantity of oxide-of-zinc ointment or simple ointment must be rubbed into the part, until all greasy feel has disappeared. Fourthly, a draw-sheet must be placed beneath the patient, and boric-acid powder sprinkled on the part on which the patient is to lie; the sheet must be changed the moment it becomes wet, whether from urine, blood, pus, or sweat. Pressure must be removed by frequent changes of position, and by suitable pads, air-cushions, water-pillows, or water-beds. The part where the edges of the cushion press is to be treated by the same preventive measures, and to be dressed two or three times a day. Lastly, it is necessary to avoid a feather-bed, and a blanket beneath the under-sheet. In many cases bed-sores are caused by careless nursing, but in others the best nursing possible cannot prevent badly nourished tissues from falling into decay.

2. When *abrasion* or roughening of the cuticle occurs, the same precautions in regard to pressure, moisture, and the use of the draw-sheet have to be observed; and in addition some specific applications are used. Sometimes the part is greased over with zinc-ointment or vaseline; this is useful in certain cases, preventing urine or other irritating fluid from touching the tender parts. At other times collodion or flexible collodion may be used. The best fluid application is rectified spirit, or camphorated spirit, with one-third water; it is necessary to add water, owing to the pain caused by pure spirit. The surface may also be mopped over with a solution of two grains of perchloride of mercury in one ounce of spirit, or with a lotion consisting of five grains of nitrate of silver to an ounce of water.

3. The treatment of the *bed-sore itself* consists in keeping the part sweet; in aiding the removal of the slough; in applying some one of the many stimulant and antiseptic lotions in use; and in preventing the neighbouring tissues from breaking down. To clean the parts, and hasten the removal of the slough, apply a compress of wet salicylic or boric-acid wool. When the discharge is foul, the part should be washed with perchloride-of-mercury lotion (1-2000) between each application of the compress.

An excellent dressing is the Balsam of Peru, both before and after the slough has separated.

When the slough is large, wet applications should not be applied, as the moisture only favours putrefaction. To prevent this, dry the sloughing surface with absorbent wool; dust it over with iodoform, or boric-acid powder; place a piece of oiled silk or 'protective' exactly over the slough; cover the whole with dry cyanide gauze or boric wool. All dressings should be fixed by strips of plaster, and not by a bandage, owing to the heat and moisture engendered by use of the latter.

The neighbouring tissues must be treated with the preventive measures already mentioned.

When the slough has separated, an attempt is to be made to heal the part by improving the patient's general health, provided the existing malady permits. The usual precautions have to be taken with the surrounding parts; and the ulcer treated by one of the methods recommended under the head of Chronic Ulcers.

JAMES CANTLIE.

UNCONSCIOUSNESS.—See CONSCIOUSNESS, Disorders of.

UNDERCLIFF, on the South Coast of the Isle of Wight.—Extends from Bonchurch to Niton. A mild, tonic climate. See VENTNOR; and CLIMATE, Treatment of Disease by.

UNILATERAL HYPERIDROSIS.—Excessive perspiration on one half of the body occurs more or less habitually, or only after exercise. It may be limited to one side of the face and head, or the neck and arm may be included; or it may implicate the whole of one half of the body. It has sometimes, and especially when limited to the face and neck, seemed to be one of the symptoms due to paralysis of the cervical sympathetic nerve. In other cases no such relation has been ascertained to exist. It has been met with principally in association with various nervous diseases, such as hemicrania, diabetes mellitus, locomotor ataxy, dementia paralytica, and Graves's disease.

TREATMENT.—In the absence of definite information as to the pathology of this affection, it is not possible to indicate any rational principles or treatment. Empirically some of the remedies used for checking perspiration, such as zinc, belladonna, and quinine, may be tried, in combination with nerve tonics, such as arsenic and strychnine. See SUDORIPAROUS GLANDS, Disorders of.

H. CHARLTON BASTIAN.

URÆMIA.—SYNON.: Fr. *Urémie*; Ger. *Urämie*. **DEFINITION.**—This term is applied to a group of symptoms, acute or chronic, which may arise when the secretion of urine is gravely interfered with in the course of acute or chronic Bright's disease, and in other maladies.

ÆTIOLOGY AND PATHOLOGY.—Uræmia occurs when there is interference with the secretion or discharge of urine; hence it is met with in all the forms of Bright's disease, in cystic, tubercular, and cancerous disease of the kidney, in suppurative nephritis, and in suppression of urine (anuria), whether of obstructive or of non-obstructive origin; in hysterical suppression, however, uræmic symptoms are generally absent. Although uræmia depends upon the accumulation within the body of poisonous products that should be eliminated by the kidneys, the immediate cause is not easy to determine. Without apparent alteration in general health, uræmic symptoms may suddenly develop. Sometimes, however, an increase in the toxic co-efficient may be attributed to conditions which provoke additional engorgement of the renal vessels, such as indulgence in alcohol or exposure to cold; the albuminuria of pregnancy may be associated with uræmic symptoms, though some women who suffer from Bright's disease may pass through pregnancy without any uræmic manifestations.

Various explanations of the uræmic process have been suggested, and it is generally admitted that it depends upon some interference with the eliminative

work of the kidney, by which some urinary constituent is retained within the system, and either exerts its influence directly or after undergoing some chemical change. The suggested explanations may be divided into (1) *Mechanical*; (2) *Chemical*.

1. *Mechanical.*—Owen Rees noted wateriness of the brain in many cases of uræmia, while Traube laid stress upon anæmia of the brain induced by œdema, which in turn he attributed to marked hydræmia and increased arterial pressure; he thought coma would ensue when the whole cerebrum was thus affected, while convulsions would occur when the middle lobes were mainly involved. Traube's theory is favoured by (1) the frequency of cardiac hypertrophy and of hydræmia in uræmia; (2) the production of coma and spasms in dogs by the injection of water into the carotid after ligation of the ureters and of one of the jugular veins. Although supported by numerous experiments, Traube's theory is not wholly satisfactory, since in clinical work cardiac hypertrophy and hydræmia are not always accompaniments of uræmia, while *post-mortem* examination frequently fails to demonstrate œdema of the brain, and even when present œdema may be a result of the convulsions, and not the cause. Still, in a modified form Traube's explanation has found several adherents. Leichtenstern and Rühle suggest modifications which link together the mechanical and the chemical theories; the former holds that in scarlet fever inflammatory œdematous conditions of the brain and its meninges co-operate with the action of some result of infection, while Rühle believes the attacks to depend upon the admixture with the dropsical fluid of a toxic substance formed in the blood.

2. *Chemical.*—One of the earliest theories of uræmia referred the process to the non-elimination of urea, its circulation in the blood, and its deposition in various parts of the body. This theory is favoured by the fact that when the excretion has been experimentally arrested by ligation of the renal arteries or of the ureters, or by extirpation of the kidney, many of the ordinary symptoms, such as drowsiness, convulsions, vomiting, and diarrhoea, are produced. The acceptance of this theory on the other hand is difficult, since frequently there may be no symptoms of uræmia, though large quantities of urea may be detected in the blood; moreover, urea administered by the mouth provokes diuresis instead of producing toxic effects. Frerichs thought uræmic symptoms might result from the transformation of urea into ammonium carbonate under the influence of a ferment. Treitz considered that this change occurred in the alimentary canal rather than in the blood. Others have thought that urochrome might be decomposed in the circulation, or have attributed toxic action to creatin, creatinin, or other extractives. Feltz and Ritter maintain that uræmia is due to potassium-salts, while Bouchard suggests that, in addition, certain organic metabolic products of the nature of ptomaines may be developed; it must be admitted, however, that these various products have not been isolated, and that their existence is purely hypothetical. The influence of the failure of the internal secretion of the kidneys is as yet unknown. At present it is impossible to accept any single theory of explanation; probably numerous causes contribute to the result, and their individual importance is not always the same, otherwise it

would be impossible to account for the different types of uræmia. In short, although the term 'uræmia' is convenient, it is possible that it includes several allied conditions whose causation is not identical.

SYMPTOMS.—The symptoms which result from auto-intoxication through deficient renal action are extremely diverse; many are to be attributed to changes in the nervous system; these may be manifested through the sensory system, the motor system, or through modifications of the other cerebral functions. A gastro-intestinal type has also been recognised, though in these cases the symptoms are probably due to eliminatory efforts rather than to nervous influence. Changes in respiratory functions may be due to both causes, although nerve-influence usually predominates.

It is convenient to divide uræmic symptoms into two classes, *acute* and *chronic*.

1. *Acute uræmia.*—This includes all varieties in which the symptoms are suddenly developed. The onset may be marked by convulsive seizures or by coma: these occur without warning, or they may be preceded for a few hours or days by premonitory symptoms, such as severe headache, apathy, drowsiness, and vertigo; nausea or vomiting may occur; more rarely there may be severe dyspnoea, pains in the extremities, spasmodic contraction of the muscles of the face or of one of the limbs. Charcot also mentions tremors of the extremities among premonitory symptoms.

Uræmic convulsions are of an epileptiform type, and range from slight passing contractions to violent spasms affecting the whole of the body. During the convulsions the temperature is usually subnormal; in exceptional cases, however, the fall of temperature for a short time is preceded by a sudden elevation to 105° F. or higher. The clonic spasms are of short duration, and, as they gradually cease, the patient passes into a drowsy or comatose condition; from this he may awake as out of profound sleep. In unfavourable cases fresh convulsions may occur, and in the intervals between the attacks, the coma become more profound. Death sometimes occurs at the height of the paroxysm or during the coma.

The convulsions may be unilateral, and they may be followed by tonic spasm of tetanic type. Frequently during the convulsion and the subsequent coma there is noisy, hissing dyspnoea, which is not attributable to laryngeal or pulmonary obstruction.

In another type of acute uræmia, after similar premonitory symptoms or without warning, coma is rapidly developed without any preceding convulsions. The coma may rapidly deepen, and death ensue within a few hours; or the patient may rally and all urgency may pass away; ordinarily, however, further uræmic symptoms may be expected. Occasionally, without convulsions or coma, delirium of a restless or active nature may supervene.

Any type, but especially the convulsive, may be followed by transient hemiplegia, hemianæsthesia, and aphasia; but, even when the face is affected, ptosis is exceptional. Bilateral amaurosis is frequent; this may be partial or complete; it is not accompanied by any obvious retinal changes, and sight is ordinarily recovered in from 24 to 36 hours. Complete or partial deafness and tinnitus have rarely been noted. After acute uræmia there is occasionally marked lethargy, a long pause preceding the answer to a question.

2. *Chronic uræmia.*—In this the cerebral symptoms are less striking, and disturbances of respiration and digestion are more frequent, though they may be due to cerebral toxic influences.

The cerebral symptoms consist of frontal or occipital headache, usually dull and persistent, but sometimes acute and paroxysmal. The headache is often associated with lethargy and slow, indistinct articulation, sometimes with dimness of sight and ringing in the ears. Frequently there is severe insomnia, though there may be drowsiness during the day. Giddiness, languor, and inertia increase, and may eventually lead to coma, delirium, or convulsive seizures like those of acute uræmia. Definite psychical disturbances, with hallucinations and insomnia, may mark exacerbations of the primary disease. Neuralgic pains and pruritus are also to be mentioned.

Uræmic dyspnoea is frequent, especially when the primary disease results from alcoholism; sometimes the attacks occur at night only, like those of spasmodic asthma. In advanced cases similar difficulty of breathing may be due to gradual circulatory failure, with pulmonary engorgement or effusion into the pleural cavity. Persistent hic-cough and Cheyne-Stokes respiration are not uncommon shortly before death.

Disturbances of the functions of the alimentary canal are extremely common. These may range from chronic dyspeptic troubles to severe vomiting and diarrhoea. Sometimes these symptoms are associated with definite lesions, but frequently they appear to result from central irritation. Vomiting and diarrhoea are often terminal symptoms of chronic Bright's disease.

Erythematous, papular, and vesicular rashes, often associated with desquamation, are sometimes associated with uræmia, while epistaxis, intestinal and cutaneous hæmorrhages occasionally occur.

DIAGNOSIS.—No great difficulty is experienced when the previous history is known or when there is definite evidence of Bright's disease in alterations of the urine, in the character of the heart and the pulse, or in the presence of general dropsy. Outward displacement of the apex-beat, accentuation of the cardiac sounds, high tension of the pulse, and albuminous urine afford indications of great diagnostic value.

In acute uræmia the nature of the convulsions and coma should be considered; the former may be mistaken for hysterical or epileptic seizures, while the latter resembles alcoholism, opium-poisoning, diabetic coma, and cerebral hæmorrhage into the pons. Hemiplegic and paralytic conditions are more frequent with cerebral hæmorrhage, which may be associated with chronic forms of Bright's disease; they may sometimes be distinguished by their greater duration. An ammoniacal odour of the breath may aid the diagnosis of uræmia, but for this purpose the temperature is of very little value; it may occasionally be high with the onset of acute uræmia, and is generally normal or subnormal at the onset of apoplexy. Uræmic coma in its early phases is rarely so deep as that of cerebral hæmorrhage; the patient may be momentarily roused to answer questions; and the hissing dyspnoea of the former differs greatly from the stertorous breathing of the latter. In opium-poisoning the pupils are contracted; in uræmia their condition may vary, and they usually respond to stimulation.

The diagnosis of chronic uræmia must frequently be based upon the results of treatment, as well as upon consideration of the state of the urine and the consecutive changes in the circulatory system. Dyspeptic symptoms and vomiting may be ascribed to uræmia when they persist in spite of treatment, when there are definite indications of chronic renal trouble, and when there are no physical signs pointing to malignant disease; the examination of the vomit and the detection of urea, or the recognition of alterations in the proportion of free acid, will afford material help.

PROGNOSIS.—Uræmic symptoms necessitate a grave prognosis. With acute uræmia death may occur in rare cases during the first attack, but the danger is greater when attacks are repeated at short intervals and the coma deepens. In acute nephritis the prognosis is more favourable when consciousness is rapidly regained and when the urine shows signs of improved eliminative work.

Some of the symptoms of chronic uræmia, such as rigidity, headache, and insomnia, are of prognostic significance as indications of progressive stages of a chronic disease, but their gravity is greatly increased when they are accompanied by a reduction in the urine, and by the development of lethargy and coma. Uræmic dyspnoea, persistent vomiting and diarrhoea, add largely to the immediate danger, while prolonged stupor, coma, or convulsions in chronic nephritis are of fatal import. Puerperal cases, although involving great immediate danger, are more fatal when they precede delivery; the prognosis is influenced by the number of seizures, their duration, and the degree of coma between the attacks.

TREATMENT.—In acute uræmia the first indication is to provide for the elimination of nitrogenous waste pending the re-establishment of the work of the kidneys. This may be effected by diaphoretics and purgatives. Warm baths, warm packs, or vapour-baths may be of great service in acute uræmia associated with dropsy. Dry cupping, leeching, or poulticing over the loins may give relief. In acute cases the removal of eight or ten ounces of blood by venesection and the injection of saline solution have been beneficial. Hydragogue purgatives favour elimination; compound jalap powder or jalap and scammony may be given when consciousness is retained, but when coma is profound croton oil may be administered. To promote diaphoresis the subcutaneous injection of nitrate of pilocarpine has been advocated; it is now very rarely employed, as it causes much distress and may seriously embarrass respiration. When there are no indications of active engorgement of the renal vessels diuretics are frequently of service, especially in chronic uræmia. Digitalis is useful as a diuretic and also for its influence upon the heart in chronic nephritis. When convulsions are severe chloroform may be employed, or bromides may be administered; the subcutaneous injection of morphine has also been advocated, but, although of service in some cases, it is generally considered to increase the risks of further convulsions; the rectal injection of chloral hydrate is preferable, unless contraindicated by the condition of the heart. Milk should be given freely, and in acute uræmia it should constitute the sole diet. Inhalations of oxygen often relieve spasmodic dyspnoea, while nitroglycerin, amyl nitrite, and other nitrites may control the severe headache, though sometimes

antipyrine and phenacetin are preferred. The diarrhoea of chronic uræmia should not be checked unless sufficiently profuse to be exhausting; efforts should, however, be made to control vomiting by iced drinks, by sucking fragments of ice, or by the use of bismuth and hydrocyanic acid. When convulsions occur during pregnancy, labour should be induced.

NESTOR TIRARD.

URETERS, Diseases of.—**SYNON.** : **FR.** *Maladies des Uretères*; **GER.** *Krankheiten der Harnleiter*.—Morbid conditions of the ureters are so generally parts of, or associated with, diseases of the bladder or kidney, and so naturally come to be described in the articles treating of these several diseases, that a separate account or distinct classification of them is perhaps scarcely called for; and a brief description of the most important will be sufficient for all practical purposes.

1. **Congenital Malformations.**—A double ureter is the most frequent malformation, the division sometimes reaching as far as the bladder. In very rare cases a triple ureter has been found. Congenital malformations leading to more or less complete obstruction of the ureter are found most often near the pelvis of the kidney. If the obstruction is complete, it gives rise to hydronephrosis (*see* **HYDRONEPHROSIS**). If incomplete, a slighter degree of the same condition results, the pelvis and calyces becoming dilated, and the kidney-substance atrophied and indurated. The chief congenital obstructions are—(1) Total obliteration of the ureter as it leaves the pelvis. (2) Valvular opening from the pelvis into the ureter. This becomes gradually more complete as the dilatation of the pelvis increases. (3) A spiral arrangement of the ureter. (4) An abnormal renal artery pressing on the ureter as it leaves the pelvis. The incomplete obstructions frequently give way at intervals, when there will be a copious flow of urine, usually of low specific gravity and pale colour.

2. **Acquired Obstruction.**—*Complete* obstructions which are not congenital may arise : First, from impaction of a renal calculus; this may take place at any point, the most frequent being at the brim of the pelvis or the vesical orifice. Secondly, from external pressure, as from uterine cancer, pelvic tumours, fibrous bands, enlarged glands, or fecal accumulations, in which case the condition would at first be incomplete. *Incomplete* obstruction arises most frequently from impediments to the discharge of urine, existing in the prostate or urethra. In the former case, the bladder being in a state of constant over-distension, the valved opening of the ureter is closed with unnatural force. In the latter the hypertrophy of the bladder increases the length of the portion of ureter lying in the bladder-walls, and the bundles of muscular fibres more or less constrict the orifice. Any cause giving rise to hypertrophy of the bladder will therefore tend to obstruct the orifice of the ureter, as is seen in chronic cystitis, stone in the bladder, and other conditions. The opening is still further narrowed by swelling of the mucous membrane, the result of subacute or chronic inflammation. Occasionally the orifice may be partially obliterated by a villous growth in the bladder. *Stricture* of the ureter is found in rare cases, apparently the result of previous inflammation and ulceration. Slight obstruction may occur during pregnancy, from the pressure of the gravid uterus.

3. **Dilatation.**—The part of the ureter above any obstruction is always found more or less dilated, according to the degree and the duration of the impediment. If the condition be acute and complete, little or no hypertrophy of the coats of the ureter will be found; but if chronic and incomplete, its walls will be thickened, both by fibroid change and by hypertrophy of the muscular coat. The dilated ureter is always tortuous, being increased in length as well as in diameter, and may even resemble a portion of small gut. The mucous membrane is always opaque and somewhat thickened, occasionally red and injected, and frequently pigmented from previous attacks of inflammation. A largely dilated ureter may sometimes be felt through the abdominal wall. There will probably be some degree of pain or uneasiness in the course of the canal or in the loin, and a tendency to sickness.

4. **Inflammation.**—Simple inflammation of the ureter is frequently found, as an extension either from the bladder or from the pelvis of the kidney. Septic inflammation accompanies septic pyelitis, due to extension of decomposition from the bladder to the pelvis of the kidney (see p. 823). Tubercular inflammation almost invariably accompanies a similar condition of the bladder or kidney.

5. **Malignant Disease.**—Cancer may extend from neighbouring organs into the ureter, but there is no reason to believe it ever primarily takes origin there.

Neither the diagnosis nor the treatment of an affection of the ureter can be separated from that of the disease to which it is secondary.

MARCUS BECK.

H. MONTAGUE MURRAY.

URETHRA, Clinical Examination of. —

Examination of the male urethra can be effected: (1) by the use of bougies, both metallic and elastic; (2) by the electric air-inflation urethroscope.

The former method is principally adapted for the detection of strictures, both traumatic and inflammatory in their origin, the latter to the diagnosis and treatment of the cause of stricture, which in the majority of cases is chronic gonorrhœal inflammation.

In the detection of strictures by bougies it is well always to commence with the passage of a large instrument. The author advises the use of an acorn-shaped head on a slender shaft, which goes by the name of Otis's exploratory bougie, the metal being preferable to the gum-elastic. By these instruments much greater accuracy in location of stricture may be obtained than by the use of the ordinary bougie, whether of steel or gum-elastic—which instruments are better reserved for treatment. When the exploratory bougie approaches the face of the stricture its passage is arrested. A smaller instrument is chosen again and again until the size that can be passed is reached. In many cases this instrument will pass into the bladder. In a certain proportion it will be arrested by a tighter stricture at a greater distance from the meatus. Smaller instruments again are taken, and the manœuvre repeated. But possibly the smallest 'explorer' (or exploratory bougie) will not pass, when we shall have to fall back on some form of filiform bougie with which to gauge the calibre of the stricture. One of the objects in taking a large instrument to commence with is that the presence of strictures of large calibre, through which a smaller

bougie would slip readily, may be detected. In connection with the use of both rigid and pliable bougies, attention must be drawn to the fact that in sensitive urethræ a spasm of the compressor muscle is frequently induced. So tightly does this muscle close the canal, that in many text-books will be found a description of a condition known as 'spasmodic stricture.' A diagnosis of stricture has often been made quite erroneously from this cause. The injection of a solution of cocaine in such cases by an urethral syringe will be followed by the easy passage of the instrument through what appeared at first sight an impassable stricture.

Considerable assistance is afforded in the examination of the urethra by digital palpation. Thickened and hardened portions of the penile urethra can be detected, and by a finger in the rectum a certain amount of knowledge can be gained as to the condition of the membranous and prostatic portions of the canal. In the case of a chronic gleet, where it is desirable to locate the portion of the canal most affected the following simple manœuvre is often of service:—

The patient is desired to hold his urine as long as possible, preferably to come to the surgeon after a night's rest without passing water. The anterior urethra is then washed out with boiled water into a 12-ounce conical specimen-glass. (It must be premised that for clinical purposes the male urethra may be divided into two portions—the anterior stretching from the external meatus to the compressor urethræ or 'cut-off' muscle, the posterior from this muscle to the internal meatus.) For this purpose a 6-ounce syringe of glass, vulcanite, or metal, with a conical and detachable nozzle, may be used; a shield attached to the syringe to prevent loss of the liquid as it spurts from the meatus is advisable. An ordinary brass or large glass dressing-syringe will serve all practical purposes, or an irrigator-tank may be used, fitted with a suitable nozzle and stop-cock. With the latter apparatus care must be taken not to hang the tank at too great a height, or the compressor will be forced and our object defeated. The anterior urethra having been washed out, the patient is directed to pass urine into a second glass, and, according as the first or second specimen contains the threads and particles of inspissated mucus, we know roughly the portion of the canal most affected.

Examination by the Urethroscope.—There are several forms of urethroscope in use, but perhaps

FIG. 1.

the most convenient and serviceable is that known as the Schall urethroscope (fig. 1). In this instrument the light is furnished by an incandescent lamp fixed in a metal holder (A). The lamp casts its light

upwards into a hood (B), which contains an arrangement of prisms by which the beam of light is rendered horizontal and projected towards (C) a glass window closing the short barrel (D), on which fits the cannula E. The tube (F) fitted with a stop-cock is connected to the rubber tube of an air-inflation bag. The light-carrier (A) moves easily in the larger chamber (G), and on its upward or downward movement the focussing of the light depends. When the light is focussed the carrier is fixed by the screw (H). The current is carried to the lamp by an ordinary insulated wire, terminating in a plug which fits into the carrier at (K), the current being made or broken by the turning of the screw (I). The urethra should first be anaesthetised by the injection of a 2-5-per-cent. solution of cocaine, or if preferred β -eucaine may be used. If the anterior urethra only is to be examined, an ordinary urethral syringe is sufficient to inject the solution, the nozzle being inserted just within the meatus. If, however, it is desirable to examine the deep urethra with the light, it is necessary to pass a catheter, or, better, a Guyon's tube (fig. 2), through the compressor, and to inject behind that muscle. The cannula should then be passed, no force being used, and if, as is often the case, the meatus is too small to take a full-sized tube, thorough dilatation or a cut with a

as we proceed. The normal urethra varies considerably in appearance, according as it is distended with air or in a flaccid condition. If the latter, the mucous membrane is of much the same colour as the healthy palpebral conjunctiva, and is folded in a radiating manner at the end of the tube. But when distended it is a more or less cylindrical tube that we see stretching away to the point where the urethra curves, the walls glistening, whitish, or pale pink in colour, and where much distension is employed the circular muscular fibres stand out in the form of white rings, and might be mistaken for stricture. Some of the openings of Littre's glands may be seen as shallow depressions, and on the floor, just in front of the compressor, are the openings of Cowper's ducts, generally invisible. The compressor shuts off the deep urethra from view, occasionally opening a little to allow the passage of air if the pressure is increased.

In the examination of the membrano-prostatic urethra a cannula with a slight elbow-bend like a *coudé* catheter, and open on the floor, or a straight tube of rather smaller size than those described, may be used. In this case air-distension is not available, as the air would simply pass into the bladder. In the centre of the urethral floor is seen the verumontanum with the sinus pocularis, on either side of

FIG. 2.

FIG. 3.

hystoury will give room. The largest tube that will pass without force is the best to use, for the larger the tube the better is the illumination. No. 24 or No. 26 (French gauge) cannulae, open at the end (figs. 3 and 4), are useful sizes, and the adult urethra will usually take the larger size easily, except sometimes at the meatus. The urethroscope is then fitted on to the end of the cannula and the light

which is the opening of the vas deferens; here the mucous membrane is of a much deeper colour than in the anterior urethra.

F. SWINFORD EDWARDS.

URETHRA, Diseases of.—SYNON. : Fr. *Maladies de l'Urèthre*; Ger. *Krankheiten der Harnröhre*.—The affections of this canal comprise urethritis with its various consequences, such as gleet, warts, periurethral abscess, inflamed follicles, and stricture; syphilis and soft chancre may also affect the urethra. For descriptions of most of these affections the reader is referred to the articles GONORRHOEA; GLEET; SYPHILIS; and VENEREAL SORE. Some forms of (1) Urethritis, (2) Neuralgia, (3) Congestion and Spasm, (4) Organic Stricture, and (5) Foreign Bodies, remain for consideration here.

1. Urethritis.—The origin of urethritis is not exclusively due to inoculation with gonorrhoeal pus, a fact of great medico-legal importance. Inflammation of the urethra, usually running a less severe course than the gonorrhoeal form, may be set up by leucorrhoeal, menstrual, and other discharges from the vagina, or result from the use of an injection which a patient may have used in the hope of warding off venereal disease, which he dreads having contracted. Traumatic irritation of the

FIG. 4.

turned on. The excess of cocaine-solution must be removed with cotton-wool on a fine sponge-holder. The window (c in fig. 1) is then closed and air admitted by turning the tap (at F, fig. 1).

The examination of the anterior urethra should first be undertaken. The cannula should be introduced only just within the meatus, and the air then turned on. By this means the urethra is inflated as far as the compressor, and the tube can be easily passed down, the state of the walls being examined

urethra may be excited by the passage of instruments or a calculus, or by the introduction of foreign bodies by the patient; in such cases soreness and scalding attend the first subsequent micturition, and swelling and discharge follow within twenty-four hours.

Asparagus, beer, arsenic, and other substances, have the power of producing urethritis in some persons; highly acid urine and oxaluria may also occasion slight urethral irritation. A very mild form of urethritis is an occasional concomitant of early syphilis; it is, however, always very limited in extent, and subsides spontaneously. In gouty urethritis the inflammation may be as severe as in well-marked gonorrhœa, and attended by the complications met with in that disease, and affecting the testes, bladder, eye, or joints. The leading distinctions of gouty urethritis are the milkiness of the discharge, and the absence or small amount of swelling of the fore part of the urethra; while scalding in the perineum and irritability of the bladder are severe and prominent symptoms.

Tuberculosis sometimes affects the urethral passage. It is always a very indolent affection, being due to the slow degeneration and ulceration of tubercular deposits in the deeper portions of the canal, and usually associated with similar disease in the prostate or bladder.

In such cases the irritability and inflammation of the bladder are always more urgent than the urethritis, while the evidence of tubercular disease in other parts of the body is usually sufficient for diagnosis. The treatment of urethritis arising from any of these causes necessarily varies in detail with such cause. The local treatment is similar to that for gonorrhœa, and is described in the article dealing with that subject.

2. Neuralgia. Pain in the Urethra.—The cause of pain in the urethra may be found in some diseased condition of the tube; or it may be independent of any local morbid action. Gouty irritation is a frequent cause, and a nervous condition produced by prolonged debauchery of various kinds is not uncommon. The gouty state is relieved by the treatment of the diathesis; the nervous irritation by suitable general treatment, to which may be added local applications which have the effect of dulling the sensibility of the urethra, such as the passage of sounds, and the use of astringent or (in obstinate cases) of caustic injections to the deeper portions of the urethra. In some cases instrumentation of the urethra excites severe pain; this is best avoided by first injecting about thirty minims of a 10-per-cent. solution of cocaine. Oxaluria and a highly acid state of the urine may sometimes produce considerable smarting at the time of micturition; the exhibition of alkalis and suitable dietary will usually suffice to relieve this, which is often a source of considerable annoyance to the patient.

3. Congestion and Spasm of the urethra are sometimes incorrectly described as congestive or spasmodic stricture; incorrectly, for although complete retention may arise from these conditions, which are due to transient causes, the effects are temporary only, and involve no permanent lesion.

Congestion and swelling of the urethral mucous membrane, with proportionate narrowing of the passage, accompany all forms of urethritis, and may also result from any cause of mechanical irritation, from exposure to cold, sexual or alcoholic excess, riding, bicycling, and the like. Simple congestion

rarely calls for much attention, provided there be no other abnormal condition present, but in cases of organic stricture or of prostatic enlargement the advent of congestion may lead to complete retention. Under such circumstances a soft indiarubber catheter should be passed, if possible; but if this cannot be accomplished, the patient should be placed in a hot bath and a morphine or belladonna-and-camphor suppository should be prescribed. The bowels must be acted on by saline aperients and complete rest enjoined. The congestion usually rapidly subsides, and the patient must then be warned of the circumstances likely to lead to its reappearance.

Spasm of the muscular fibres surrounding the urethra, and of the deep perineal muscles, may accompany or be independent of congestion of the mucous membrane. It is induced by any cause of mechanical irritation, and occurs in cases of stricture of any part of the canal, especially if a rude attempt be made to pass an instrument. Spasm also sometimes results from irritation about or operations on the rectum. A highly acid state of the urine may induce spasm of a painful nature. The treatment is practically that indicated for congestion; if spasm is sufficient to arrest the onward passage of an instrument, it usually may be overcome by steady gentle pressure for a few moments, but the instrument must never be forcibly pushed onwards; chloroform is occasionally, though rarely, necessary.

4. Organic Stricture.—The average distensile capacity of the urethra reaches a diameter of ten, or a circumference of thirty, millimetres. This measurement varies in different portions, being widest behind the triangular ligament (the anterior layer of the deep perinæal fascia), slightly less in the bulbous portion, and least of all at the meatus. The meatus varies very much in size, between a mere pinhole and a diameter of fourteen or fifteen millimetres, the most common size being a circumference of twenty-five millimetres. In different persons the general distensile capacity of the urethra ranges between twenty and forty millimetres in circumference.

Strictures are abrupt abnormal contractions of the urethra at any given point of its course.

In the great majority of instances organic stricture is the result of long-continued inflammation following gonorrhœa, leading to exudation into the sub-mucous tissue. This exudate subsequently organises into a low form of fibrous cicatricial tissue, the contraction of which leads to the permanent narrowing. A similar result may also follow on injury of the urethra (*traumatic stricture*), and is then more severe, the new tissue being very dense. The cicatrix left by the healing of a urethral chancre may likewise cause stricture. Congenital narrowing of the meatus is common, and congenital strictures are sometimes met with within the second inch from the meatus.

Organic strictures may be situated at any part of the urethra except the prostatic, being most common in the first inch from the meatus.

The tightest and toughest strictures are generally found near the junction of the bulbous and membranous portions of the urethra; that is, about five inches from the meatus. The membranous portion is only affected when there is a large amount of cicatricial tissue spreading backwards from the bulb. The new fibrous tissue is developed in various

orms; thus it may be present as a membranous fold stretching across (*bridle-stricture*), or occasionally encircling (*annular stricture*) the canal. There may be only one bridle or several.

Superficial scars of healed ulcers and warts may give rise to patches of tough tissue. Indurated areas and fibroid nodules in the submucous tissue, standing forwards on the surface of the canal, cause irregular projections as well as unyielding indurated patches. These twist the course of the canal and impede the passage of bougies. In other cases, instead of being in limited patches, the indurated tissue may extend evenly along the canal for some distance, making it smooth and gristly, and diminishing its calibre.

The indurated new tissue may form only a thin layer of fibres beneath the mucous membrane, or may extend more deeply, infiltrating the whole thickness of the corpus spongiosum, or even extending beyond it into the tissues of the perinæum, rendering them dense and unyielding. The degree of narrowing of the passage depends in great measure upon the age of the stricture, being greater as time goes on; it may be temporarily increased by muscular spasm or inflammatory congestion. The canal never becomes obliterated, as the term 'impermeable stricture' would seem to imply. Strictures are always permeable to urine, but may not be so to the passage of an instrument. Strictures vary in behaviour: some yield easily to dilatation and slowly recontract; others are rigid, and can be dilated only to a small extent (*indurated strictures*). Lastly, some dilate quickly, but as quickly shrink back to their previous size (*resilient strictures*). These differences are in the main dependent on the age of the new tissue: when quite young the scar is soft and yielding, although after dilatation it may quickly recontract. In old strictures the fibrous tissue is dense, hard, and indurated.

SECONDARY EFFECTS OF ORGANIC STRICTURE. The urethra in front of a stricture may be quite healthy, but if the condition has existed for some time the mucous membrane between the meatus and narrowest contraction is often puckered and indurated, or is excoriated or ulcerated. Sometimes just in front of the stricture artificial openings are found; these are the mouths of false passages which have been made by inexpert instrumentation. False passages may, after passing outside the urethra in front of the stricture, run for some distance, ending as *cul-de-sacs*; or they may reopen into the urethra behind the stricture; less often they extend up for some distance between the bladder and rectum, or open into the latter. At the seat of stricture the mucous membrane is often roughened, puckered, and of a dull white opaque colour; behind it the urethra is dilated, pouched, pigmented, and even ulcerated; the mucous membrane may be coated with muco-pus, sometimes mixed with phosphates. The pouches, formed by distension of the follicles, may be the starting-point of perinæal abscess, which may burst into the urethra or on to the surface of the perinæum; or, lastly, may burrow upwards between the bladder and rectum and round the prostate. If a perinæal abscess bursts into the urethra and on to the surface of the perinæum, fistulous tracts are formed, which ultimately become very dense and unyielding. Such fistulae are often multiple, and may open in various situations. The bladder, ureters, and kidneys will, in neglected cases, show evidence of secondary mischief. The

changes induced are partly dependent upon the obstruction to the free flow of urine, and partly inflammatory as the result of decomposition of the retained urine. Thus the bladder-walls hypertrophy in order to overcome the obstruction; but if the compensation is inefficient, dilatation and sacculation will ensue. The ureters dilate, and the walls hypertrophy; the pelvis dilates, and the pyramids of the kidney-substance become flattened, crescentic, and subsequently wasted; the remaining renal substance is stretched and sclerosed, and the condition known as hydronephrosis results. If the urine should decompose, acute cystitis, becoming chronic, will follow, and the micro-organisms will find their way to the ureter and pelvis of the kidney, exciting pyelitis, and in severe cases acute nephritis with numerous points of suppuration—the so-called 'surgical kidney' (see p. 823). These results only occur in cases which have not been treated at all, or only imperfectly.

SYMPTOMS AND DIAGNOSIS OF ORGANIC STRICTURE.—The symptoms of organic stricture of the urethra are more evident in the case of an old and narrow stricture. Few symptoms attract observation before the stricture is well advanced. The most common and the earliest is a scanty muco-purulent discharge. This sign is, indeed, very often the indication of the chronic inflammation of limited areas of the passage which ends in stricture. When the stricture is developed the symptoms are more definite, namely, slight dribbling of urine after micturition has apparently ceased; small size of the stream, which may be forked and twisted; and gradually increasing difficulty, with straining and pain, in micturition, which is more frequent than normal. Any or all of these symptoms may be absent, even when the canal has lost as much as two-thirds of its distensibility. Usually to these troubles are added occasional attacks of complete retention of urine from temporary spasm or congestion. There may also be the signs caused by the various secondary complications.

Examination of the urethra by means of a steel sound or gum-elastic bougie will reveal the number and situation of the strictures present. The distensible capacity of the various parts of the passage can be determined by the urethrometer.

TREATMENT.—The treatment of organic stricture consists, first, in removing from the habits and diet of the patient all causes of functional disorder.

Temperance in alcoholic drinks, in stimulating or highly seasoned foods, in sexual indulgence, and in some forms of exercise, such as horse- and bicycle-riding, must be enforced. Due attention to the condition of the skin and bowels, and sufficient bodily exercise, are requisite. Although attention to these matters will not in any way remedy the existing condition of a stricture, yet they will prevent congestion and spasm, and so obviate the temporary and often dangerous aggravation of the sufferings caused by these conditions.

Locally the passage must be restored to, and maintained at, such calibre as, on the one hand, will enable the bladder to empty itself completely by each act of micturition; and, on the other, will allow a sufficient margin to prevent stoppage of the flow of urine during occasions of temporary swelling or spasm. Such an expansibility would seem for most persons to be about equal in circumference to that of No. 10 English; though in practice it is advisable to dilate somewhat further (No. 12 English)

than this, to allow sufficient margin for neglect on the part of the patient. In all organic strictures there is a tendency to contract again; hence, when sufficient expansibility has been established, it must be maintained by the frequent passage of a bougie. In most cases the patient should be taught to do this for himself.

Various methods, none of which is applicable to all cases, are employed for dilating the strictured part of the passage. Some methods, such as the use of caustics, or the cautery and forcible dilatation, have fallen into desuetude; those in modern use are (a) gradual interrupted dilatation; (b) gradual continuous dilatation; (c) internal urethrotomy; (d) external urethrotomy.

(a) *Gradual interrupted dilatation* is attained by passing metal sounds or flexible bougies (preferably the latter) through the stricture. At the first sitting that size which will just pass through the stricture should be used; subsequently larger sizes must be used, until No. 12 or 13 English can be passed. It is probable that in most, if not all, cases the stricture is partly stretched and partly torn in this method of treatment. The instruments may usually be passed at intervals of two or three days.

(b) *Gradual continuous dilatation*.—In this method a flexible catheter is passed through the stricture and tied in. As the stricture yields the instrument must be removed, and a larger one introduced from time to time, lest, being loose, the catheter escape from the urethra. A week or ten days usually suffice to dilate the stricture to the requisite dimensions. The nature of the process appears similar to that of a seton in ordinary sinuses or cellular tissue; the fibrous tissue becomes loose and succulent, and its fibres permeated by leucocytes; superficial ulceration with destruction of the cicatricial tissue also occurs in some cases.

(c) *Internal urethrotomy* is accomplished by means of a concealed knife conducted to the stricture by running in a split sound which passes through it into the bladder. As the knife is pushed on it is made to project and divide any resisting tissue met with. A full-sized catheter is then passed, and the bladder emptied. At the end of ten days instrumentation should be commenced, in order that the passage may be kept properly dilated.

(d) *External urethrotomy*.—When attacked from without, the situation of the stricture is indicated by a staff passed down to or through it. In the former case the cicatrix is divided from before backwards, and in the latter from behind forwards. Cutting from before backwards is the more common operation, since if the staff can be passed through the stricture internal urethrotomy can usually be done. If the urethra is laid open in front of the stricture the orifice must be sought for—too frequently a long and tedious process—and the contraction then slit up along a fine director which has been passed into the bladder.

Various instruments have been devised and are employed for carrying out the methods shortly described here, some more suited than others to particular cases.

Comparison of the different methods.—Gradual interrupted dilatation is applicable in a larger number of cases than is any of the other methods described. It is attended by least evil consequences, and is most effectual in strictures of recent formation situate near the bulb. Objections to this method are the rapidity with which recontraction takes place

if the passage of bougies be neglected by the patient, and the impossibility in some cases of dilating the stricture beyond a certain calibre without exciting shivering, pain, pyrexia, or even local inflammation and abscess. Epididymitis is sometimes set up by the passage of instruments. Indurated strictures are sometimes so tough and dense that they cannot be sufficiently dilated.

Gradual continuous dilatation is easy and rapid, but is liable to be followed by speedy recontraction. It is useful in cases in which it is necessary to obtain a rapid dilatation of a very narrow stricture, in consequence of advanced vesical or renal disease. In these the bladder must be given rest without delay, yet the condition of the kidneys is most unfavourable to any operation. If there is great difficulty in passing an instrument into the bladder, it is advisable, when it is passed, to tie it in. The objections to continuous dilatation are that it confines the patient to bed, and in some cases excites local irritation and constitutional fever sufficiently severe to require its abandonment.

Internal urethrotomy is applicable with best results in young patients, in whom renal changes are absent or only slight. It is also preferable for those patients who prove intolerant of interrupted or continuous dilatation, since serious disturbance rarely follows incisions made in strictures between the meatus and the bulb. The locality of stricture has much to do with deciding upon the adoption of internal division. The shallow constrictions, so-called 'bridle-strictures,' and the elastic rapidly yielding and as rapidly contracting resilient strictures, are always situate in the penile portion of the urethra, and are specially amenable to incision, while they are very little affected by the passage of bougies.

The great thickness and toughness of certain strictures of the bulb render their division the only mode of securing even moderate duration of their dilatation. The recontraction of a stricture after it has been divided would seem to follow less speedily than after it has been treated by gradual dilatation.

External urethrotomy is needed in comparatively few cases. It is advisable when the perinæum is hardened and beset with fistulae; or in those still more rare cases in which no instrument can be introduced into the bladder. Under such circumstances it is requisite to attack the stricture from the surface.

5. Foreign Bodies impacted in the Urethra.—Foreign bodies of various kinds may be introduced into the urethra, and may lodge in the canal, impeding the free flow of urine, or even arresting it, and eventually exciting inflammation and abscess. Calculi passing from the bladder may lodge behind a stricture, or close to the meatus. Portions of a bougie or catheter may be broken off in attempts to pass a stricture. *See also* p. 332.

The symptoms pointing to the presence of a foreign body are usually pronounced. There is pain, with difficulty in passing water, and perhaps complete retention; while the foreign body can usually be felt in the canal, and can be seen through the endoscopic tube.

TREATMENT.—The foreign body must be removed by means of appropriate forceps introduced through the largest-sized endoscopic tube which can be passed. If this is found to be impracticable, the urethra must be opened from without.

CHARLES STONHAM.

URIAGE, in Isère, France.—Thermal muriated sulphur-waters. See MINERAL WATERS.

URIC-ACID DIATHESIS.—SYNON.: Lithæmia, lithiasis, Lithuria; Fr. *Diathèse Urrique*.

The most definite manifestations of what has been commonly called the uric-acid diathesis are seen in gout and uric-acid gravel. It is necessary, however, to discuss under the same head the more vague conditions of lithæmia, so-called; using the term with the somewhat special meaning first attached to it by Murchison, who ascribed certain symptoms, one of which is a more or less permanent appearance of uratic deposits in the urine, to a functional derangement of the liver, with excessive production of uric acid. To this condition Murchison gave the name 'lithæmia,' and the name, with the same connotation, has of late come into fresh prominence. It is further necessary to bear in mind in dealing with this subject, that a view has also recently gained attention in which uric acid is held to play a much more comprehensive part, and to be the chief factor in a large number of apparently very diverse disturbances.

But, since the deposition which occurs in gout and gravel is, almost certainly, not due to any increased production of uric acid in metabolism, but to quite other factors, any term meant to associate these two sufficiently dissimilar ailments would better be some other than that which heads this article. Again, closer examination seems to show that the condition called lithæmia by Murchison is scarcely capable of even loose definition; and, even if we are able to recognise the existence of a symptom-group consistent with his description, there is no proof that the condition it betokens is due to the special influence of uric acid. Lastly, those who ascribe to this substance the extensive influence in disease referred to above, expressly disavow any belief in a special diathesis; the troubles being assumed to arise from errors of diet and faulty elimination. It will be seen, therefore, that there is probably no justification for the retention of the term 'uric-acid diathesis,' except those of custom and convenience.

ÆTIOLOGY, &c.—Although uric acid is closely related to urea chemically, and takes the place of the latter substance in the urine of birds and reptiles, it is probable that in the mammal its metabolic history is quite distinct from that of urea. Recent physiological study has shown that of the total quantity excreted, only a part arises from the essential metabolism of the tissues. Another part takes origin directly from precursors in food-stuffs, and the amount of this portion depends to a great extent upon the quality as well as upon the quantity of the diet. The two moieties of the excretion—that which is independent of the intake and that which arises directly from it—are conveniently, if not very appropriately, termed the endogenous and exogenous portions respectively.

While the daily output of urea rises and falls with the amount of nitrogenous material absorbed, and, under normal circumstances, very nearly proportional to the amount of proteid ingested, the output of uric acid, on the other hand, varies only with the amount of certain quite special constituents in the diet. We may choose a dietary, rich in proteid, which scarcely affects the uric-acid excretion at all; in other words, upon such a dietary the exogenous production is absent. The essential

character of such a diet is freedom from organised tissue-elements. It must contain no muscle, especially no glands (sweetbread, liver, kidney, &c.), and none of the preparations which come under the head of soups and meat-extracts. With any of these the exogenous production of uric acid rises in proportion to the amount taken. A satisfactory explanation of these facts is ready to hand. As essential constituents of cells, and especially of their nuclei, are certain phosphorus-containing proteids—the nucleo-proteids. These are found, when hydrolysed by laboratory processes, to yield among their decomposition-products certain bases, the xanthin-, alloxur-, or purin-bases, which are closely allied to uric acid. Other proteids yield none of these, and no products so immediately related to uric acid. This distinction would seem to hold in the processes of metabolism, and it thus happens that only a dietary which contains nucleo-proteid, that is, one which comprises cellular elements—animal or vegetable—increases (in virtue at least of its proteid content) the exogenous uric acid. Proteids such as the myosin of muscle, the caseinogen of milk, the albumen of eggs, or the gluten of wheat, give rise to no increase when ingested. It is true that muscle, no less than the glands or other organs more or less commonly consumed as food, contains, in addition to its nucleo-proteids, certain products of its own previous metabolism ('extractives'), some of which may act also as precursors of uric acid; in the case, indeed, of an ordinary meat-meal these contribute a large proportion of the excretory increase which follows its consumption.

A dietary leading to scarcely any exogenous production may consist of such materials as milk, cheese, eggs, white bread, rice, potatoes, and most green vegetables, other than those of the leguminous variety.

For that moiety of uric-acid production in the body which is independent of diet—the endogenous product—it is, of course, more difficult to trace precursors. But the facts justify the supposition that it arises in the main from the metabolism of the nucleo-proteids of the tissues, and does not spring, in company with urea, from the breakdown of proteids in general. There is evidence that at least some fraction arises by synthetic processes occurring in the liver or, as is less likely, in the kidney.

The total excretion varies considerably in different individuals, but is never large. The limits may vary from 5 grains or somewhat less to 15 grains or a little more in 24 hours. From what has been said it will be understood that the amount excreted will be affected by the character of the food; but it may vary within the above limits in different individuals when all are taking an ordinary mixed diet. A person excreting, say, 12 grains upon an ordinary dietary may excrete as little as 6 or 7 grains upon a diet of milk and eggs; the latter figure indicating in this case what is practically his 'endogenous' production.

It is quite certain that the sufferer from lithiasis is not necessarily one whose uric-acid excretion is higher than the average.

We have but little experimental evidence bearing upon the amount of uric acid in the blood and tissues under normal conditions. Most recent observers have failed to find any at all in the blood. But it may be impossible to demonstrate it even in the blood of birds (Luff), and this fact has been used as an argument—not wholly conclusive—of its

formation in the kidney. In mammals, the small amount excreted makes it impossible to draw any such conclusion; 10 or 12 grains of an excretive could of course be brought to the kidneys in the course of 24 hours without detectable quantities being present at any moment in a sample of the blood. Conclusions drawn from older observations pointing to the presence of proportionately large amounts in the spleen are erroneous, in so far as such uric acid is probably formed in the organ *post mortem* from certain precursors. While we are without strict proof of the matter, there is much justification for looking to the liver as the chief seat of uric-acid formation.

As regards the quantity of the substance in the blood when pathological conditions exist, the classical observation of Garrod, showing the increase in gout, remains alone in the abundant confirmation which it has received. There is, however, no doubt that a large increase is found in certain types of leucæmia, here arising from increased production, and not merely from the retention—due to aberrations of solution and elimination—which is the feature of gout. The researches of v. Jaksch point to an increase in the blood in pneumonia, in renal disease—especially with granular kidney—and in cases of advanced anæmia. In none of these conditions can we assert that uric acid exerts *per se* a toxic influence in the proper sense, apart from mechanical effects due to its deposition. There is no toxic symptom common to these various disorders in which an excess of uric acid is present in the body. Certain combinations of the symptoms, which Murchison held to indicate a condition of lithæmia, are common enough in the dyspeptic, though it may be doubted if those he enumerated are often seen in such definite combination as to warrant their being grouped under a name suggesting that they have a common toxic factor in their production, and together constitute some sort of pathological and clinical entity. In any case, the name seems an undesirable one for such conditions as he describes, for there is no evidence whatever that such patients have any excess of uric acid in their blood. The symptoms enumerated constitute, it is true, a picture very similar to that seen in latent or irregular gout, just as they are also very similar to those of the chronic dyspeptic; but Murchison himself urged that 'they are also very common in persons who neither inherit articular gout nor ever have it themselves.'

That a tendency to deposition in the urine of pigmented urates goes commonly with certain dyspeptic symptoms is undoubtedly true, though it is probably due (as in colds and fevers) to the general character of the urine rather than to an increase in the day's excretion of urates, for the precipitation of these is never a proof of an increased proportion. It is also true that many people take habitually an excess of food of a kind which keeps their 'exogenous' uric acid high; and if they also happen to consume chiefly alcoholic beverages, with a proportionately small quantity of efficient diluents, they pass an acid concentrated urine naturally prone to deposit its urates. But the ills which follow this course of life are not to be attributed to any special toxic effects on the part of uric acid, nor can such individuals be said to suffer from a dyscrasia in any legitimate sense.

It is essential, at least at the present time, when 'the uric-acid diathesis' and drugs to combat it are

so insistently kept before the eyes of the medical profession and of the public, to bear in mind that, save in gout and gravel, where its physical properties and those of its salts play so indubitable a part, the pathological influence of uric acid is wholly hypothetical. It may be taken for granted that the circulation and toxic effects of the products of deranged and abnormal metabolism are common factors in disease; but to ascribe so much to one particular metabolite, without good evidence, and to employ a name which embodies an assumption, is but to delay more discriminating study in an important field of chemical pathology. Uric acid is probably not a poison in the proper sense at all, and but for its insolubility it might have been as little heard of in pathology as that other normal metabolite, the excretion of which is in comparable amount—creatinine.

Quite distinct, of course, from the present tendency to popularise the uric-acid 'diathesis' is the endeavour, already referred to, to extend the field of influence of uric acid into the causation of such disorders as epilepsy, asthma, bronchitis, Raynaud's disease, diabetes, and many others (Haig). This is not the place to discuss these views in detail, but the following remarks may be permitted.

Quite essential to the theory involved is a proof that in this or that condition there is at one time or another an abnormal retention of uric acid in the circulation and tissues. The evidence which is relied upon in proof of such retention is, broadly stated, as follows: Uric acid and urea are first assumed to be formed in the body in a definite relation one to the other, which varies but little from the ratio of 1 to 33. It follows that if, on a given day, the ratio of uric acid excreted to the urea excreted fall below this value, retention must have occurred; if it rise above this figure, urates previously stored in the body must have been brought to excretion. A period showing a low ratio means, therefore, a period of accumulation.

But if recent physiological teaching is correct, and uric acid has no common origin with urea, it is, to say the least, unlikely that the two substances appear in metabolism in a continuously balanced ratio. The following considerations with regard to the point are based entirely upon experiments, many times repeated. If upon a fixed diet of any sort a healthy individual is found to excrete, say, one gramme of uric acid for each thirty grammes of urea, it only requires that about a pint and a half of milk should be added to his intake to lower the ratio at once to 1 : 40; for milk, as already stated, scarcely affects the uric-acid output, while the quantity mentioned will produce ten grammes of urea. It is clear, therefore, that an alteration in the ratio may be no proof at all of retained urates. One other line of evidence for retention has been employed in the exposition of the theory. Certain granules, produced in the blood by admixture with ammonium chloride, are assumed to consist of urates, and these, when counted under the microscope, are said to be increased in conditions when, in the view under discussion, retention might be expected. It is sufficient to say that such granules may form in blood which, when examined in quantity, is found to yield no detectable amount of uric acid (Luff).

If the evidence for retention be rejected, close examination of the remaining arguments will show that they have lost their force, so far at least as

they aim at the ascription of symptoms to uric acid itself.

At the present time, then, we have no really satisfactory evidence to show that uric acid is a factor in disease, save in conditions where it or its salts are obviously deposited; that is to say, in gout and lithiasis. With the former of these this article is only indirectly concerned; there remain for consideration certain facts related to the ætiology and pathology of uric-acid gravel.

Whatever view may be held as to any deeper relationship between gout and gravel, there is no doubt that there are fundamental differences in the chemical side of their pathology; the final factors involved in producing the actual deposition of urates on the one side of the kidneys, and of uric acid on the other, are essentially diverse. As Sir William Roberts insisted, the conclusion is clear 'that gravel should be regarded as a primary vice of the urinary function; that it requires to be studied by and for itself; and that the urine is the proper and natural field for the investigation of its ætiology and therapeutics.'

Normal urine usually contains much more uric acid than it can hold in simple solution, and most specimens eventually deposit nearly the whole of this excretive in a crystalline form. But this never occurs within the urinary passages, and, as a rule, even after the urine is voided the deposition is long delayed. The urine of sufferers from gravel may, on the other hand, sparkle with crystals when it is passed, and in any case rapidly yields a crystalline sediment.

The factors concerned in the physiological maintenance of solution, and, on the other hand, in bringing about the normal slow separation, are complex. Roberts put our knowledge of certain of these factors upon a definite basis, and showed how variations in them may render urine unable to hold its uric acid even while warm and within the passages.

The percentage of uric acid is of influence. Although, as already urged, a tendency to gravel or stone does not depend upon increased production of uric acid, but may exist when the habitual output is below the normal and be quite absent when the excretion is abnormally high, it is yet clear that, other things being equal, and the tendency to precipitation present, there will be greater danger and, it may be, worse results when the urine contains excess than when the proportion is low. The existence of a proportionately large amount of uric acid in the excretion of children probably accounts for the relative frequency with which they suffer from lithiasis.

A second and prepotent factor in determining deposition is the degree of urinary acidity. An alkaline urine cannot, of course, deposit free uric acid, and there is always an increased tendency to separation with increase of acidity.

Yet another character in the urine which promotes separation is a deficiency in inorganic salts. The immunity from stone and gravel displayed by sailors has been attributed to the large quantity of salt which they take with their food (Plowright).

Lastly, there is a character of less importance, a deficiency, namely, in pigments. To this Roberts attributed the free sedimentation which often occurs in the pale urine of contracting kidneys.

These factors are undoubtedly important, and the first three and most influential can, fortunately,

be controlled with great benefit in the treatment of gravel. At the same time, it must be admitted that other urinary variations of a character at present unknown make themselves felt. Urine may deposit its uric acid very rapidly when analysis shows it to contain no excess of the excretive, and none of the aberrations just enumerated (Smith-Jerome).

Moreover, there seems to be no doubt that heredity plays a part in the ætiology of gravel, and what is transmitted can only be partly and superficially expressed in urinary characters such as have been discussed, which are, after all (with the possible exception of the acidity), very variable even in the habitual sufferer from gravel. With regard to the acidity, it appears to be the case that some people—and among them some prone to lithiasis—habitually pass a hyper-acid urine under conditions which offer no obvious cause for the phenomenon. It is conceivable that some anomaly in metabolism may lead to the habitual excretion of an acid product or products not yet recognised. This is, of course, entirely hypothetical; but it is perhaps useful to remember, in this and other connections, that we have, in cases of cystinuria (p. 359) and alkaptonuria (p. 48), such metabolic anomalies—'chemical malformations' as they have been called—which have been recognised because the abnormal products give such obvious indications of their presence. It is not impossible that there may be other anomalies of this kind not yet discovered.

Nature of Deposits.—The appearance of uric acid as it separates from the urine is too familiar to need detailed description. The crystals are, almost without exception, pigmented, and in the commonest case have the colour and, after sedimentation, present the appearance of cayenne pepper. Sometimes they are yellow or brown. Under the microscope their shape is found to be very various, departing always from the developed rhombic forms of the pure substance (by the suppressing of angles or faces, and by cohesion) and forming rectangular prisms, or falling into 'whetstone,' 'barrel,' or 'dumb-bell' forms. Sometimes they are aggregated, and occasionally the aggregates are of considerable size. Their departures from the typical forms are due to the effect of associated impurities, an albuminous or mucoid substance, and the colouring matters (Ord). The shape assumed largely depends upon the nature of the associated pigment (A. E. Garrod). Their pigmentation, insolubility in acids, and solubility in alkalis, are sufficient to characterise them.

In the kidney, concretions may be seen *post mortem* as glistening yellow-brown sand, as somewhat larger tuberculated masses, or, of course, as still larger calculi, ranging even to several ounces in weight. Stones which occur in the kidney-substance are always composed of nearly pure uric acid and are dense and hard; those which have been long in the pelvis may contain urates or phosphates, with uric acid as a basis; these are more friable. We are still without information as to why some patients with lithiasis pass gravel for years without calculus-formation, while others, less fortunate, tend to build up stones. The albuminous material which is always associated with a calculus undoubtedly affects the mode of aggregation; but there is nothing to explain these individual differences.

SYMPTOMS.—The symptoms enumerated by Murchison as indicating a condition of lithæmia comprise, in addition to the pathognomonic urinary deposits, an extensive group, from which we can select some or others which will fit any case of disturbed metabolism—flatulent eructations, constipation, disturbed appetite, furred tongue, excessive accumulation of mucus in the fauces, circulatory disturbances, headache, vertigo, and dimness of sight. To all these, and others, some more recent authorities (Da Costa and others), in drawing the picture of 'lithæmia,' have added and have laid stress upon inflammatory conditions of the external coats of the eye.

The condition of lithiasis, apart from calculus, can always be recognised by a sufficiently frequent examination of the urine. The separation of crystals in the freshly voided urine may not occur at all hours of the day, but is nearly always seen in the early morning urine; and in well-marked cases, not under treatment, is seldom absent at any time.

In some people this objective sign in the urine may exist for years without associated symptoms, but as a rule there are sooner or later some indications of renal irritation, and the condition should not be left without treatment.

In other cases symptoms may be more urgent. In children there are frequently colicky abdominal pains, usually occurring suddenly and located at the umbilicus or iliac regions. In severe cases there may be some nausea and vomiting, and perhaps slight hæmaturia. Strangury may be present in boys. In adults there may be a dull continuous pain in the loins, often attributed to lumbago, but disappearing with any treatment which keeps the urine free from deposit. The pain may radiate and be mistaken for other conditions. The disorder is often very chronic, and Levison has followed cases for twenty to thirty years without seeing true renal colic or other severe symptoms supervene. When gravel is associated with or gives place to calculus, there are the familiar signs of that affection; but as none of these are special to uric-acid stones, they need not be enumerated here.

TREATMENT.—In conditions of lithiasis it is clearly of importance to keep the production of uric acid as low as possible, and to this end the diet should be regulated. As was stated above, taking a dietary of milk, eggs, white bread and green vegetables results in an almost complete disappearance of that moiety of uric acid which arises from the food and largely reduces the excretion, a fact of real importance in treatment. But such a diet should not be prescribed empirically nor without due observation of its effects. Many patients are apt to take too little proteid when employing it, and such deficiency, if long continued, may lead to results more serious than can be attributed to uric-acid gravel. White meats can usually be added with safety, but even with this addition so unstimulating a diet does not suit all cases. The extractives of meat undoubtedly increase uric-acid production, but there is evidence that they may subserve physiological functions; for instance, in stimulating the secretion of gastric juice (Pawlow). But the proteid in the diet, while it should be sufficient, must never be in excess, and the flesh-food should not be in disproportion to the vegetable food taken; this, not because there is any essential difference between animal and vegetable proteids in their effect upon uric-acid production, but because

flesh-food increases and vegetable food diminishes the alkalinity of the urine. Luff looks upon the mineral constituents of vegetables as having a special power of keeping uric acid in solution, a power more marked than their chemical nature as revealed by analysis can be made to explain.

It has been satisfactorily proved by quantitative study that quinic acid, a constituent of many fruits, definitely diminishes the production of uric acid in the body, probably by interfering with its synthesis (Weiss). As a result of these experiments certain compounds of quinic acid have been introduced as drugs. These are 'Urosine' (quinic acid of lithium), given in doses of about ten grains, and 'Sidonal' (quinic acid of piperazine), the dose of which is about the same. These are of too recent introduction for any knowledge of their benefit to be available; but it is certain that the administration of quinic acid, especially when combined with a dietary introducing no uric-acid precursors, leads to a remarkably low excretion of urates.

With the end of preventing the separation of the acid from the urine, abundant water-drinking should be recommended, and the free use of table-salt is a desirable procedure. During any acute stage of the disorder the urine should be kept fully alkaline by the free administration of alkalis. Valuable, but perhaps not more valuable than the above means, is the use of various alkaline or saline mineral waters, the choice of which must depend upon the particular case under treatment. If drunk at their source the action of such waters is assisted by accessory hygienic factors.

There are various organic substances which form highly soluble compounds with uric acid. Used as drugs it would seem that they do not reach the urine in sufficient concentration to exert much influence as solvents. The benefit which is said to follow their use can, therefore, be only empirically explained. Prominent among these are piperazine and piperidine, the latter base being given as a tartrate in 10-grain doses (Tunncliffe and Rosenheim).

F. GOWLAND HOPKINS.

URINARY CALCULUS.—A calculus formed in any part of the urinary apparatus. See CONCRETIONS; and RENAL CALCULUS.

URINARY DEPOSITS.—Under healthy conditions the normal urine does not deposit a sediment, unless that flocculent suspension floating at various levels in the clear fluid and composed of thin mucus entangling a few epithelial cells be called a deposit. But even trivial deviations from the normal habit of body are prone to be indicated by the presence of a sediment in the urine, while in grave general disturbances and severe local derangements the composition of the urine is often materially altered, and may then contain substances which reveal themselves either immediately after it is passed, or after it has been allowed to stand for a while. With these sediments naturally deposited, i.e. without the intervention of reagents, it is proposed to deal here.

Method of examination.—Some 5 or 6 ounces of the urine to be examined are placed in a conical or cylindrical glass vessel, and after standing for some hours the supernatant fluid is decanted off. A sample of the sediment may be more easily and quickly obtained by the use of the centrifuge, and this instrument may become a necessity should the

solid particles be scanty or of light specific weight. It is often advisable to add some preservative, the best of which are formalin and chloroform; but if the centrifuge be used this addition is unnecessary, unless the sediment be required for future demonstration.

After noting the naked-eye characters of the deposit, a drop or two should be pipetted on to a slide and submitted to microscopical examination. The examination of the sediment may be facilitated by the use of staining reagents, such as methylene-blue, fuchsin, methyl violet, iodo-potassic iodide, smic acid, Sudan iij, mucicarmine, muchæmatin, &c. These staining reagents may be run under the cover-glass or previously added to the sediment.

For microscopical examination low and medium powers are usually amply sufficient, though occasionally it may be needful to employ an immersion lens. When examining unstained samples, it is advisable not to use too much light, as some objects, such as hyaline casts and cylindroids, may be easily escape observation owing to their great transparency. As a rule, renal tube-casts are easily recognised, but cylindroids, aggregations of small crystals and granular debris, epithelial scales and minute fragments of wood, are from their somewhat cylindrical shape sometimes mistaken for renal casts. Some of the difficulties are removed by the use of staining reagents, and these should always be employed if doubts arise as to the exact nature and origin of cells.

The substances to be dealt with may be divided into three classes—unorganised, organised, and adenitious, and though most may be designated sediments or deposits, to some the terms 'suspensions' or 'scums' seem more appropriate.

Unorganised Deposits.—*Uric acid* (Lithic acid) is found in the free state, in urine which has, or has had, an acid reaction, as yellow or brownish-yellow crystals. Though the type-form is a rhombic prism, the shape of the crystals is extremely variable. From their microscopic appearance they have been compared to lozenges, whetstones, flat plates, cubes, and long spikes. Often the crystals are massed together in irregular agglomerations and in stellate or rosette-like clusters. Clusters of these crystals are frequently met with in cases of uric-acid gravel, and then resemble red sand or Cayenne pepper at the bottom of the vessel. In size also they exhibit considerable differences; the Cayenne deposit being composed of quite large grains, while on other occasions so small are they that a high power is required to make out their characters. Uric-acid crystals are recognised by their yellow colour and their shape, and the diagnosis may be confirmed by their micro-chemical reactions. They are soluble in caustic alkalis, and respond to the murexide test.

Urates are met with both in an amorphous and in a crystalline form, and are not infrequently associated with uric acid.

Amorphous urates consist of a mixture of sodium, potassium, and ammonium urates, the sodium urate usually predominating. They are deposited from urine with an acid reaction, and make their appearance as soon as the fluid cools. The sediment is coloured by urinary pigment (uroerythrin), and its hue varies from a pale fawn colour to pink or red, and very occasionally purple. The ruddy deposit is known as lateritious or brick-dust urates. Any doubts as to the nature of the deposit may be re-

solved by heating the fluid, when the turbidity disappears, or by applying the murexide test.

Urates also occur in a crystalline form as striated yellow spherules with and without projecting colourless spicules or spines, and also as small dumb-bells. Those in which the spicules are large and a distinctive feature (hedgehog) are found in urine with an acid reaction, and also *post mortem* in the bladder and kidneys of children. They are composed of *urate of sodium*. Dark yellow, almost opaque spherules, often showing a few small spicules, and consisting of *urate of ammonium*, are formed in urine which is alkaline from ammoniacal fermentation. Sometimes these crystals are quite small, and when paired assume a dumb-bell shape. *Urate of calcium* is occasionally met with in the urine, both as an amorphous white deposit and as acicular crystals, much resembling the urate of sodium in gouty deposits.

Xanthin, which very rarely occurs as a deposit, forms colourless rhombic plates. In composition it is very closely allied to uric acid, but may be distinguished therefrom by dissolving on heating, by the addition of ammonia, by its insolubility in acetic acid, and by not giving the murexide test.

Hippuric acid has occasionally been observed in the urine after eating certain fruits (cranberries, bilberries) and vegetables, and after the administration of benzoic acid, occurring as longish white rhomboid prisms; it is soluble in ammonia and insoluble in hydrochloric acid.

Oxalates.—Crystals of oxalate of lime are found in acid urine, especially after standing. Occasionally they may be found in quite fresh urine. They may be detected by the naked eye as white specks on the mucus-film, on contaminations, or on the sides of the urine-glass. Their presence is, however, usually discovered on microscopical examination, when they are seen as colourless or white octahedra, the so-called 'envelope crystals,' of variable size. Sometimes oxalate of lime assumes a dumb-bell or hour-glass shape, but these are usually accompanied by the common 'envelope' form. Oxalates are insoluble in acetic acid, but they dissolve in strong mineral acids without effervescence.

Carbonate of lime and sulphate of lime occasionally occur in human urine, the former as small spherules or as dumb-bells, the latter as colourless needles, or thin, elongated plates. The reaction of the urine in the first instance is alkaline, in the latter acid. Carbonates dissolve with effervescence on the addition of acids. Sulphates are insoluble in ammonia, and in acetic and sulphuric acids.

Phosphates occur in urine both in an amorphous and in a crystalline form. *Amorphous phosphates* form a white deposit in alkaline or neutral urine. They are a mixture of calcium and magnesium phosphates. The deposit is easily dissolved by acetic acid, and is undiminished or even increased by heat.

Crystalline Phosphates.—1. *Phosphate of lime*.—Neutral or stellar phosphate is found as a sediment and also as a scum on the urine. The single crystal is an elongated prism pointed at one end. The crystals may be discrete or arranged like stars or rosettes, the pointed end being directed towards the centre. They are easily soluble in acetic acid.

2. *Triple phosphate*.—Ammonium-magnesium phosphate occurs in alkaline urine, especially after ammoniacal fermentation. The most common form of the crystal is a triangular prism with bevelled

ends (coffin-lid); there are, however, numerous deviations from this type. Triple phosphate also crystallises in feathery flakes, occurring singly, in pairs, or crossed.

3. *Magnesium phosphate*.—This has been met with, but only very rarely, in strongly alkaline urine. The crystals are depicted as highly refractive elongated prisms with blunt-pointed ends.

Cystin.—*Cystic oxide* occurs usually in faintly acid urine which readily undergoes ammoniacal fermentation with production of sulphuretted hydrogen, due to the large amount of sulphur (about 26 per cent.) the substance contains. The crystals are colourless, hexagonal plates, and these are frequently imbricated or superimposed. They are insoluble in water, alcohol, and acetic acid, but readily dissolve in ammonia. See CHOLESTERIN, p. 295; CYSTINURIA, p. 359; LEUCINE, p. 864; TYROSINE, p. 1782.

Bilirubin and *hematoidin* are deposited in the urine, chiefly as fine needle-like crystals, singly or in tufts, also as amorphous granules and occasionally as rhombic plates. In colour they vary from yellowish-red to dark red. They have been found in inflammatory and malignant disease of the urinary apparatus, severe jaundice (icterus catarrhalis, gravis, neonatorum), cancer of the liver, and phosphorus-poisoning. They are soluble in acids and caustic alkalis and many other micro-chemical reagents, and with nitric acid give Gmelin's reaction.

Indigo has been found in urine undergoing ammoniacal fermentation; it occurs as rough, irregular masses of a dark blue colour, and as acicular crystals, scattered or in clusters. In the nascent condition it has the property of staining substances and structures such as uric-acid crystals, urates, cells, fungi, and also the urine, blue. Hence its presence is easily recognised. As blue indigo it is not a common deposit, though its immediate antecedent, indican, is frequently present in urine.

Fat occurs in urine in chyluria, after much fatty or oily food, in chronic Bright's disease either free or in casts and cells, in diabetes, in phosphorus-poisoning, and also as an accidental, and occasionally as an intentional, contamination. The highly refractive globules of varying size are easily recognised by their optical appearance, or by staining with osmic acid or Sudan iij, or by their ready solubility in ether.

Organised Deposits.—*Mucus* exists only in small quantity in normal urine and then appears as a cloudy deposit or as a suspension. It is without definite organisation, and is only recognisable by its delicate and irregular striation and by the foreign particles (dust, debris, cells, crystals) it entangles. Under certain morbid conditions it becomes inspissated and increased in quantity, as in cystitis, where it is ropy and copious. It may be seen as long longitudinally-striated ribands (cylindroids), having often much resemblance to hyaline casts, in the urine of nephritis, &c., and even in normal urine. Long bands of mucus are found in the urine of urethritis (urethral threads), and these may entangle epithelial cells, pus-corpuscles, and microbes, e.g. gonococci. Mucus is precipitated by acetic acid, and may be stained with mucicarmine or with mucæmætin.

Epithelial cells.—In normal urine a few epithelial cells, mostly squamous, may be found on microscopical examination. In diseased conditions of the urinary passages and of the kidneys, cells of various

kinds are not infrequent, and, though it might be anticipated that their shape would give evidence of the locality of origin and so aid in diagnosis, this is often far from being the case. In the case of an inflammatory or a cancerous process, the cells from the part affected are abnormal *ab initio* and liable to changes arising from degeneration, contact with morbid secretions, pressure, or osmosis. Taking these pathological conditions into account, as well as the absence of any distinctive criteria in the cells of transitional epithelium derived from different portions of the urinary tract, it is obvious that caution is required in coming to a conclusion as to the exact source of origin of cells found in the urine. Still, certain cells may be definitely recognised, such as squamous epithelium from the vagina, or from the anterior extremity of the urethra and prepuce; and columnar cells from the male urethra, the uterus, and the prostate; but while those from the vagina are common, the others are comparatively rare. Transitional epithelial cells may proceed from other parts of the urinary tract, but they present few localising features, though in all probability a multinuclear, polyhedral cell comes from the bladder. Bladder cells are not infrequently large and squamous. Renal epithelium is cubical or polyhedral, with comparatively large and well-defined nuclei. It is well to bear in mind that leucocytes, owing to imbibition, swell up to quite a large size; and if there be the slightest doubt about the nucleus it is advisable to stain the sediment, lest, with a too great regard for tradition, they be assigned to a renal origin and a desquamative nephritis.

Tumour-cells and tissue-fragments.—Cells from malignant or inflammatory growths affecting the bladder, ureters or kidneys, or adjacent structures, e.g. uterus and rectum, may be discovered in the urine, and it is sometimes possible to verify a diagnosis of cancer or other neoplasm by detecting keratinised epithelial cells, pigmented cells, cells with inclusions or cancer-bodies, portions of new growth, and fragments of organised tissue. It is rare, however, to make a diagnosis of cancer or other tumour from a microscopical examination of urinary sediment without some previous clinical indication.

Spermatozoa may often be observed in the urine. The presence of a few of them is devoid of special significance. Sometimes, however, glairy or whitish flakes are seen in urine, and these on examination are found to consist of mucus containing spermatozoa. Spermatozoa are easily recognised by their characteristic shape, which is fairly uniform, though occasionally a few individuals are abnormal both as to shape and size. Their average length is about 50 μ . They can be stained by anilin dyes, but this is scarcely necessary, as they are easily seen with high and even medium powers. It is not advisable to swear to the identity of single specimens if incomplete, e.g. if the tail have broken off short by the neck. They have no resemblance to *Trichomonas vaginalis* either in shape or size.

Blood (Erythrocytes; Red Corpuscles).—When there is admixture of blood with the urine, the colour of the fluid and the character of the sediment vary with the source. If from the kidney, the supernatant fluid is reddish or smoky, and the deposit is mostly of a dirty brown hue, the sediment containing casts, crystals, cells, granular debris, &c., as well as blood-corpuscles. If from the bladder

or ureter the urine is generally red, and the deposit may contain, among other things, actual blood-clot. Owing to the different density and reaction of different urines, the red corpuscles may or may not lose their typical bi-concave appearance, and either swell up so as to resemble circular colourless discs, or shrink and become crenated. They last longer in acid than in alkaline urine, in which they are quickly destroyed. In hæmoglobinuria the urine is of a dark brown hue, and deposits a more or less copious brownish sediment. This sediment consists chiefly of the blood-colouring matter in the condition of yellow granules, but may also contain casts, mostly granular. The microscopical diagnosis may be confirmed by the 'guaiacum and ozonic æther' test, by the brown-coloured precipitate formed on boiling with liquor potassæ, by the hæmin-crystal test, and by the spectroscope.

Leucocytes (White Corpuscles; Pus).—Leucocytes of fairly normal appearance are occasionally met with in normal urine. In the deposit of nephritis they occur both free and in casts, and sometimes are quite numerous. In suppurative inflammation of the urinary tract below the kidney a yellowish-white or drab sediment may be deposited, which, if the reaction be acid, is loose and flocculent, and if alkaline, as in some cases of cystitis, viscid and stringy. Pus in bulk, when treated with caustic alkali, becomes a slimy, tenacious, ropy mass. On microscopical examination the leucocyte is a granular spheroidal cell, the nucleus of which is of irregular shape and may be imperceptible. Like the erythrocyte, its size and appearance are variable, and for similar reasons (end- and exosmosis and reaction). By treating a sample with acetic acid the granules clear up, and the nuclei become more evident. The nucleus is single and irregular in shape, or multiple (1-4) and fragmented. Iodopottassic iodide stains pus-corpuscles dark brown (glycogen-reaction). In cases where it may be important to distinguish the nucleus of the leucocyte from that of the epithelial cell, staining with hæmatoxylin or with anilin pigments is advisable.

Bacteria (Bacteriuria).—Normal urine is not only clear but sterile. Under disease-conditions, however, it may not only contain bacteria, but be cloudy or turbid from their presence. In some cases the bacteria are found chiefly in the sediment, but in others they are disseminated as a suspension throughout the fluid. The conditions in which they occur are both local and general, and the organisms most frequently met with are *Gonococcus*, *Bacillus tuberculosus*, *Pyogenic cocci*, *B. coli communis*, and *B. typhosus*. The microbes of glanders, actinomycosis, and relapsing fever have also been found in urine. The foregoing list does not include organisms casually introduced from without, e.g. through the intermediary of a catheter, &c., for these are rather accidental contaminations than disease-germs proper.

For the morphological characters and special methods of detecting bacteria, see BACTERIA.

Entozoa.—In cases of *hydatid* of the kidney, vesicles, hooklets, and shreds of laminated membrane of echinococcus may be found in the urine.

The eggs and ciliated embryo of the *Distoma hæmatobium* are found in the bloody urine of cases of the endemic hæmaturia of North and South Africa. The ova, which are about 0.12 mm. long and 0.4 mm. broad, or the ruptured shell-cases, are easily recognised by their oval shape and the characteristic terminal or latero-terminal spine.

The contents appear granular, or resemble a collection of spherules. The ripe ova are easily hatched on a warm stage, so that the free-swimming embryo can be observed.

In cases of chyluria, the embryos of the *Filaria sanguinis hominis* are usually present in the milky urine. Manson recommends that the coagulum should be broken up with a glass rod, and after an hour or two the sediment examined after the manner of looking for casts (see p. 1798).

Adventitious Matter.—Normal urine is quite sterile, and if passed aseptically will keep indefinitely and remain perfectly clear, though crystals of uric acid may be deposited. Under ordinary conditions, however, the acidity of the urine may increase at first (acid fermentation), but soon, according to the temperature and its own constitution, it becomes neutral or amphoteric, and finally alkaline (alkaline fermentation). The exact cause—indeed, the existence—of the acid fermentation is disputed, but that of the ammoniacal is due to the action of microbes, *Micrococcus ureæ* and other bacteria, which secrete a ferment, urase, by which the urea is converted into ammonium carbonate. Besides these, other adventitious microbes belonging to hyphomycetes, blastomycetes, and schizomycetes may settle in the urine and develop more or less rapidly according as its composition and reaction and the temperature are suitable. Certain urines are specially prone to decompose, such as those containing blood or pus, the urine of cystitis and of diabetes, and that containing cystin.

While the fermentation is in process, and after it has subsided, the sediment of a sample of normal or of abnormal urine will mostly be found to contain organic and inorganic débris, crystals, casts, various cells in different stages of degeneration, and fungi (moulds, yeasts, bacteria). The nature of the sediment will materially depend on the substances originally entering into the constitution and composition of the urine.

In addition to the above-mentioned active and living bodies and their sedimentary effects, the presence of certain inert particles may be remarked, such as wool, cotton, linen, and silk fibres, hairs, feathers, wood, and dust. These are of constant occurrence as accidental contaminations, and they must be recognised by their special and peculiar characters. Among other extraneous substances met with in the urine may be mentioned oil-globules, starch-grains, fæces, sputum, and menstrual blood. See PLATE.

R. G. HEBB.

URINARY FEVER.—SYNON. : Urethral Fever; Catheter-Fever.

DEFINITION AND VARIETIES.—The above terms have been applied by different writers to various conditions which may arise after mechanical irritation of the urethra. The resulting symptoms vary, according to circumstances, in their nature, mode of onset, severity, and prognosis. The subject of urinary fever has been much discussed, and various views as to its nature have been advanced; and this is doubtless partly due to the fact that the ill-effects consequent on instrumentation of the urethra have not been sufficiently differentiated. These injurious consequences may be conveniently grouped as follows:—

1. Shock, slight or severe in nature, appearing immediately after the passage of the instrument, transient in duration, and ending in recovery.

2. An acute febrile attack, occurring some time after instrumentation (usually following the first act of micturition), transient in nature, but of some severity while it lasts, and ending in recovery. *Acute transient urethral fever; urinary sepsis.*

3. Acute recurrent attacks, similar in nature to that just mentioned. *Acute recurrent urethral fever; recurrent urinary sepsis.*

4. Acute septic infection, with definite pyæmic lesions and secondary centres of inflammation. This condition is precisely similar in all respects to septic infection arising in a wound of any other part of the body.

5. An insidious attack, without any well-defined symptoms, but marked by gradual loss of health and strength, often with an ultimately fatal termination. *Urinary cachexia.*

ÆTIOLOGY.—Any form of mechanical irritation of the urethra may lead to one of the conditions just mentioned. There is no doubt that unfavourable symptoms are most likely to occur if the disease rendering instrumentation necessary is situated in the membrano-prostatic portion of the urethra. Urinary fever, using the term in its broad signification, may occur alike in those who have been subjected to instrumentation before, and in those on whom a catheter has been passed for the first time. In the case of patients accustomed to catheterism, an attack of urinary fever may be determined by the use of an instrument of larger size than customary, because such an one is likely to cause some slight lesion of the mucous membrane unless used with care and by a skilled hand. In many cases of the more severe forms of urinary fever there is evidence of disease of the kidneys, but in others these organs are apparently healthy, or the disease is so slight, as shown by *post-mortem* examination, that it seems inadequate *per se* to account for death.

PATHOLOGY.—Setting aside cases of obvious septic infection, and those in which the patient is suffering from pronounced renal mischief, considerable difference of opinion exists as to the nature of urinary fever. Two separate theories have been advanced, and each of them has its advocates and opponents. In the opinion of the writer, both these theories are essential for the rational explanation of the conditions above-mentioned, each playing its own part, as will be shown.

1. *Neurotic theory.*—It is contended by the supporters of this view that urinary fever is directly traceable to reflex congestion and inflammation of the kidneys, resulting from the irritation of the sympathetic and cerebro-spinal nerves of the urethra. That the nervous excitability of the urethra is very great is undoubted, and is fully proved by numerous observations. It has already been stated that irritation of the membrano-prostatic urethra is more likely to be followed by untoward results than is that of the penile portion, and it is worthy of note that it is precisely in this part that the nervous supply is most abundant. That irritation of the nerves of the urethra may produce reflex effects upon the kidneys excites no surprise when it is remembered that the sympathetic nerves of the urethra are derived from the abdominal sympathetic, and are therefore in direct anatomical continuity with the nerves of the renal plexus. Irritation of the urethral nerves might thus induce extreme congestion of the kidneys, associated with suppression of urine, followed by hæmaturia.

If such a condition were excited in kidneys previously healthy it would be transient in nature, and would, under ordinary circumstances, speedily terminate in recovery; on the other hand, if the kidneys were already the seat of some inflammatory mischief, it is by no means improbable that the fresh irritation would seriously interfere with the functions of organs already damaged. See p. 823.

It is perfectly well known that an involuntary shudder often accompanies the end of the act of micturition in healthy men. The state of shock which occasionally follows the introduction of a catheter is no doubt largely explained by this physiological phenomenon. It shows that in some men a nervous system exists so sensitive as to be seriously impressed by even a normal act; much more so, then, by so rude a measure as the passage of a catheter. Irritation of the sympathetic nerves of the urethra might reflexly induce engorgement of the abdominal vessels, and thus induce the temporary faintness and shock not infrequently met with as the result of catheterism.

2. *Septic theory.*—Although some of the conditions arising from mechanical irritation of the urethra are, and others may be, due to nervous influences, yet in the majority of cases of acute febrile attacks there is little doubt that the ill-effects are dependent upon sepsis. Acute septic intoxication and septic infection may occur through a wound in the urethral mucous membrane or in the bladder, as they may do in the case of a wound of any other part. But while this is fully recognised and conceded, it is asserted by some that, irrespective of the undoubtedly septic and infected cases, so-called urinary fever (excluding shock) is dependent upon the absorption of toxic matters from the urine as it passes over the wound made in the urethra by instrumentation. It is highly probable that this view is correct in the majority of cases. Traumatism is a constant accompaniment of acute urinary fever, a few drops of blood following the withdrawal of the instrument. In support of this septic theory it must be borne in mind that the temperature remains normal until after the first act of micturition succeeding instrumentation: the urine, charged with septic material, is thus brought into contact with the wounded surface; the septic matter is absorbed, and the febrile symptoms follow. If the urine be in a healthy condition and antiseptic precautions be taken, urinary sepsis is much less likely to occur. Further, if a perineal opening be first made, and thus free drainage be afforded, urethral operations for stricture are not followed by urinary fever. And again, ill-consequences of this nature rarely follow internal urethrotomy, although they may have done so in the same case when an attempt has been made to treat the case by dilatation, thus pointing to the conclusion that free drainage is an important preventive measure.

In most cases of stricture and of enlargement of the prostate with residual urine there is an ample supply of septic material, which, under suitable circumstances, would be readily absorbed. In the recurrent form of urinary fever it is almost certain that each attack of fever occurs in response to the absorption of a fresh dose of poison, for it is difficult to suppose (unless we are prepared to admit that the mere passage of the urine, without absorption, can produce a febrile attack) that the nervous system is responsible for repeated attacks at in-

intervals of time during which no fresh mechanical irritant has been applied.

Some cases, perhaps, are of a complex nature, due in part to reflex congestion with inflammation of the kidneys, and in part to some form of septic absorption.

SYMPTOMS, PROGNOSIS, AND TREATMENT OF THE VARIOUS FORMS.—(1) *Urethral shock.*—In certain persons, especially those of a neurotic temperament, the passage of an instrument, even when used with the greatest dexterity and gentleness, produces symptoms of more or less severe shock. In the slightest, and fortunately by far the most frequent, cases, the patient, although not experiencing pain, becomes pale, breaks into a profuse cold sweat, feels dizzy, and not infrequently faints. Rarely the state of insensibility is accompanied by convulsive movements of the whole body. These symptoms are more likely to occur when an instrument is passed for the first time, or when the surgeon uses one of a larger size than that to which the patient has been accustomed. Recovery ensues in a few moments, and the patient experiences no further ill-effects. Fresh air, the recumbent position, and a dose of sal volatile is the only treatment necessary at the time; but the patient should be directed to keep quiet for the remainder of the day.

In very rare cases this condition of shock is very much more serious, and may terminate fatally within twenty-four hours. In such there is total suppression of urine; and *post mortem* the kidneys are found to be intensely congested, although they are often otherwise healthy; it is probable that the fatal termination is due to cessation of the excretion of urea. Treatment is of little avail. Free purging by croton oil or elaterin, hot stupes to the loins, warm diluent drinks, the hypodermic injection of pilocarpine, and the hot vapour-bath offer the best chance of success.

(2) *Acute transient urinary fever.* *Acute urinary sepsis.*—The symptoms characterising this condition come on soon after the first act of micturition following instrumentation. In most cases it will have been noticed that there was perhaps some slight resistance to the onward passage of the instrument—resistance, it may be, so slight that moderate pressure easily overcame it; on withdrawing the instrument a drop or two of blood was observed to follow it, indicating the infliction of a wound.

No symptoms occur immediately, but after micturition the patient is seized with shivering or perhaps a severe rigor, and experiences pain in the loins and back, often severe in nature. The temperature rises, and may reach 105°; the pulse is accelerated; headache and nausea are fairly constant; and vomiting and diarrhoea are occasional accompaniments of the condition. The urine is diminished in quantity and may be bloody. The cold stage is quickly succeeded by profuse sweating and a feeling of great heat. The temperature falls, the pains diminish and ultimately disappear, the urine loses its bloody tint (if such was present) and is secreted in larger quantity, and the patient quickly recovers and experiences no ill after-effects.

Such an attack usually lasts from twenty-four to thirty-six hours. No doubt it may attack alike those whose kidneys are known to be diseased and those in whom these organs are apparently healthy. In some cases the patient may remain febrile for a longer period than above stated—a matter for

anxiety, as it may indicate the supervention of acute nephritis. Subsequent instrumental attempts may induce other attacks, but by no means necessarily do so. That this form of urinary fever is of septic origin there can be no doubt, and for its prevention the surgeon should endeavour to avoid injury to the urethra, and should adopt antiseptic precautions. Those who believe in the neurotic origin of this form of fever advise the administration of quinine and opium for some days before any instrumentation is resorted to, but this treatment is of no practical value.

The treatment of the patient during the attack is conducted on ordinary principles. During the cold stage the patient should be wrapped in blankets, and hot bottles should be applied; hot drinks may be freely taken, but alcohol is to be avoided. The sweating stage hardly calls for treatment; it is in itself a sign of recovery. The bowels should be opened by croton oil placed on the back of the tongue, and hot fomentations may be applied to the loins if there be much pain. Complete rest for some days is advisable, and all irritation of the urethra must be avoided.

(3) *Recurrent urinary sepsis.*—In some cases recurrent febrile attacks similar to that just described may occur at intervals of two or three days, quite independently of any fresh mechanical irritation. During the interval between successive attacks the patient is apparently quite well. Such cases appear to be analogous to chronic septic intoxication as met with in wounds elsewhere. The treatment is conducted on the same lines as above indicated; the bowels should be kept open freely, and diuretics with diaphoretics are useful. In malarious subjects quinine may prove beneficial.

(4) *Acute septic infection with or without suppuration* may occur after instrumentation with wound of the urethra as in wounds elsewhere. Secondary centres of inflammation in the viscera and distant parts, suppuration of the joints, with repeated rigors, high temperature, and the usual symptoms attendant on infective processes, serve to distinguish the case from one of acute urinary sepsis.

(5) *Persistent urinary fever.*—In some instances, especially in cases of enlarged prostate with residual urine necessitating the daily employment of the catheter, the patient falls into a general state of ill-health, insidious in its onset and progress, and not infrequently ending in death.

In such cases it will be found that there is old-standing disease of the kidneys. The irritation of the urethra appears to light up fresh mischief—mischief in many cases added to by the concomitant absorption of septic material. In cases of enlarged prostate with residual urine, there is unfortunately in many cases an ample source of septicity in the decomposing urine present in the bladder.

The symptoms may date from the first passing of the catheter. There is very rarely any decided rigor, and the symptoms, unless distinctly septicaemic in nature, may be at first indefinite. The patient complains of general malaise, loss of appetite, and perhaps a feeling of chilliness. Fever may be entirely absent, and is never very marked. The urine is not diminished in quantity as a rule, nor is there any noticeable alteration in the excretion of urea. Perhaps the symptoms of this condition are best explained by the statement often made by the patient himself—‘He is not the same man that he

was before using the catheter,' and yet he is unable to state definitely from what he suffers.

In the later stages of a fatal case the condition of languor so commonly met with becomes more marked. The patient becomes drowsy and apathetic, and may wander a little at night. Sometimes there may be temporary improvement, only to be followed by a relapse. Death may occur in from six weeks to as many months. Fortunately many cases after some few weeks gradually recover.

In all cases in which the surgeon deems it necessary to resort to the habitual use of the catheter, it is most important that every care should be taken to avoid urinary fever. The patient should be confined to his room, which should be kept at an equable temperature; the bowels should be regulated, and the action of the skin and kidneys promoted; the diet should be light, nutritious, and non-stimulating. If the amount of residual urine is considerable, it should on no account be all drawn off at once, but the bladder must be gradually emptied in the course of a few days. Attention to these fundamental points will do much to ward off serious effects. Should they, however, in spite of all precautions, manifest themselves, the patient must be kept quiet in an equable temperature, and instrumentation must be carried out carefully and as seldom as is consistent with the exigencies of the case. The action of the bowels, skin, and kidneys must be regulated. If rest be broken, opium or some other form of narcotic must be given; but the use of opium requires prudence and supervision in view of the renal imperfection. Stimulants are frequently necessary. C. STONHAM.

URINE, Incontinence of.—The involuntary discharge of urine, the patient being either unable to retain it or unaware of its escape. See MIC-TURITION, Disorders of; and SPINAL CORD, Diseases of.

URINE, Morbid Conditions of.—As a result of morbid processes the normal constituents of the urine may be either increased or diminished in amount, or abnormal substances may be present.

Quantity.—The quantity of urine secreted may be either increased or diminished; if increased, the increase may be permanent or temporary. The conditions affecting the quantity of urine secreted are: (1) the amount of fluid ingested; (2) the quantity of fluid lost by other channels, more particularly the skin, the lungs, and the bowel; and (3) the quantity of fluid actually present in the tissues. The last factor does not vary greatly in conditions of health, but in renal diseases and other diseases accompanied by dropsy, great variations in the amount of the fluid in the tissues are met with, influencing the quantity of urine secreted. The proximate cause of the quantity of urine secreted is the rate of flow of the blood through the glomerular vessels; all conditions tending to diminish this are accompanied by a scanty flow of urine. There is further experimental evidence to show that great diminution in the amount of renal tissue (as, for instance, the removal of large portions of one kidney and the whole of the other) causes a great and permanent increase in the quantity of urine excreted.

A temporary increase in the quantity of urine excreted is seen in a number of conditions, some of nervous origin, as, for instance, the large excretion

which may occur not only in nervousness and fear, but also in a number of functional diseases of the nervous system, such as after epileptic seizures or asthma. In such diseases as diabetes insipidus and diabetes mellitus and in a large number of organic diseases of the kidney, more especially in granular kidney, in the contracted white kidney, in the amyloid kidney, and in cystic degeneration, the quantity of urine excreted is permanently increased. The latter are diseases diminishing the quantity of available kidney-substance.

In other renal diseases, as, for instance, ordinary chronic Bright's disease, the flow of urine is often diminished; but in these cases it is possible that the real cause of this is not always an incapacity on the part of the kidney to excrete, but rather the simultaneous presence of dropsy. Subsidence of dropsy is invariably accompanied by an increase in the excretion of urinary water without any other prominent change occurring in its composition. The quantity of urine is diminished in all conditions which impair the efficiency of the circulation through the organ, as in passive congestion and active congestion, and also in a certain number of destructive diseases, more especially acute and certain forms of chronic Bright's disease.

The diminution in the quantity may be so great as to amount to suppression, and two varieties of suppression are usually recognised, the obstructive and the non-obstructive. In *obstructive suppression* there is some mechanical impediment to the exit of urine along the ureter, produced by the impaction of a calculus or the pressure of a tumour. In some cases mere inflammatory thickening of the mucous membrane of the ureter is sufficient to cause obstruction. In true obstructive suppression little or no urine is pent up behind the obstruction, the secretion of the kidney having undergone complete arrest, and the term 'suppression' should be limited to this. In other cases the obstruction may lead to the distension of the ureter and pelvis, and so produce a hydro- or pyo-nephrosis.

Suppression may occur without the presence of any obstruction, and at least two forms of *non-obstructive suppression* may be recognised: (1) One, that in which where the circulation through the organ is arrested, either as a result of embolism or thrombosis of the renal vessels, large or small, or else owing to the presence of extreme congestion brought about by inflammation, set up by cantharides, scarlet fever, and other poisons, &c. (2) Non-obstructive suppression may also be seen without any serious lesion of the renal blood-vessels, and then it occurs apparently as a result of reflex influences, originating in some other part of the body. Such complete suppression may result from the passage of a catheter or from an exploratory nephrotomy, or even from the presence of acute disease in other parts, e.g. cystitis, peritonitis, &c. In most of these instances the kidney-tissues are not thoroughly healthy, but cases have been described where complete and fatal non-obstructive suppression has occurred as a result of injury or disease in some other part of the body, and yet the kidneys have not presented any signs of gross disease. See URINE, SUPPRESSION OF.

Colour.—The normal colour of the urine is dependent mainly on the presence of urochrome; small quantities of urobilin, uro-erythrin, and hæmatoporphyrin are also present. The urine also contains a number of chromogens, especially those

giving rise to indigo and skatol-pigments, in the form of indoxyl- and skatoxyl-sulphates of potassium. Indoxyl is also present in combination with glycuronic acid, and the normal urine may yield as much as twenty milligrammes of indigo. Several of these pigments and chromogens of normal urine have probably an intestinal origin, and this is certainly so in the case of indican. The source of the urochrome is by no means certain, and it has been thought to owe its origin to the action of microbes on bile-pigments in the alimentary canal; but several cases of biliary fistula with complete obstruction of the bile duct have been described where, notwithstanding the discharge of the whole of the bile to the surface of the body, the urine has maintained its normal yellow colour. The colour of the urine is necessarily influenced by the quantity secreted, and thus in all diseases where there is a copious flow of urine the colour is usually pale. This is notably the case in diabetes and in renal diseases. In many renal diseases the colour, however, is pale, notwithstanding that the increase in the amount of the secretion is not necessarily very great. This is especially seen in some forms of chronic Bright's disease and in the granular kidney. Dark-coloured urines are secreted in conditions where the quantity of urine is diminished as a result of profuse perspiration, and also in a number of diseased conditions where the quantity is diminished, but in disease the dark colour is often dependent on the presence of abnormal pigments.

Urobilin normally occurs only in traces in the urine, but in a number of diseases it may be excreted in sufficient amount to cause the urine to become a dark mahogany colour. It was at one time supposed that this urobilin differed slightly from normal urobilin. This view is not now held; the two bodies are considered identical, the anomalous colour of the urine being dependent on the excretion of the urobilin in such large amounts. The presence of large quantities of urobilin in the urine causes the urine to assume a colour somewhat resembling that seen when bile is present. The two conditions can be distinguished by spectroscopical examination and by the absence of the reaction of bile. Urobilinuria is seen after free internal hæmorrhage, in pernicious anæmia, in cirrhosis and other diseases of the liver, in some febrile diseases, and in porphyria.

Hæmatoporphyrin.—This body is present in traces in normal urine, but occasionally it is excreted in sufficient amount to cause the urine to be of a deep red colour. Its presence in large amounts is especially associated with the administration of sulphonal, but only in exceptional instances. Smaller quantities of the same pigment are excreted in Addison's disease, in various destructive diseases of the liver and also in rheumatic fever. See HÆMATOPORPHYRINURIA, p. 615.

Hæmaturia.—In hæmaturia blood-corpuscles are present in the urine. See HÆMATURIA, p. 621.

Hæmoglobinuria.—In this condition the blood-pigment only is excreted. See HÆMOGLOBINURIA.

Choluria.—See JAUNDICE.

Melanuria.—Melanin is a sulphur-containing pigment and, in rare instances, is excreted in the urine; in such conditions the urine is often of a *café au lait* colour. On the addition of an oxidising agent, such as nitric acid, the urine becomes black owing to the conversion of the chromogen into melanin. Melanuria is seen as a rare complication

in several wasting diseases, but more especially in patients suffering from melanotic sarcoma. It is, however, not an invariable accompaniment of this condition, and a high degree of melanuria may exist without the presence of melanotic sarcoma. The only instance of melanuria seen by the writer was one of melanotic sarcoma of the liver secondary to a melanotic sarcoma of the eyeball. The addition of ferric chloride in cases of melanuria yields a greyish-brown or black precipitate soluble in excess of ferric chloride. Bromine-water gives a yellow precipitate which gradually turns black.

Pyrocatechin.—Pyrocatechin is said to occur in minute traces in the normal urine, but it is present in considerable amount, together with hydroquinone, in cases of carboluria. Both these substances exist in the urine as aromatic sulphates. The urine when passed is of a normal colour but darkens on exposure to air, and if large quantities are present may become quite black.

Alkaptonuria.—See p. 48.

Chyluria.—See pp. 300 and 543.

A number of drugs impart more or less characteristic colours to the urine. Santonin causes acid urine to become yellow or greenish in colour; the addition of a caustic alkali causes the urine to become a cherry-red or purple, the colour disappearing on the addition of an acid. The administration of rhubarb or senna may cause the urine to become red, on the addition of an alkali, from the presence of chrysophanic acid.

Reaction.—The acidity of normal urine is dependent on the presence of acid phosphates and, according to some authorities, to traces of free organic acids, such as lactic and hippuric (see ACIDITY, p. 14). The degree of acidity is not constant, being most marked in the morning urine and least marked after meals, when it may become not only neutral but even alkaline. The mixed urine of the twenty-four hours, however, is acid, and it is unusual even for the urine voided after a meal to be alkaline, although that secreted by the kidney may be; in other words admixture takes place in the bladder with previously secreted acid urine. The acidity of the urine is diminished by a vegetable diet and by the administration of alkalis or their compounds with vegetable acids, such as the citrates. The acidity is increased by a meat-diet, and is still more marked in cases of diabetes when diabetic coma is present. In this latter condition, however, the acidity is dependent on the presence of abnormal acids, especially β -oxybutyric acid (see DIABETES, p. 831). The acidity is liable to be increased if the quantity of urine is diminished, as in febrile conditions. In diseases of the stomach, especially in dilatation of the stomach, the acidity of the urine may be diminished, and it may even be alkaline.

Alkalinity of the urine may be due to the presence of either fixed or volatile alkali (see ALKALINITY, p. 44). The latter is a serious condition, dependent on the decomposition of the urine in some part of the urinary tract as the result of microbial infection. The infection usually reaches the urine owing to the introduction of a dirty catheter, but it is possible for the infecting agent to reach the urine in other ways, as, for instance, by the rupture of an abscess into some part of the urinary tract. It is also possible that the infecting agent may reach the bladder by passing up the urethra, or may reach the urine by excretion

through the kidney, as there are a great number of conditions in which micro-organisms may be excreted by the kidney.

Alkalinity of the urine owing to the presence of fixed alkali is not usually a condition of great moment. It may lead, however, to the excretion of a milky urine owing to the precipitation of phosphates.

Specific Gravity.—The specific gravity in health varies between 1015 and 1025. It is rare for it to be below this in health, although exceptional cases have been recorded with the lower limit of 1010, and others where it has been as high as 1038. Observations on the specific gravity of the urine are of little importance unless made with a specimen of the whole twenty-four hours' urine, as the specific gravity of individual samples of urine is influenced by a great number of conditions, e.g. drinking, sweating, nervousness, &c. A low specific gravity, if constant, is often a sign of disease, such as diabetes insipidus, and of a number of conditions in which the quantity of kidney-tissue is greatly diminished, as for instance cystic disease, hydronephrosis, granular kidney, amyloid disease, and some varieties of chronic Bright's disease. In a number of functional diseases, such as epilepsy, asthma and hysteria, large quantities of dilute urine may be secreted from time to time, and more especially after the subsidence of paroxysmal seizures. The specific gravity is raised by the presence of large quantities of urea and of salts in the urine, and especially by the presence of sugar. It is usual to suspect glycosuria where the specific gravity is over 1035. The real characteristic of glycosuria is rather that a pale, dilute-looking urine has a high specific gravity. Sugar may, however, be present with a specific gravity as low as 1010. The presence of albumin increases the specific gravity slightly, but in renal disease the specific gravity is usually low owing to the excretion of a urine poor in saline ingredients, and often deficient in urea and other extractives.

Urea.—From 20 to 40 grammes of urea are excreted daily in health, the average being approximately 30 grammes, corresponding to '5 grammes of urea per kilogram of body weight. The quantity excreted is greatly influenced by diet and also by the quantity of water drunk. Copious water-drinking increases notably, at any rate temporarily, the quantity of urea excreted. If very large quantities of nitrogenous foods are consumed, the whole of the nitrogen ingested is not excreted as urea owing to the production of diarrhoea whereby the excessive ingesta are got rid of. Quantitative observations on the amount of urea excreted in disease are of comparatively little value unless accurate determinations of the nitrogen in the ingesta and in the feces are made simultaneously. In diabetes mellitus large quantities of urea are excreted owing partly to the increased appetite, and also owing to the proteid tissue-waste that occurs in this disease. In diabetes insipidus the quantity is also slightly increased. In many diseases there may be no absolute increase, but only a relative increase; in other words urea-excretion may remain approximately at the normal amount notwithstanding a great diminution in the ingesta; this is notably the case in many febrile diseases.

In those diseases of the liver in which the liver-pancreas is diminished in amount, the excretion of urea is diminished, e.g. hepatic cirrhosis, primary and secondary atrophy, phosphorus-poisoning. In

acute yellow atrophy urea may almost disappear from the urine, the quantity excreted being so small. In all wasting diseases, such as carcinoma, and especially in carcinoma of the stomach, the amount of urea excreted may be very small.

In renal diseases great variations exist; in many chronic destructive diseases of the kidney, quantities of urea equal to the normal or but little below them may be excreted notwithstanding the great destruction of renal tissue, e.g. hydronephrosis, cystic kidneys, granular contracted kidney, and some forms of chronic Bright's disease. The percentage excreted, however, is nearly always below the normal, but there is not such a great diminution in the total amount owing to the increased excretion of urine seen in many of these diseases. In acute nephritis and in some forms of chronic nephritis the quantity excreted may be small. In some instances a sudden diminution in the quantity of urea excreted in chronic renal disease may point to the imminence of uræmia, but this complication may occur at a time when the patient is passing quantities of urea, little, if at all, below the normal. In many cases of renal disease the diminution in urea excreted is more apparent than real, and is dependent not so much on any incapacity on the part of the kidney to excrete, as upon the associated vomiting, diarrhoea, and albuminuria all diminishing the amount of proteid available for conversion into urea. The persistent excretion of a low percentage of urea is very suggestive of the existence of one of the more chronic and insidious forms of renal disease.

The name *azoturia* has been given to a condition in which the excretion of urea is excessive in proportion to the weight of the body. This may occur in persons who are apparently perfectly healthy, or it may be associated with gastric and intestinal derangement, together with various nervous symptoms.

Uric Acid.—Uric acid is present in the normal urine in quantities varying from half to one gramme, creatinin being more abundant but being of less importance owing to its free solubility. Uric acid derives most of its clinical importance from its insolubility, being soluble to the extent of 1 in 15,000 of cold water and at the temperature of the body of 1 in 7,000 to 8,000 parts of water. The normal urine may contain as much as two grammes of uric acid dissolved in the 1,500 to 2,000 c.c. of urine. Different authorities have explained the increased solubility of uric acid in the urine in different ways. According to some the uric acid is present in the urine in the form of a soluble quadriurate. According to others the uric acid exists in the urine in the form of an acid urate of sodium. The main reason for thinking that the uric acid in the urine was in the form of a quadriurate rested on the fact that, if the urine was allowed to stand without undergoing decomposition, a considerable proportion of the uric acid was deposited in the form of free uric acid. Further, the analyses of several urinary deposits yielded, according to Bence Jones, Scherer, and Roberts, results showing that the uric acid was present in larger amount than that necessary to form a biurate with all the bases present. Moreover the action of distilled water on these so-called quadriurates led to the formation of free uric acid and biurate of sodium in sensibly equal proportions, and this has been looked upon by some as a characteristic reaction of the quadriurates. The alterna-

tive view is to regard what have been looked upon as quadriurates as mixtures of uric acid and acid urate of sodium, and further that the deposition of free uric acid from urine kept from decomposition is dependent on an interaction between the acid urate of sodium and the acid phosphate of sodium. The liberation of free uric acid from an uratic deposit by the addition of distilled water may be dependent on the existence of uric acid in an amorphous form and its subsequent crystallisation as a result of the action of the water. Recent analyses of natural uratic sediments have shown that a certain quantity of phosphoric acid is present, and hence for these reasons the existence of quadriurates cannot be looked upon as certain. The deposition of uric acid from the urine is influenced mainly by the acidity of the urine, the quantity of pigment, and of salts present. The uric acid excreted in the urine has a double origin, part being derived from alloxur-bases in the food and part from the metabolism of the tissues. Milk, eggs, rice, white bread, potatoes, salad and cauliflower contain practically no alloxur-bases, and with a diet constructed from these substances the uric-acid secretion will be greatly diminished. It is not possible, inasmuch as part of the uric acid arises from the metabolism of the tissues, entirely to eliminate this substance from the urine.

The uric-acid excretion is diminished in many chronic diseases, in chlorosis and during the paroxysms of gout. It is increased in pernicious anæmia, in splenic leucocythæmia, in certain febrile diseases, in ague, and in some forms of diabetes mellitus. Uric acid normally is excreted in the form of an urate, and the normal urine does not deposit free uric acid when it cools. Further the quantity of urates is usually such that they are easily soluble in the urine when cool, but if the quantity of urate be diminished, or that of the urates much increased, it may readily come about that the urates are deposited in the well-known pink amorphous uratic sediment when the fluid cools. This deposition is more especially liable to take place in febrile diseases and in a large number of affections of the stomach, liver and digestive organs. Urates are also deposited freely in the dense urines secreted in cases of diseases of the heart and lungs. In some instances in addition to the amorphous urates of sodium, calcium, potassium and ammonium, crystalline urates of sodium and ammonium are excreted in the form of 'dumb-bell' and 'hedgehog' crystals or of rosettes, which may cause considerable irritation of the urinary passages, especially in children.

Oxalates.—Approximately 20 milligrammes of oxalic acid are excreted in the urine daily in the form of calcium oxalate, which is kept in solution owing to the acidity produced by the acid phosphate of sodium. It is probable that the oxalates do not arise from metabolism of the tissues of the body, but entirely from the oxalic acid contained in various articles of diet. The deposition of oxalate of lime in the urine may depend not so much on the quantity present as on other factors—e.g. the acidity of the urine may be such that it cannot hold it in solution. The mere deposition of oxalates in apparent abundance must not be taken as indicating a so-called oxaluria or increased excretion; this can only be determined by quantitative observations. Some cases of oxaluria, where the quantity excreted is large, are dependent on fermenta-

tion of the gastric contents associated more especially with a diminution in the secretion of the hydrochloric acid of the gastric juice.

The form of crystallisation of oxalate of lime is greatly influenced by the presence of colloid material, so that the presence of pus, blood, mucus or albumin in the urine may determine the formation of large crystals of oxalate of lime and so produce the nucleus of a calculus. See OXALIC ACID IN URINE, p. 1136.

Phosphates.—The phosphates present in the urine are the phosphates of potassium, sodium, calcium, and magnesium, the acidity of the urine being dependent on the acid phosphate of sodium. Approximately two-thirds of the phosphoric acid is in combination with the bases potassium and sodium in the form of soluble phosphates, the remaining third being in combination with calcium and magnesium forming the so-called earthy phosphates. From two to six grammes of phosphoric acid are excreted daily in the urine. Sodium and potassium phosphates are freely soluble in the urine, whether the salts formed be acid, neutral, or basic. The earthy phosphates are only soluble in acid urine and become deposited in neutral and alkaline urines, and to a small extent in faintly acid urines. Urines alkaline from the presence of ammonia contain ammonio-magnesium phosphate, which is readily deposited in the form of so-called triple-phosphate crystals. Occasionally small quantities of ammonio-magnesium phosphate may be deposited from urines still faintly acid. The quantity of phosphates excreted is largely dependent on the amount ingested in the food, but the quantity is to a certain extent influenced by the metabolic processes in the body, and in the later stages of febrile diseases it undergoes an increase. According to some authorities the phosphatic excretion is increased in certain forms of neurasthenia, and a condition of so-called phosphatic diabetes has been described where large quantities of urine are passed containing an excess of phosphates but no sugar. The quantity of phosphates can only be determined by quantitative determination, and the deposition of the earthy phosphates from the urine is no indication of the presence of an excessive excretion of phosphoric acid. The earthy phosphates tend to be deposited in all conditions in which the acidity of the urine is diminished, and hence it is common for the urine secreted after meals to be cloudy or even very turbid from the deposition of amorphous phosphates. Occasionally stellar phosphate or di-calcium phosphate occurs in the urine in some quantity. This has been described in diabetes and other maladies, especially wasting diseases where there is grave disturbance of nutrition. The deposition of triple phosphate from urines alkaline from decomposition is of serious import if it occurs in the bladder or urinary passages. The deposition of earthy phosphates due to a diminution in the acidity of the urine is usually readily ameliorated by measures directed to improving the digestion or by the administration of acids. Faintly acid or neutral or alkaline urines when heated often show a cloud owing to the precipitation of earthy phosphates, and if precautions are not taken to acidify the urine prior to the boiling this phosphatic cloud may be mistaken for the presence of albumin. It is probable that the precipitation of phosphates is dependent on the boiling of the urine causing a decomposition so that two molecules of di-calcic phosphate and one molecule of mono-calcic

phosphate lead to the formation of one molecule of triple and one molecule of di-calcic phosphate, and the tri-calcic phosphate being insoluble is precipitated.

Sulphates.—Sulphur is excreted in the urine in three forms. A small quantity is in combination with amides, forming bodies of the taurin-group. Cystin, a substance which is sometimes excreted in large quantity, is a body of similar constitution, taurin being amido-ethyl-sulphonic acid and cystin amido-sulpho-lactic acid (*see* CYSTINURIA, p. 359). The great bulk of the sulphur is excreted in the form of sulphates combined with the bases of sodium, potassium, and magnesium. A portion, however, of the sulphuric acid is in combination not only with one of these bases but also with aromatic bodies such as phenol, indol, skatol, cresol, forming the so-called aromatic sulphates. The sulphuric acid present both in the inorganic and aromatic sulphates is derived in part from the food and in part from the metabolism of the tissue-proteids. The aromatic sulphates are formed by the decomposition not only of proteids of the tissues, but also of the proteid matter present in the intestine. Normally, twelve to twenty times as much sulphuric acid is excreted in the form of inorganic sulphates as is excreted in the form of aromatic sulphates. The excretion of aromatic sulphates is greatly increased in all conditions of intestinal putrefaction and retention of intestinal contents, e.g. intestinal obstruction, intestinal ulceration, and peritonitis. They are also increased in such conditions as pulmonary gangrene and in pyæmia and deep-seated collections of pus. The increase is not only relative but also absolute. The ingestion of aromatic radicles, like phenol and other anilin-bodies, is followed by their excretion in the form of aromatic sulphates, and consequently there is a great diminution in the amount of ordinary sulphates in the urine in carbolic-acid poisoning.

Chlorides.—From ten to fifteen grammes of sodium chloride are excreted daily, but the quantity depends very largely on the amount in the food. In many febrile diseases the quantity of chlorides excreted is diminished during the height of the pyrexia, and this is more especially the case in pneumonia where, during the height of the disease, the chlorides may almost disappear from the urine. This diminished excretion is not, however, restricted to pneumonia, but may occur to a less extent in the other diseases where the body-temperature is high, as, for instance, tonsillitis.

Proteids.—The proteids usually met with in the urine in renal diseases are serum-albumen and serum-globulin and various forms of albumoses. The albuminuria of renal disease is probably always dependent on morbid changes in the epithelial structures of the kidney, both tubular and glomerular, and it is probable that the albuminuria is dependent on the action of various toxic substances damaging this epithelium, and so allowing the proteids of the blood to pass through. The origin of the albumosuria is more obscure (p. 35), inasmuch as the blood normally does not contain these bodies in quantity, if at all. The amount of proteid lost in the urine *per diem* is very variable, but may amount to as much as forty or more grammes. The greatest loss is seen in cases where the quantity of urine is considerably increased at a time when it contains a moderate percentage of albumen. Acute Bright's disease may lead to the excretion of a urine

loaded with albumin, but owing to the diminution in quantity of urine the total amount lost may not be as great as in cases of chronic renal disease where the percentage amount is less, but owing to the greatly increased quantity of urine excreted the total amount is greater. Amyloid disease and the contracted form of Bright's disease are the two conditions in which the greatest loss of albumin occurs. In the granular kidney and the cystic kidney the amounts are usually small, and in acute Bright's disease and in chronic Bright's disease, though the percentage amount is high, the total amount is moderate. *See* ALBUMINURIA; and ALBUMOSURIA.

Casts—hyaline, granular, epithelial, or consisting of blood or pus—are generally moulds or casts formed by the exudation of proteid matter into the tubules of the kidney. In other instances the epithelial elements of the tubules are incorporated in the casts forming the well-known epithelial casts, the cells of which may show signs of fatty degeneration. *See* URINARY DEPOSITS; and CASTS.

Ehrlich's Reaction is described on p. 1772.

JOHN ROSE BRADFORD.

URINE, Retention of.—A morbid condition in which there is difficulty or inability to expel the urine from the bladder. *See* MICTURITION.

URINE, Suppression of.—SYNON.—Fr. *Suppression de l'Urine*; *Anurie*; *Ischurie*; Ger. *Harnverhaltung*.—This term signifies an arrested or greatly diminished secretion of urine, which may result from some obstruction to the outflow, or from some interference with renal excretion, acting primarily or reflexly upon the kidney.

1. Obstructive Suppression.—When one kidney has already been rendered useless by disorganisation following tuberculosis, or as a result of renal calculus or other cause of hydronephrosis, the impaction of a calculus in the ureter of the opposite kidney may produce obstructive suppression. When both kidneys are physiologically active, the excretion may be arrested by any pressure simultaneously affecting both ureters, as with uterine cancer, which may either exert direct pressure or may occlude the ureters by dragging on the walls of the bladder, and thus narrowing the orifices of the ureters. Under these conditions a small quantity of urine may be passed, characterised by low specific gravity, by the small proportion of urea and of other normal constituents, and occasionally by the presence of a trace of albumen. Apart from the suppression of urine, the symptoms differ with the cause. When due to calculus, suppression is usually preceded by one or more attacks of renal colic and hæmaturia; suppression may remain the chief symptom for seven or eight days, and then death may occur suddenly, or for two or three days before death there may be muscular twitchings and weakness, contraction of pupils, drowsiness, and fall of temperature. Convulsions, dropsy, and ammoniacal or urinous odour of the breath are commonly absent.

2. Non-obstructive Suppression.—This may occur in the course of acute nephritis, with sub-acute nephritis in tubal or interstitial forms of Bright's disease, or with severe congestive conditions which may result from toxic agencies, from cholera or from other diseases. It may also ensue after irritation or injury by a catheter, or after

severe abdominal injuries or operations, especially when followed by acute peritonitis. Extensive burns are sometimes associated with suppression. In many of these conditions suppression must be regarded as a symptom produced reflexly through the nervous system, but in diphtheria and in scarlet fever it may result from irritation of the renal epithelium by toxins, comparable to the irritation of mineral acids, turpentine, and cantharides. The symptoms of non-obstructive suppression usually follow a rapid course; acute uræmic symptoms, severe vomiting, headache, convulsions, and coma cause death within two or three days.

When suppression occurs as a symptom of hysteria, the clinical aspect is far less grave; the arrest of the excretion of urine is as complete as in the other varieties, but it is accompanied by persistent vomiting of fluid which contains an appreciable quantity of urea. This condition ordinarily terminates with polyuria. These attacks may be repeated, and they may alternate with other hysterical manifestations. Hysterical suppression does not entail risk of uræmia.

TREATMENT.—This necessarily depends upon the cause of the suppression. The *obstructive* forms are occasionally amenable to surgical measures, which should be undertaken early, before the onset of muscular twitchings. In the *non-obstructive* varieties, especially when due to congestive or inflammatory affections of the kidneys, hot baths and other sudorific treatment are usually beneficial, and hydragogue purgatives may be employed. It is important to avoid the use of all diuretic remedies. *Hysterical* suppression is best treated with antispasmodics; no attempt should be made to check the vomiting.

NESTOR TIRARD.

UROSTEALITH.—See CONCRETIONS, p. 329.

URTICARIA.—SYNON.: *Cnidosis*; Nettlerash; Fr. *Urticaire*; Ger. *Nesselausschlag*.

DEFINITION.—Urticaria is an eruption accompanied by sensations of stinging, itching, and burning, like those produced by the sting of a nettle, and is characterised by the formation of wheals.

SYMPTOMS.—Urticaria is a very common disease, and is remarkable for its very variable and fugitive character, and for the great variety of circumstances under which it is developed. In all cases, however, the presence of wheals or some equivalent eruption is pathognomonic of the disease. The wheal consists of a circumscribed swelling of the skin, attended by active congestion of the vascular layer and an exudation of serum into the immediate neighbourhood of the vessels. This exudation does not usually extend into the epidermic structures. The degree of swelling is very variable, and depends on the amount of exudation. The occasional, almost sudden, disappearance of these curious formations is explained by the close proximity of the serous exudation to the absorbent vessels; for when the fluid finds its way into the epidermis, the process of resorption is much slower, and traces of the inflammation are often left behind for several days. Usually the central part of a fully developed wheal is pale, compared with the circumference. This is said to be due to the increased pressure of the exudation at that point, which is often so great as to empty the capillaries of the skin; it may, however, be caused by a

spasmodic contraction of the muscular coats of the vessels. At all events, vaso-motor disturbance is always present in the formation of a wheal.

The size, form, and general appearance of the wheals vary greatly. Sometimes they are no larger than a split pea, while at other times they may occupy a considerable surface, and cause much swelling of the skin. In typical examples they are round or oval; not infrequently they take the form of streaks or irregularly shaped patches. Sometimes the only eruption consists of a diffuse erythematous bright red blush. But whatever be its form, it is very evanescent, and liable to appear and disappear almost suddenly, leaving little or no trace behind. In all cases the subjective phenomena are nearly the same, and consist in excessive itching, tingling, stinging, and burning sensations. Sometimes the itching preponderates, at other times, perhaps, the stinging and burning sensations are the most marked, for, like the eruption itself, they are liable to constant change. These subjective sensations are by no means always proportional to the amount of visible eruption, and often remain long after this has disappeared. The rash occasionally appears with a sudden outburst all over the body, while at other times it is developed more slowly, and appears successively on different parts. It is roughly symmetrical, though the wheals have no definite arrangement. Sometimes the mucous membrane of the mouth, tongue, and larynx is involved. The sufferer invariably rubs and scratches the skin. This greatly aggravates the symptoms, and brings out fresh wheals wherever the finger-nails are applied, and, in severe cases, small excoriations and little spots of coagulated blood may be seen scattered about the skin as the result of scratching. An ordinary attack of urticaria may last from a few hours to several days, and in chronic forms of the disease one attack follows so closely on another as to give the impression that they are continuous; this, however, is not the case, as there are always remissions and exacerbations, and generally short intervals of complete freedom.

ÆTIOLOGY.—Urticaria is often only a symptomatic rash, and differs also from most other eruptions in the fact that it is a frequent attendant upon other diseases of the skin. The circumstances under which it is commonly met with may be divided conveniently into five groups: (1) It is extremely apt to complicate other irritable affections of the skin, such as scabies, phthiriasis, prurigo, and eczema. This is especially the case in children. The production of nettlerash under these circumstances is due to reflex action set up by scratching. (2) The bites and stings of poisonous insects, and the hairs of stinging plants, such as the common nettle, will produce in some people pretty severe local attacks of urticaria; a bee-sting will sometimes produce general urticaria, with much swelling of the face and limbs. (3) Nettlerash produced by irritation of some part of the mucous tract is not uncommon, and belongs also to the group of reflex nervous actions. We often meet with examples of this kind dependent on uterine irritation from pregnancy and other causes; also in children who suffer from worms. (4) Certain kinds of food are apt to produce nettlerash; among these may be specially mentioned shell-fish, mushrooms, acid wines, and many kinds of fruit; but in these cases much depends on the idiosyncrasy of the individual.

To this category belong the red rashes which are occasionally produced by certain drugs. Among the best known of these are copaiba, capsicum, turpentine, cubebs, and quinine (*see* DRUG-ERUPTIONS). (5) The most common form of urticaria is met with in people in whom it is impossible to trace a definite exciting cause, or in whom the exciting causes are trivial and various. In these cases the disease is distinctly and wholly of nervous origin, and occurs in people whose nervous system has been overtaxed, being often associated with such nervous symptoms as neuralgia. This form of the disease is always recurrent. It may come on with great regularity at a certain time of the day, and even replace neuralgia. Urticaria is occasionally rheumatic.

VARIETIES OF URTICARIA.—In addition to the ordinary form there are three principal varieties of urticaria: (1) Acute febrile urticaria; (2) Urticaria papulosa; (3) Urticaria pigmentosa.

1. *Acute febrile urticaria* is an idiopathic affection but rarely met with. It is ushered in with febrile symptoms, especially headache and sickness; the pulse and temperature may both be high, and the tongue furred. The characteristic feature is the suddenness of the attack, and the general outburst of red rash, which may cover the whole of the trunk, face, and limbs, and produce much swelling of the skin. The mucous membrane is also liable to be affected. This is especially the case about the fauces and throat, which become suddenly swollen, so as even to threaten suffocation. The disease may be distinguished from scarlet fever by the suddenness of the attack, the swelling of the skin, and the subjective sensations.

2. *Urticaria papulosa* is a disease which is met with chiefly in children, and is commonly known as lichen urticatus; it is very obstinate, usually lasting for several years, but with intervals of subsidence. The itching and irritation are very great, especially at night; this is always aggravated by the scratching of the patient. The eruption consists of wheals mixed with permanent pruriginous papules, which are probably the result of urticarial exudation into the cuticular structures. It is often mistaken for scabies, but does not especially affect those parts of the body which are liable to the attacks of the latter disease.

3. *Urticaria pigmentosa* is a peculiar and rare form of persistent urticaria, associated with buff-coloured pigmentation of the skin. The eruption appears as persistent nodules, and red measly-looking patches, mixed with yellowish pigment-spots, resembling pityriasis versicolor. The peculiarity of the colour, and the persistence of these spots, constitute the chief characteristics of this rare variety of urticaria. Usually, after the disease has lasted for some time, the neurotic symptoms subside, leaving simply raised patches of yellowish skin, either with or without nodules; but the more active symptoms may be reproduced by rubbing and scratching.

TREATMENT.—As has already been stated, urticaria, unlike most other skin-diseases, is a symptomatic rash rather than a definite disease. That it is very difficult to deal with is proved by the vast number of different remedies recommended by writers on this subject. The first point in any given case is to ascertain whether there is any definite local cause of irritation giving rise to the nettlerash; and with this view the skin should be

carefully examined for bug-bites and pediculi, which are very common exciting causes among the poorer classes. It must not be forgotten that the dye or dressing of the underclothes is sometimes a local irritant to the skin. If we fail to find any external cause of irritation, our attention should next be directed to the alimentary canal. Worms in children are not an infrequent cause of urticaria, and injudicious feeding may be also mentioned as occasionally giving rise to it; therefore, in treating urticaria of this kind, a careful and well-regulated diet is in all cases indicated. With regard to medicines, those are most efficacious that promote the process of digestion; one of the most generally useful is a mixture containing carbonate of magnesium and bicarbonate of sodium, with some aromatic or bitter infusion, taken before each meal.

Subacute urticaria of the ordinary kind produced by poisoning from shell-fish or fungi or some other poisonous food is best relieved by a simple emetic and a quickly acting saline purge, so as to remove the offending matter from the stomach and intestinal canal.

A large proportion of cases of chronic urticaria are distinctly of neurotic origin, and are often associated with other disturbances of the nervous system. Of all remedies for this class of cases, the most generally useful is complete rest both of mind and body. Of medicines, quinine and arsenic may be mentioned as often beneficial, especially when the attacks are of a periodic character. Complete change of air sometimes succeeds when all other remedies fail. The malady is, however, always very obstinate.

The diseases of the uterus will be considered in the following sections:—

Methods of Physical Examination, p. 1810.

General Ætiology and Pathology, p. 1813.

Inflammatory and Congestive Diseases, p. 1813.

Displacements, p. 1816.

Carcinoma, p. 1818.

Other Tumours, p. 1820.

Methods of Physical Examination.—

1. *Digital Examination.*—Of all methods of examining the uterine organs, the most important is by the finger alone, nor is the necessary *tactus eruditus* by any means easy to acquire. In this country the lateral position is generally adopted, and, except under special circumstances, is preferable as involving less exposure than the dorsal. The patient should lie on her left side, with her hips as near the edge of the bed as possible. The semi-prone position is the most convenient, the patient lying more or less on her face, her left arm being placed behind her back, her knees being flexed, the upper one more so than the lower. A good position much facilitates a complete examination of the pelvic cavity, and attention to these details is never superfluous. The index finger of the right hand is now carefully introduced, at first in the axis of the vaginal outlet, and then in that of the pelvic brim. The unimpregnated uterus is suspended, as it were, at the top of the vaginal canal, into which the cervix projects. The latter is the part of the uterus

which the finger first reaches. As the normal direction of the uterus corresponds with the axis of the upper part of the pelvis, or, roughly speaking, with a line extending from the umbilicus to the coccyx, the cervix, in a healthy state, projects into the vagina, and points backwards towards the sacrum. Its shape varies in women who have had children, and in the unmarried or nulliparous. In the latter it is conical or nipple-shaped, and the opening of the os uteri is felt at the apex of the cone, as a circular aperture about the size of a pea. The anterior and posterior boundaries of the os uteri are known as the lips of the cervix, and they are very liable to alterations in size, becoming congested or enlarged under various morbid states, one often to a greater extent than the other. In women who have borne children the shape of the cervix is altered, and it becomes shorter and less regularly conical. The os is also changed from a circular opening into a transverse fissure, which is often more or less nodular and irregular at its edges, from lacerations of its tissues during labour; and is sometimes sufficiently open to admit the tip of the finger. When healthy, the mucous membrane covering the cervix is smooth and velvety to the touch; and through the speculum it is seen to be of a uniform rose-pink colour. Under various morbid conditions it becomes rough, granular, stripped of its epithelium, and covered with hypertrophied papillæ, and these alterations are of much importance from a diagnostic point of view. Having ascertained the conditions of the cervix, paying particular attention to its size, shape, density, and sensibility, and to the shape of the os uteri, we may next proceed to examine the body of the uterus, passing the finger for this purpose past the cervix into the vaginal *cul-de-sac* behind, in front, and on either side of the uterus. In this way we feel whether the uterus is of normal size, or hypertrophied, as it often is; whether it is painful on pressure, or not; whether the uterus is freely movable by the finger, as it ought to be; or whether it is fixed and immovable in any part of its contour, as is often the case from inflammatory adhesion in its vicinity. Then again, in the same examination, we ascertain if any swelling exists in any part of the vaginal *cul-de-sac*, in front, behind, or at either side; and if so we try to determine its form, density, mobility, sensibility, and whether it is attached to the uterus, or is independent of it—all points of importance in arriving at an accurate diagnosis.

2. *Palpation*.—In this part of the examination we may often gain much assistance by combining *abdominal palpation* with vaginal examination. This method of bi-manual examination is always of great utility, and is sometimes indispensable for accurate diagnosis, and it is not so generally practised as it ought to be. It may be used to some extent while the patient is still lying on her side, the left hand being passed over her right hip. But to practise it thoroughly we must make the patient turn over on to her back, and then by pressing down the abdominal parietes with the left hand, acting in concert with the examining finger, we may thoroughly explore the pelvic cavity, and ascertain much more completely the form and relations of any tumour within it, than by vaginal examination alone. In some cases valuable information can be obtained by a rectal examination, especially when there is a swelling or tumour in Douglas's pouch, or attached to the posterior part

of the uterus, which may often be more accurately examined in this way than *per vaginam*. Simple abdominal palpation is often necessary in investigating the nature of any tumour supposed to be uterine. This is best carried out by laying the patient on her back, with her knees elevated, so as to relax the abdominal parietes. Percussion may often be advantageously combined with palpation. By using one or two fingers of the left hand as a pleximeter, and percussing with the right, we get a dull or tympanitic sound. If the latter is marked where there is much abdominal distension, we know that it indicates bowel distended with gas, and that there is probably no tumour. If there be dulness we can limit its area, and thus verify the results of palpation by mapping out any abdominal swelling met with. By these means also we discover the existence of fluid, either free in the abdomen, as in ascites, or contained in an ovarian cyst, the presence of fluctuation being often very readily determined.

3. *Use of the Speculum*.—We now proceed to consider the means at our disposal for examining the lower segment of the uterus with the eye; and from the re-invention of the speculum by Recamier, in the early part of the present century, we may date the commencement of the accurate study of uterine diseases. Numerous varieties of specula have been used. One often employed is Cusco's bivalve speculum (fig. 1). This has the advan-

FIG. 1.—Cusco's bivalve speculum.

tage of being easy to introduce, and of being adapted for either a capacious or a narrow vagina. It exposes the cervix well. The objections to it are its expense, and the fact that the metal is apt to be affected by various applications made to the cervix. Personally the writer prefers the tubular (Fergusson's) speculum (fig. 2), made of glass and

FIG. 2.—Fergusson's speculum.

covered with caoutchouc; and that which is bevelled at the end is the easiest to introduce, and the best for exposing the cervix. For cleanliness and brilliancy of illumination nothing can equal it. It is unaffected by any remedy used for local application, and has the advantage, which is wanting in all other specula, of embracing and steadying the cervix. In certain cases requiring local medication this is of great value. The objection to this form of speculum is its fragility, and the necessity of having instruments of various sizes, adapted to vaginæ of different dimensions. Practitioners, therefore, at a distance from surgical-instrument makers, will do well to provide themselves with the

more expensive instrument. Another form of speculum much used of late years, and in some cases superior to all others, is the 'duck-bill' speculum (fig. 3). This acts on the principle of drawing

FIG. 3.—The duck-bill speculum.

aside the perinæum and posterior vaginal wall, so as to allow air to distend the canal, and thus expose the cervix. For certain operations it is invaluable, and is most valuable even in ordinary examinations if the practitioner be skilled in its use. Considerable practice is required, however, to employ it satisfactorily, and it has the further drawback of necessitating the assistance of a second person.

The passing of a speculum, without pain, is an operation requiring some little practice to perform skilfully. In using a tubular glass speculum we must first choose one corresponding to the size of the vagina. This is a point of some importance; for the attempt to pass a large speculum into a small vagina causes much suffering; and if, on the other hand, too small an instrument be used, the cervix is not properly exposed. The patient should lie in the ordinary lateral position. The speculum should then be taken in the hollow of the right hand, its bevelled extremity resting on the under-surface of the index finger, the point of which should project a little over its edge, so as to guide it through the ostium vaginae. The point of the finger having been inserted into the vagina, the mouth of the speculum, the centre of which is grasped gently by the other fingers of the right hand, is held by the left hand, and the instrument, guided along the under-surface of the right index finger, is gently insinuated into the vagina, pressing back the perinæum as it enters. When it is fully introduced, it is turned gently round until the cervix is well exposed.

By the speculum we can speedily recognise any changes in the cervix and os uteri; we can see if the mucous membrane covering the former be pale or congested, smooth or abraded, or perhaps covered with granulations which bleed on being touched. The character and amount of discharge should be noted, and it may be wiped away with cotton wool held in the speculum-forceps. If the discharge come in great measure from the interior of the cervix and body of the womb, it is glairy, transparent, and very tenacious, and it may often be seen oozing out of the os uteri like white of egg. This is a certain sign of some morbid state of the mucous lining of the uterus. If the discharge come from the surface of the cervix, it is yellow and purulent in appearance. We can also recognise any abnormal growth that exists about the cervix, as, for instance, small gelatinous polypi which have evaded the sense of touch.

4. *Examination with the Sound.*—In certain cases in which more accurate information regarding the state of the uterus is required, other accessory means of examination are used. One of these is

the uterine sound (fig. 4), by means of which we can explore the interior of the uterus, measure its length, ascertain its direction, &c. The instrument is a thin rod of flexible metal, which can be bent into any desired shape, as it is sometimes necessary to adapt it to the altered curve of the uterine cavity. Its length is divided into inches by means of small notches in the metal, and at two and a half inches from its point is a small knob, indicating the normal length of the healthy uterus. In introducing the sound, the index finger of the right hand is passed into the vagina until its tip rests on the opening of the os uteri, which can be felt as a dimple or depression at the extremity of the cervix. The handle of the sound being lightly held in the left hand, its point, previously rendered aseptic and oiled, is guided along the palmar surface of the index finger of the right hand, until it enters the os uteri. It is a good plan to pass the sound through the vagina with its concavity looking towards the perinæum, and, after it has entered the os, to turn it gently round, so that its further progress may be in the ordinary direction of the uterine cavity. It is now gently pushed on, no force whatever being used, until its point is arrested by the fundus uteri. The tip of the right index finger is now placed at the os, and withdrawn in contact with the sound, so that the exact length to which it has entered may be ascertained. Considerable practice is required to pass the sound easily and without pain. Gentleness is necessary above all, and the sound should be coaxed to pass, being withdrawn if any resistance is met with, and never pushed on by force. Sometimes the sound will not pass in the ordinary direction, and then an endeavour must be made to adapt it to the curve of the uterine cavity, by bending it, or by passing it with its concavity backwards, as in the cases of retroflexion. The kind of information to be derived from the use of the sound will be best appreciated when treating of the separate diseases of the uterus.

FIG. 4.

5. *Dilatation of the Cervix.*—Another mode of examination, sometimes of much use, is the dilatation of the cervix by sponge or laminaria tents, or by Hegar's dilators, so as to admit of the introduction of a finger, and complete exploration of the uterine cavity. This is of immense service in cases of profuse menorrhagia, when the existence of an intra-uterine polypus, or portion of retained placenta, is suspected. The tent is a mass of compressed sponge, or a cylinder of *Laminaria digitata*, sufficiently small to enter the cervix, where it swells by the imbibition of moisture, and in doing so expands the surrounding tissues. These contrivances are properly now rarely used, on account of the difficulty of keeping them aseptic. Hegar's dilators are a series of graduated uterine bougies, made of vulcanite or metal, one of which is inserted into the uterus for about two minutes, beginning with No. 1, and gradually progressing to No. 23 or 24. By this means comparatively rapid and very effective

dilatation can be produced. Careful antiseptic precautions are essential, the dilators having been thoroughly boiled, and the operation must be performed under an anæsthetic. In the hands of an expert this is the best method at our disposal. Dilatation of the cervix is an operation that should not be undertaken without due consideration, as it is occasionally followed by considerable irritation.

General Ætiology and Pathology.—Much as is the attention which has been paid to uterine disease of late years, the opinions of the profession are as yet far from being decided on many elementary facts connected with it. It is beyond doubt that in this class of disease there are a series of symptoms common to all cases alike, such as pain in the lower part of the abdomen and back, inability to walk, leucorrhœal discharge, and disordered menstruation. If, however, modern writers on gynecology are consulted, it will be at once seen how various and irreconcilable are the explanations given of these symptoms. Thus some have taught that in inflammation and congestion, either of the cervix alone, or of the body or lining membrane of the uterus, we have the key to uterine pathology, and that all other changes detected in the uterus, such as displacements or flexions, are merely secondary results of the primary affection. On the other hand, many influential gynecologists have referred all uterine disease to mechanical causes: these considered displacements to be the primary cause of nearly every morbid state of the uterus, inflammation and congestion being merely secondary results; and naturally limited their treatment to an endeavour to replace and support the uterus in its normal position. The want of sufficient pathological study of morbid states of the uterus accounts for these varying opinions, which are much to be regretted; for, while one set of theorists apply themselves to an endeavour to relieve the inflammatory symptoms which they find, and which undoubtedly generally exist, by leeches, rest, and suitable local applications, they are apt to undervalue and neglect the mechanical means by which the displaced organ may be supported and steadied, on which their opponents too exclusively rely, but the real value of which it is impossible to call in question. Hence it follows that these partial and one-sided views lead to neglect of really important measures in one direction or the other, and to an amount of uncertainty in the mind of the profession which materially impedes a due recognition of the true importance of uterine disease. The fact, no doubt, is that neither of these opposing views is entirely right, but that there is a large measure of truth in both. Of the importance of inflammatory conditions no one, who impartially studies the clinical history of cases coming under his care, can entertain any reasonable doubt. The large, tender, and congested uterus, with its thickened and hypertrophied walls, the inflamed and granular mucous membrane covering the cervix, and pouring out abundance of morbid secretion, are conditions too obvious to be overlooked, and which are very frequently indeed associated with displacements, resulting from alterations in portions of the hypertrophied and overweighted organ. In some of these cases treatment directed to the original inflammatory condition may, of itself, suffice to effect a cure; in others this fails, unless attention be at the same time paid to the secondary displacements. On the other hand, it is equally impossible to ignore the

occasional remarkable influence of a simple displacement in producing disease. Who, for example, that has witnessed the long chain of distressing symptoms following a traumatic displacement, such as retroflexion from a fall, and the instantaneous relief sometimes following the introduction of a suitable pessary, can doubt this? In fact, all these conditions act and re-act on each other, and too excessive attention to one set of symptoms, based on theoretical dogmas, is as fallacious in uterine as in all other forms of disease.

The causes of uterine disease are very numerous. Among the most common may be mentioned errors in the mode of life consequent on the habits of modern society, such as tight-lacing, want of proper exercise, heated rooms, imprudence during menstruation, and the like. By far the most prolific source of uterine disease is to be found in the changes in the uterus consequent on parturition. Many accidental circumstances are apt to check and arrest the involution of the hypertrophied muscle-fibres which normally occurs after delivery. Hence the uterus remains large, congested, heavy, tender, and in the condition known as sub-involution, its cavity, as measured by the uterine sound, being elongated. In such cases the symptoms of uterine disease creep on insidiously after abortion or child-bearing, and, in a large proportion of cases, it will be possible to trace its origin to this source.

i. Inflammatory and Congestive Diseases.—Under this heading we may consider together those morbid states of the uterus which are variously described under such terms as *acute and chronic metritis*, *chronic parenchymatous metritis*, *areolar hyperplasia*, *acute and chronic endometritis*, *cervical endometritis*, *chronic uterine catarrh*, *granular degeneration of the cervix*, *ulceration of the cervix*, *congestion of the uterus*, and others.

This course involves the disadvantage of describing together diseases which, while they are very generally associated, and have much that is common in their symptomatology and treatment, may often, on the other hand, occur separately, and require important modifications in their management, according to the particular parts of the uterus affected. It is impossible, however, in so short an article, to discuss their individual peculiarities, as would naturally be done in a systematic treatise.

Acute inflammatory affections of the uterus, whether of its body or of its lining membrane, are of comparatively rare occurrence when unconnected with the puerperal state; and if a contrary opinion is expressed in many of our gynecological works, it is probably because various other inflammatory diseases, especially localised inflammations of the peritoneum and cellular tissue near the uterus, have been confounded with inflammations of the uterus itself. No practical harm will result, therefore, if we limit ourselves to the consideration of the more *chronic* conditions which are of such common occurrence, and produce such important consequences. One of the most common is undoubtedly congestion of the uterus, associated with enlargement of its vessels, and very often leading secondarily to more important and lasting disease, such as inflammation of its lining membrane, and the condition described as *areolar hyperplasia* or *chronic parenchymatous metritis*.

ÆTIOLOGY AND ANATOMICAL CHARACTERS.—The causes of such congestions are very numerous,

and indeed they occur normally in connection with every menstrual period, and may readily be perpetuated. By far the most important, however, is some interference with the proper involution of the uterus after delivery or abortion, to which a large proportion of such disease may be traced. If such congestion continue to be repeated, whatever be its cause, it very often leads to inflammation of the mucous membrane lining the cervix or body of the uterus; and then the diseases known as *corporeal* and *cervical endometritis* are established, which are of much importance. In these the largely developed glandular structures of the mucous membrane are the parts chiefly involved. On microscopical examination they are found altered in character, dilated at their mouths, and pouring out abundantly the transparent glairy mucus which is so characteristic of these affections. The villi of the cervix, both those within the canal and on its exterior, become altered, stripped of their epithelium, and eventually hypertrophied. These enlarged and abraded papillæ on the surface of the cervix, when seen through the speculum, form the characteristic red, strawberry-like abrasions round the os, which, under the name of ulceration, have formed so fruitful a subject of controversy in uterine disease. The detection of this condition—which is in no sense of the word an ulceration, since the epithelium is the only structure destroyed—is of much importance from a diagnostic point of view, but chiefly as leading to a knowledge of the more deep-seated changes which have produced it as a secondary result, which are themselves beyond the sphere of observation, but which are truly at the root of the evil. Hence the granular and abraded state of the cervix must be looked upon as a mere indication of disease elsewhere, not as being in itself a primary disease. Moreover, it is to be noted that many apparent abrasions of the cervix are really due to laceration of its tissue, and eversion of its altered lining membrane, a condition which can only be satisfactorily made out when the duck-bill speculum is used.

In more advanced stages of these inflammations of the mucous membrane deeper-seated alterations occur. The glands become obliterated or atrophied, and sometimes undergo cystic degeneration; and the whole mucous membrane may become adherent, stripped of its epithelium, covered with granulations, or finally converted into a layer of connective tissue covered with polymorphous cells (Klebs). In no long time, moreover, other morbid states of the uterus are developed. The organ becomes enlarged and tender to touch, and very often there is more or less forward or backward displacement. The cervix especially is apt to be hypertrophied, the os patulous, much leucorrhœal discharge is present, and all the distressing chain of symptoms accompanying confirmed uterine disease is established. Pathologically, this enlarged and tender state of the body and cervix of the uterus is, by most recent writers, believed to depend on excessive growth of the connective tissue, associated with vascular hyperæmia and hyperæsthesia of the nerves. It should be remembered, however, that it is identical with the condition commonly described as *chronic metritis*, the essentially inflammatory origin of which has long been an axiom in gynecology.

SYMPTOMS.—The symptoms accompanying these morbid states of the uterus are, in a great measure, those which are common to a large number of

uterine complaints. Pain in the lower part of the abdomen and back, increased by exercise of any kind; pain in defecation or micturition, and, in married women, on sexual intercourse; profuse glairy, tenacious, or purulent discharge, in old-standing cases very abundant; disordered menstruation, either scanty or irregular, or more often profuse, and frequently very painful; and eventually, if the true character of the disease be not recognised, a long and distressing catalogue of general symptoms, such as dyspepsia, hysteria, sickness or vomiting, headache, and others too protean in their character to be described, are among those which are most commonly observed.

The conditions met with on physical examination vary with the duration and extent of the disease, and the tissues of the uterus chiefly implicated. In the simpler cases the uterus is merely somewhat heavy and enlarged, and tender to the touch. When there is cervical or corporeal endometritis to any extent, the cervix is somewhat puffy and enlarged, and the external os patulous, so that the sound passes easily; and, in the same way, a dilated state of the cervical canal and internal os is recognised. Very generally also the surface of the cervix is rough, granular, and greatly abraded, bleeding on being touched, while strings of the characteristic gelatinous discharge are seen to exude from the os, and the cervix may be extensively fissured. Lastly, on bi-manual examination, in the more chronic and confirmed cases, the whole uterus will be found to be distinctly enlarged, probably somewhat elongated when measured by the sound, and very commonly the subject of some of the forms of displacement to be presently described.

PROGNOSIS.—The prognosis of these diseases must, of course, depend on their extent and duration. In their earlier stages they are readily susceptible of improvement and cure. In old-standing cases, which have lasted for years, and produced all the local and general results above described, the treatment is surrounded with difficulties, and the prospect is far from encouraging. It is of such states that Scanzoni speaks when he says, 'We do not remember a single case in which we have cured an abundant uterine leucorrhœa of several years' standing'—a dictum which was doubtless true with reference to the methods of treatment generally employed, but which fortunately cannot be endorsed by those who have employed more radical means of cure applied directly to the seat of the disease.

TREATMENT.—The treatment resolves itself into *general* and *local*. With regard to the former, the indications are to do all in our power to improve the nutrition and general health by ordinary means of treatment, such as attention to diet, fresh air, and the administration of appropriate remedies, of which such drugs as quinine, small doses of arsenic or strychnine, various ferruginous preparations, and bromide of potassium, either alone or in combination with other remedies, especially when there is much nervous irritability, are among the most generally useful. In old-standing cases resort to some of the Continental watering-places is occasionally of much service. These points, however, all depend on general principles, and cannot be further dwelt upon. Among the local measures, one of the first and most important to attend to is *rest*. If moving about produce pain, repose in the recumbent attitude ought certainly to be enforced,

and in recent and acute cases it should be absolute. In chronic cases continuous rest leads to the evils of deterioration of the general health, and the risk of acquiring habits of chronic invalidism. This must, then, be decided by the exigencies of the particular case, and the judgment of the practitioner. Generally, some daily gentle exercise, short of fatigue, should be advised, such as walking a little distance, driving in an easy carriage or bath-chair, or sitting in the open air. We may safely assume that exercise which does not produce or increase pain is doing good.

In cases of simple hyperæmia, especially when not of old standing, and when the uterus is tender to the touch, the local abstraction of blood is often of marked benefit. This may be effected either by applying from two to four leeches to the cervix through a cylindrical glass speculum, or, still better, by puncturing the cervix with a scarificator made for the purpose. Another very effectual means of relieving congestion and tenderness of the uterus is the use of pledgets of cotton wool, to which a string is attached, thoroughly soaked in glycerine, or in equal parts of simple glycerine and glycerine of ichthyol. If one of these is introduced into the vagina at night, and removed by means of the string in the morning, it will be found to produce an abundant watery discharge which saturates the linen of the patient. Great relief is thus given, and there is hardly any form of congestive uterine disease which is not benefited by this treatment, which most women can apply for themselves. The glycerine pledgets may be used every night, and they do not interfere with other modes of treatment. Continuous irrigations of hot water at 110° , night and morning, are also most serviceable, but to be of use not less than from one to two gallons must be used, with a suitable cistern-syringe. When properly applied these give immense relief. When the uterus is enlarged as well as tender, much benefit may be derived from the application of a pledget of iodised cotton to the cervix once a week. This should be passed through the speculum, and retained in position by a large pledget soaked in glycerine. It rarely causes pain; if it do, it should be at once removed; and it often remarkably reduces the size of the subinvolved and hypertrophied womb.

When there is evidence of endometritis, cervical or corporeal, other treatment is required. Now the desideratum is the application of alternative remedies to the diseased mucous membrane, not with the view of destroying it, but of so modifying its circulation and nutrition as to set up healthy action. The want of success so common in treating these cases may be traced to the fact that remedies have not been applied directly to the interior of the cervix or uterus, but that practitioners have contented themselves with treating the abraded or granular condition of the cervix, thus leaving the real seat of the disease untouched. Of late years much advance has been made, and we need not now talk of these chronic inflammatory affections of the lining membrane of the uterus in the same hopeless strain as before. One of the earliest modes of intra-uterine medication was the injection of fluids into the uterine cavity, such as tincture of iodine, or solutions of nitrate of silver. It was soon found that such injections, when the cervix had not been previously dilated, were apt to be followed by very alarming and dangerous symptoms; and it is now

generally admitted that they are inadmissible, unless the cervix has been previously dilated. This in itself is a procedure not to be lightly undertaken; and to repeat it frequently for a length of time—as would be essential in the treatment of these chronic cases—would be altogether out of the question. Some other method of attaining the desired object is therefore necessary, and this we obtain in perfection in the local application of the desired alternatives on suitable probes covered with a thin layer of cotton wool. By this means we can reach the mucous membrane at any part of the uterine cavity, and apply our remedies to it, without the necessity of any preliminary dilatation. The probes used by the writer are made of flexible metal (fig. 5), attached to a wooden handle, and of such a size that, when tightly wrapped round with a thin film of wool, they are not thicker than an ordinary uterine sound. They are covered by teasing out a small portion of wool, which is flattened between the palms of the hands. The probe is then dipped in water, to cause the wool to adhere, and by twisting round the handle, the wool being held between the forefinger and thumb of the left hand, the wool is smoothly and firmly wrapped round it. A little practice enables us to effect this with great neatness. The cervix being generally abnormally patulous, there is no difficulty in passing the probe through the os, previously exposed by the speculum, so as to reach the entire uterine cavity. The writer is in the habit of using a mixture of equal parts of crystallised carbolic acid and glycerine, as a local alternative, than which, he believes, there is no better application. Others, however, employ tincture of iodine, iodised phenol, or strong solutions of

FIG. 5.—Uterine Probes.

nitrate of silver; or they even, as recommended by Courty of Montpellier, pass a solid piece of nitrate of silver into the uterine cavity, leaving it there to melt and flow over the mucous membrane. The writer first swabs out the uterine cavity with one or two probes covered with dry wool, so as to remove the glutinous discharge as much as possible, and then passes in another probe, covered with the carbolic solution, so as to paint over the lining membrane of the cervix and body of the uterus, the external abrasions on the cervix being subsequently swabbed over with the same solution. This rarely gives rise to any pain or discomfort, and may be combined with the other plans of treatment already mentioned. Intra-uterine medication is most useful in the week immediately succeeding menstruation, when the superficial layer of the mucous membrane has been shed. If used too near the advent of the next period it may prove too irritating, and may bring on menstruation prematurely. As a rule, two applications, at intervals of a few days, in the early part of the inter-menstrual interval are amply sufficient, and it may be necessary to continue the treatment for many weeks or months. The writer has found the application of the negative pole of a galvanic current, through a

carefully insulated sound, a still more efficient and much more rapidly effectual method of intra-uterine medication. Some three or four applications of about 100 milliamperes will often effectually cure an intra-uterine leucorrhœa of long persistence. Unfortunately this is a method of treatment that is not generally applicable, since it requires an expensive plant, and very considerable practical experience, in order that it may be safely and efficiently used. Should laceration of the cervix and ectropion exist, Emmett's operation of trachelorrhaphy may be indicated. In very severe and obstinate cases of this kind Recamier used to scrape the uterine mucous membrane with a curette, so as to remove the granulations, especially when there was much metrorrhagia, and where there was reason to suspect the existence of a granular condition of the intra-uterine mucous membrane. This operation, 'curettement' or 'curetting,' has been much used of late years in such cases, as well as in chronic metrorrhagia. With strict antiseptic precautions it is quite safe and often effective. For its exact technique the reader must be referred to treatises on operative gynecology. The Dublin physicians recommend the application of fuming nitric acid, the cervix having been first dilated. This is a very strong measure, which we would not willingly adopt; but it is only fair to say that in the cases in which the writer has used it he has found it exceedingly useful. Valuable as intra-uterine medication certainly is in suitable cases, it should never be rashly or indiscriminately employed, and the writer would strongly insist that, before resorting to it, we should satisfy ourselves that the uterus is likely to bear it with impunity. Whenever, therefore, there is much tenderness of the womb on being touched, even when the case is otherwise suitable, the writer deems it advisable first to remove the congested condition by rest, the local abstraction of blood, the use of glycerine pledgets, hot-water irrigations, and other appropriate means; and, above all, the slightest evidence of any concomitant mischief or irritation, recent or of old standing, in the neighbourhood of the uterus, as shown by tenderness on pressure in the region of the broad ligaments, or fixity of the uterus, should be an absolute contra-indication.

2. **Displacements.**—Under this head we have to discuss a variety of diseases which have furnished a fruitful theme for controversy among gynecologists. Practically, physicians have divided themselves into two great schools with regard to these affections. One of these schools teaches that deviations of the uterus, in whatever direction they occur, whether forwards, backwards, or to either side (for descent of the uterus is of a different character, and must be separately discussed), form of themselves serious maladies accompanied by definite symptoms; and, as a logical deduction, that their treatment should primarily consist in the endeavour to replace the dislocated uterus in its normal position, and to maintain its position by mechanical contrivances known as *pessaries*. The other, and much larger, school holds that versions or flexions are not *per se* the cause of the undoubted symptoms which are met with in the cases in which they are found to be present; that flexions may, and often do, exist, without giving rise to any symptoms at all; that in all cases the symptoms may be traced to the uterine engorgements and congestions which accompany the deviations, and are their primary cause; and

that, therefore, it is unnecessary to pay attention to the displacement, which may be left to itself, while associated conditions are remedied by appropriate treatment. As is generally the case in all such controversies, it is probable that neither side is entirely in the right, and that the truth is to be found between the two. It is certain that in some cases, and under certain peculiarities of constitution, flexions produce symptoms which cannot be explained by the accompanying condition of the uterine structures, which can only be relieved by mechanically supporting the dislocated womb, and frequently are so relieved in the most remarkable manner. It is unquestionable, however, that marked flexions often exist without producing any appreciable symptoms; and as these are only found out accidentally, when, from some other cause, an examination is made, it is not improbable that such cases are much more common than is generally supposed. Upon the whole, the writer is inclined to think that displacements are rather the result than the cause of the associated morbid state of the uterus, and that one of the chief elements of treatment is to get rid of the congested, hypertrophied, or sub-involted state of the organ which produces them. But, even if this be admitted, it by no means follows that proper mechanical support is not needed. Far from this being the case, the writer believes it to be of the greatest possible value in supporting and steadying the overweighted and misplaced organ, thereby facilitating the removal of its morbid states, as well as relieving its most urgent symptoms.

Properly speaking, displacements of the uterus should be divided into two classes, *versions* and *flexions*. In the former the body of the uterus retains its normal shape, but not its normal direction, the entire organ being displaced either forwards (*ante-version*), backwards (*retro-version*), or to one side (*latero-version*). In the latter the shape of the uterus is altered, and its body is more or less acutely bent over the cervix in the form of a retort, producing the analogous conditions of *ante-flexion*, *retro-flexion*, or *latero-flexion*. But these states are very closely related to each other. Very often they are combined, they arise from similar causes, and they produce similar results. For the sake of brevity, therefore, they will be discussed together.

ÆTIOLOGY AND PATHOLOGY.—In order to understand how uterine displacements are produced, it is necessary to remember the means by which the uterus is maintained in its natural position. In the healthy state the uterus is situated high in the pelvic cavity, its fundus projecting somewhat above the plane of the pelvic brim, to the axis of which—that is, to a line drawn from the umbilicus to the coccyx—its own axis corresponds. It is maintained in this position partly by the muscular column of the vagina below, on which it is, as it were, poised; partly by the folds of the peritoneum forming Douglas's pouch behind, especially that portion of them called the utero-sacral ligaments; and partly by fibrous portions of pelvic fascia in front, attached to the pubes and passing by the side of the bladder. These are fixed to the uterus above the points of junction of the cervix and body, which is, therefore, the part of the organ least liable to change of position, and that at which flexions almost invariably take place. The fundus and body are much more mobile, but their movements are somewhat controlled by the round ligaments in front

and the broad ligaments at the side. The shape of the uterus is further maintained by the well-marked inherent rigidity of its tissue, and when this is altered by disease, as by congestion, sub-involution, and the like, displacements are much more apt to occur. The axis of the uterus is naturally apt to alter its position under various conditions. Thus it falls less or more forwards, according as the bladder is distended or otherwise. The uterus is also so placed that it ascends or descends with more or less freedom, and, as it does so, its axis corresponds with the axis of the pelvis at the particular level of that part. This fact goes far to explain why similar causes should at one period produce a forward, and at another a backward, displacement. The causes of displacements are chiefly any conditions which weaken the supports, or the resisting power, of the uterus. They are, therefore, most frequently found in association with the results of parturition—sub-involution, congestion, hyperplasia, and endometritis—which all diminish the inherent tonicity of the uterine walls, as well as weaken its supports, and prevent its regaining its natural shape when accidentally altered. The displacement itself may be caused or favoured by a variety of conditions, such as blows, falls, tight clothing, fibroid tumours developed in the uterine walls, and many other analogous states. When a flexion has been produced, the venous capillaries at the point of flexion are more or less obstructed, and the return of blood through them hindered, while the arteries continue to supply blood. The fundus, therefore, becomes congested, and subsequent structural alterations are developed. This point was insisted on by Graily Hewitt, and there can be no doubt of its accuracy. This explains the fact that, even when flexions are secondary, it is impossible to treat them satisfactorily by general means alone, and that, in course of time, a flexion, originally secondary in its causation, may require to be the chief object of treatment.

SYMPTOMS.—The symptoms of flexion of the uterus are in no way special. They are very much those which have already been described as accompanying the inflammatory varieties of uterine disease, and there are none which would enable the practitioner to foretell its existence with certainty. Among those most commonly observed are pain, weight, and bearing down, often decidedly increased by exercise of any kind, not infrequently rendering locomotion an impossibility; pain in one or other ovarian region; pain, and sometimes difficulty, in micturition; and various disorders of the menstrual function, more especially dysmenorrhœa and menorrhagia. After these have lasted some time the secondary derangements of the general health, so common in uterine disease, become established, and they lead to very serious consequences.

DIAGNOSIS.—The diagnosis of displacements is not difficult on vaginal examination. Supposing we have to do with a flexion, the cervix is found in its normal position; but either in front, behind, or, more rarely, on one or other side, is a rounded swelling about the size of half an orange, which can be pushed away by the examining finger. This might be confounded with various other conditions, such as small uterine fibroids, inflammatory exudation, hæmatocele, and small ovarian tumours. The diagnosis can, however, be readily cleared up by the sound, which will only pass in the direction in which the uterus is flexed; and, when it is turned

gently and cautiously round, the flexed fundus is lifted with it, and can no longer be felt in its former position. In ante- or retro-version, in addition to feeling the body of the uterus in its abnormal situation, we also find that the cervix is lifted out of its usual central position, and points forwards or backwards respectively.

TREATMENT.—In arranging a plan of treatment for uterine displacements, the concomitant conditions should be carefully attended to, and endometritis, congestion, and other complications relieved, if they exist. Unless this be done, the treatment may entirely fail, or may be very unnecessarily prolonged. Here we must limit ourselves to a very brief description of the best plans of mechanical treatment, strongly insisting, however, that they should not be too exclusively relied on. In backward displacements we have a very satisfactory means of supporting the misplaced organ in the well-known Hodge's pessary, numerous modifications of which exist. The important point to bear in mind is to select an instrument not too bulky, nor too long, for the individual case; the best material being either wire covered with soft india-rubber, vulcanite, or aluminium. The treatment often fails from want of proper selection; since a pessary, to be thoroughly useful, should be fitted as accurately as a shoe to a foot. Before introducing it, the sound should be gently passed, and the uterus replaced and held in its proper direction for a few minutes; and this manœuvre should be repeated from time to time, until the uterus does not re-assume its abnormal position. Even then, however, the pessary should be worn continuously for several months, until we feel quite sure that the displacement is permanently relieved. In many cases relief is instantaneous and remarkable; in others the fundus is too tender to bear the pressure of the pessary at all. When this is the case it should be removed, and an endeavour should be made to prepare the uterus for the use of this support by the local abstraction of blood, hot irrigations, the application of glycerine pledgets, or sedative pessaries. In introducing the Hodge's pessary, care should be taken to guide its upper part into its proper position behind the cervix, so as to press up the fundus; and, as the case improves, a larger instrument should be introduced, so as to follow up the re-treating fundus. Reposition of the uterus must, of course, never be attempted if there is reason to think that the fundus is bound down by adhesions, or if the uterus is very tender. In suitable cases, however, it materially facilitates the cure.

Anterior displacements must be treated on the same principles. Unfortunately, we do not possess anything like an equally good means of mechanical support, and a thoroughly efficient ante-flexion-pessary is still a desideratum. After trying a good many, the writer has come to the conclusion that the best is Graily Hewitt's vulcanite cradle-pessary, of a size suitable to the case. It is, however, difficult to introduce and remove. Nor can it always be borne. A well-fitting abdominal belt—and the best is that known as the American belt—is often of great assistance, by removing the weight of the superincumbent intestines. When all other means of restoring a flexed uterus fail, an intra-uterine stem-pessary may possibly succeed. Great caution, however, is necessary, and it should never be used unless the patient is under constant supervision, so that it may be

removed on the slightest appearance of undue irritation. Various operative measures have lately been adopted for the radical cure of uterine flexions. During the treatment of all flexions, rest is of paramount importance—not absolute, but as much as possible; and exercise should be very sparingly permitted, and only in a tentative manner. In this (and the same remark applies to every other form of uterine disease), care should be taken that local examinations should be as infrequent as the necessities of the case will allow. In all such cases there is a distinct danger that ill-judged and unnecessarily frequent local treatment may end in producing neurotic complications which may prove to be worse than the disease they profess to cure.

Prolapsus.—The only other displacement of the uterus requiring mention is descent or *prolapsus*, for the corresponding condition of undue elevation is of little practical importance. Descent of the uterus is far from rare, and it sometimes causes much discomfort. In it the uterus descends from its normal position to a varying extent, so that the prolapsus may be only partial, or it may be complete. When the entire uterus lies outside the vulva, along with the everted vagina, the mass is known as *procidencia uteri*.

ÆTIOLOGY AND PATHOLOGY.—Descent of the uterus depends upon a variety of causes which lead to a weakening of the uterine supports, either from above or below. These supports are chiefly, above, the various uterine ligaments, with the cellular tissue of the pelvis; below, the muscular column of the vagina. When from any cause, such as imperfect recovery after childbirth, senile absorption of adipose tissue, or rupture of the perinæum tending to prolapse of the vagina, they are no longer able to support the uterus efficiently, a comparatively slight cause may suffice to allow the womb to be pushed or drawn out of its place, as, for example, straining, lifting heavy weights, undue weight of the organ itself, and many other causes. As soon as the organ is prolapsed, to whatever degree this may occur, various morbid alterations are pretty sure to follow. The uterus becomes irritated, congested, and hypertrophied; and the everted mucous membrane of the vagina, which then covers it, becomes greatly altered, and assumes almost the appearance of skin. The most characteristic change, however, is generally elongation of the cervix, through traction from below, especially in cases in which prolapse follows previous descent of the vaginal walls. This elongation is due to yielding of the elastic tissue of the cervix, especially that portion above the roof of the vagina, which becomes greatly elongated, so that the sound introduced into the procident organ may pass for six or seven inches. When the uterus is replaced, the normal elasticity again comes into play, and the cervix rapidly contracts. This is the condition described by Huguier as *hypertrophic elongation of the cervix*, and it is rarely absent.

SYMPTOMS AND DIAGNOSIS.—The symptoms of prolapse of the womb are mainly due to the mechanical discomfort attending it, such as weight, difficulty in progression, interference with micturition, and much general inconvenience. The diagnosis is a matter of no difficulty. In the greater degrees the procident organ, covered with the hardened and altered vaginal mucous membrane, is at once apparent. The only condition with which it is at all likely to be confounded is old-standing inversion of the

uterus, and from this mistake the presence of the os uteri at the apex of the tumour will at once guard us. In the slighter degrees the cervix will be felt low in the vagina, or even at its orifice.

TREATMENT.—The treatment comprises two principal indications: First, rest, and consequent reduction of the size and weight of the procident organ; thereby greatly facilitating the second indication, namely, reposition, and maintenance of the uterus in its normal position. The effect of mere rest in diminishing the size of a prolapsed uterus is often very remarkable. A week or ten days in bed will often, of itself, reduce the cervical elongation to a considerable amount. Reposition is generally easily effected, and the chief difficulty is in support. In devising mechanical contrivances for keeping the uterus in position, the chief thing to bear in mind is that we should strengthen the natural uterine supports, so that they may regain their lost power of keeping the organ in its place. Hence the old ball-pessaries, which greatly distend the vagina, are absolutely inadmissible. In the slighter degrees an ordinary Hodge's pessary may answer every purpose, an endeavour being, at the same time, made to give better support from below. This is generally best done by a perineal pad, and also sometimes by using an astringent to the vagina, so as to make it a more efficient column of support, such as alum or oak-bark injections. In the greater degrees the best kind of pessary is that known as the 'vaginal stem,' which is in the shape of the cup of the ordinary toy known as the cup-and-ball, on the extremity of which the cervix rests, the other end being attached to a perineal band. If this does not answer, the pessary known as Zwancke's may succeed. This has the advantage of supporting the uterus without unduly distending the vagina. These measures are merely palliative, and a more radical cure may be hoped for by various operative procedures, into the details of which it is impossible to enter. It may suffice to say that they consist of: First, the removal of a small portion of the elongated cervix, either by the galvano-caustic wire or by the écraseur, in the hope of stimulating the remainder to contract, a procedure only occasionally required, but sometimes of undoubted utility. Secondly, the making of a new perinæum, in cases in which the prolapse seems secondary to undue descent of the vagina—a very valuable resource. Thirdly, narrowing of the vagina itself, for which a variety of operations are practised, which, like removal of a portion of the cervix, are rarely required.

3. **Carcinoma.**—Carcinomata are of common occurrence in the generative organs of females, and indeed they are more often met with in these than in any other part of the body.

ÆTIOLOGY.—Malignant disease of the uterus is most common about the middle period of life, the largest number of cases occurring between forty and fifty years of age. Occasionally we meet with it in old women who have long ceased to menstruate, or with rapidly advancing cases in younger women under thirty years of age. Hereditary predisposition apparently plays some part in its production, but not so much as was formerly believed. Frequent child-bearing has a decided influence in favouring its development, since the proportion of cases is larger in *multiparæ*. To this may be added any causes of constitutional debility, since malignant disease unquestionably occurs more often in

weak and unhealthy, than in strong and robust women.

ANATOMICAL CHARACTERS.—All the recognised forms of cancer occur in the uterus, but some of them are more common than others. Scirrhus is that which is least frequently observed, and medullary carcinoma most often. Klebs, however, has pointed out that in the earliest stages of carcinomatous disease the fibrous element preponderates in the affected part; while, as the malady progresses, cell-growth rapidly advances, so that in old-standing cases, and at *post-mortem* examinations, the medullary carcinoma is that which is found, although, at first, the scirrhus form may probably have existed. Another common variety is the epithelial cancer, which chiefly affects the mucous membrane of the cervix. In the large majority of cases the cervix is the part first affected, although, in exceptional instances, the disease may originate in the body of the uterus, the cervix being at first unimplicated.

At the commencement of the more ordinary variety the cervix is hard, somewhat nodular, and hypertrophied. It is comparatively rare for the disease to be seen at so early a stage, and, as the uterus is then quite movable, it is impossible to distinguish it from enlargement of the cervix due to congestive forms of disease. As the disease progresses, more and more tissue is involved; and the roof of the vagina becomes implicated, so that the uterus is fixed in a mass of new-growth. Before long a destructive process commences; portions of the growth slough and come away; hæmorrhage takes place from the opening of vessels; and in advanced stages of the disease, the cervix may be entirely destroyed, and even the bladder or rectum opened, so as to form a common opening with the vagina. The epithelial variety of cancer commences on the mucous surface of the cervix by the growth of its villi into a papillary tumour, which, at first, it may be impossible to distinguish from similar growths of a benign character. It rapidly spreads, however, soon forming a fungating soft mass, not unlike the flower of a cauliflower in appearance; hence its popular name 'the cauliflower excrescence.' As in medullary carcinoma, destructive changes soon occur; ulceration progresses; and, as the disease advances, the neighbouring structures are implicated. When the disease involves the more deeply seated tissues, *post-mortem* examination shows that the malignant growth there assumes more of the character of medullary cancer.

SYMPTOMS.—The earliest sign that arouses suspicion as to the existence of carcinoma is generally the occurrence of hæmorrhage, at first merely an excessive menstrual flow, subsequently loss of blood, sometimes very great in amount, at irregular intervals. Sometimes it is brought on by trivial causes, and a not infrequent complaint is that it always occurs after sexual intercourse. Excessive hæmorrhages, which are sometimes very alarming in amount, do not, as a rule, occur until advanced stages of the disease, when destruction of tissue is taking place. Another marked symptom is profuse discharge, often having a peculiar and pathognomonic fœtor, from the admixture of minute portions of sloughing tissue. In medullary carcinoma the discharge is not usually abundant, but it is sometimes very ichorous in character, producing excoriations, intense pruritus, or other disagreeable symptoms, in consequence of its irritating property.

In epithelioma it is often very abundant, watery in character, and tinged with blood. Pain is sometimes excessive. The writer has often, however, seen cases terminate fatally without any pain at all. General constitutional disturbance soon results; the peculiar cachexia of malignant disease is developed; and the patient becomes sallow, emaciated, and extremely debilitated.

DIAGNOSIS.—In advanced cases vaginal examination at once clears up the nature of the case. The cervix and roof of the vagina are infiltrated with the characteristic hard growth, and the uterus is quite fixed. If ulceration is advanced, the ragged broken edges of the cervix are apparent, bleeding on being touched, and breaking down under the finger. In a case of this kind mistake is hardly possible. In the earlier stages, before fixation and ulceration have advanced, error is easy, and it is far from uncommon to find non-malignant alterations of the cervix which have been mistaken for cancer, and even the reverse. Nothing but time will clear up such doubtful cases, and care should be taken not to give a positive diagnosis, unless the character of the case is marked and undoubted. The most difficult cases to diagnose are those in which the body of the uterus is alone affected. Here hæmorrhage, foetid discharge, and recurrent attacks of spasmodic pain (probably caused by the efforts of the uterus to expel discharge collected in its cavity) may arouse suspicion; but nothing except dilatation of the cervix, and thorough exploration of the uterine cavity, can clear up the nature of the case. On account of the friability of the tissues, this must always be done with great caution. In epithelial cancer the soft, fungating, bleeding, and easily broken-down mass can hardly be mistaken for anything else.

PROGNOSIS.—The prognosis, is of course, most unfavourable. There are, no doubt, a few authentic cases on record in which the patients have recovered after amputation of the cervix, but these are of the utmost rarity. In the vast majority death takes place, in a time varying from a few months to one or two years. Probably the disease advances most rapidly in younger patients, but few last longer than two years. Death takes place either from exhaustion, hæmorrhage, septicæmia, or some other complication. The writer has seen it on one or two occasions result from uræmia, the consequence of occlusion of the ureters through extension of the cancerous growth.

TREATMENT.—In the large majority of cases seen for the first time at an advanced stage, treatment must, of necessity, be palliative only. Here there are two chief indications—the maintenance of the general health; and the relief of pain, fœtor, or other distressing local complications. For the former we must rely mainly on a suitable diet, and the administration of some tonic which may be found to agree with the patient. The preparations of arsenic, as a rule, answer better than either iron or quinine. For the relief of pain the use of opiates, either in the form of morphine suppositories or administered subcutaneously, must be our sheet-anchor, and, when the pain is severe, it may be necessary to exhibit them in large doses. Fœtor may be best arrested by the local use of antiseptics. The plan which the writer has found to be most successful for the purpose is to introduce at night into the vagina a pledget of cotton wool, soaked in the glycerine of tannic acid, to which a small

quantity of the glycerine of carbolic acid has been added, in the proportion of about one ounce of the latter to eight ounces of the former. This effectually destroys foetor, while the astringent property of the tannic acid serves to check unduly rapid cell-growth, and prevent hæmorrhage. In the morning the vagina may be syringed out with a weak solution of creoline. Iodoform pessaries are also extremely useful for this purpose. When hæmorrhage is excessive, local hæmostatics, such as the diluted solution of perchloride of iron, must be used, and, if necessary, the vagina plugged. Surgical treatment may be adopted in the hope either of entirely removing the disease, or of lessening the hæmorrhage and discharges, and so retarding its progress. Either indication is most easily fulfilled in epithelial cancer. When this is limited to the cervix, and there is a fair margin of healthy tissue between the diseased portion of the cervix and the body of the uterus, supra-vaginal amputation or amputation by the galvano-caustic wire or wire écraseur should be resorted to, the actual cautery being subsequently freely applied to the stump, to destroy, as much as possible, any infiltrated cancer-cells. Even when this fails to prevent the recurrence of the disease, it will certainly prolong the life of the patient, and increase her comfort. In other cases destruction of the exuberant growth, both in epithelial and medullary cancer, may be advantageously effected by local caustic applications, such as strong solutions of chloride of zinc, nitric acid, or bromine. The same object has been sought by excising the diseased tissue, or by scraping it away as much as possible by peculiar scoop-shaped curettes made for the purpose, after which one of the above-mentioned caustics, or the actual cautery, may be applied. It is in the epitheliomatous form of malignant disease that this procedure is most valuable, and a carefully performed operation may prolong life for months or years.

Vaginal extirpation of the uterus has been largely practised, and improved technique has now reduced the mortality of the operation to very small limits. It has certainly not been followed by a satisfactory proportion of good results, as in most cases the disease has recurred within a comparatively short period. If, however, the disease is detected early, when the uterus is absolutely mobile, and there is good ground for hoping that there is no spread of the disease to the neighbouring glands and tissues, then the operation is certainly indicated; for even if the disease eventually recurs, the patient will have been saved much suffering from the sloughing of the uterine tissues, and she will at least have had the chance of complete cure. Some more thorough operative procedure is desirable, which shall do for uterine cancer what surgery has lately done for mammary cancer.

4. Other Tumours.—(1) *Fibroid Tumour.* By far the most common variety of uterine tumours—so common that, according to some authorities, it is found in 60 per cent. of women who die after middle age—is the so-called fibroid tumour (fibro-myoma).

ÆTIOLOGY.—Fibroid tumours are most common after twenty years of age, and in certain races—the African especially, they occur with great frequency. Beyond this nothing is known of the causes which produce or favour their growth.

ANATOMICAL CHARACTERS.—Fibromata are limited hypertrophies of the substance of the uterus,

existing in the form of more or less globular tumours, contained loosely in a capsule of fibro-cellular tissue. Structurally they are homologous with the tissue of the uterus itself, consisting of connective tissue, mixed with unstriped muscular fibres. They are found of every size, varying from dimensions scarcely larger than a millet-seed, up to enormous masses weighing as much as fifty pounds. Most generally they occupy the fundus and body of the womb, and they are conveniently divided into three classes, according to the position they occupy, namely, the *sub-peritoneal*, occupying chiefly the outer surface of the uterus; the *intra-mural*, chiefly developed in the substance of the walls; and the *sub-mucous*, which project into its cavity; and these may be either completely sessile, with a broad base of attachment, or they may have become more or less pedunculated, and then approach in character to the fibroid polyp.

When once formed, the future progress of fibroids of the womb varies much. Generally they are of very slow growth, and although malignant degeneration of their structure has been observed in rare instances, they most commonly exist for the rest of the patient's life, without giving rise to any troublesome effects, beyond those resulting from mechanical pressure, provided they are not accompanied by hæmorrhage. They are, however, subject to certain occasional alterations, such as inflammation and even sloughing, when mechanically injured, fatty and calcareous degeneration, and even to complete absorption. The possibility of their entire spontaneous disappearance has been strongly questioned. The writer has published several instances coming under his own observation, and the fact is now pretty generally admitted, the explanation probably being that on account of similarity of texture to the tissue of the uterus, they are subject to a process of involution like that which the uterus undergoes after delivery.

SYMPTOMS.—The symptoms of fibroids of the womb depend to a great extent on their position. The sub-peritoneal and interstitial varieties, when not very large, are often unaccompanied by any symptoms whatever, and those that exist are chiefly the result of mechanical pressure, such as weight, difficulty in walking, irritability of the bladder, constipation, and the like. In the sub-mucous variety, the prominent symptom is hæmorrhage, which sometimes occurs to a very alarming extent, and may even put the patient's life in danger. The source of the hæmorrhage is probably, in the majority of cases, minute capillary vessels in the mucous membrane covering the tumour, which keeps up irritation and congestion in its neighbourhood. It is similar in its origin, therefore, to the discharge in menstruation, and is greatest in amount at the menstrual period. The more severe hæmorrhages are probably caused by openings in various vessels developed in the periphery of the tumour, where the vessels are increased in size, just as they are in pregnancy.

The physical signs vary with the size and situation of the tumours. If large enough to be perceptible on abdominal palpation, they have generally a more or less rounded or lobular outline, and a hard, firm feel, without any fluctuation, which serves to distinguish them from other varieties of abdominal growth. Small tumours, however, growing from the sides of the uterus, may be easily confounded with other conditions, especially flexions

of the uterus, and deposits or exudations in its vicinity, such as hæmatocele, or pelvic cellulitis or peritonitis. The mobility of the uterus, which in the latter conditions is generally impaired, and the use of the uterine sound, which shows, in tumours, that the cavity of the uterus is considerably elongated, ought to enable us to avoid such mistakes.

TREATMENT.—The treatment resolves itself into *medical and surgical*. The former may be said to be powerless, all the so-called absorbents—iodides, bromides, preparations of calcium, Kreutznach and other waters, being admitted to be of no reliable value whatever. The subcutaneous injection of ergotin, in doses of half a grain to a grain daily, is said by Hildebrandt to be of great value, and is favourably spoken of by Atthill and other authors. It is, however, not reliable, and has often to be discontinued on account of the irritation produced by the injections. Of late years the treatment of such tumours by the electrical current, chiefly advocated by Apostoli, has been much discussed. It is claimed that electro-negative puncture has a decided effect in promoting absorption. The writer believes this to be frequently the case, but the procedure is not without risk, and it seems to him to be only very rarely permissible. Surgical methods of treatment are chiefly called for when the hæmorrhages are excessive and exhausting.

(a) The hæmostatic effect of the electro-positive current applied to the uterine cavity by an insulated platinum or carbon sound the writer believes to be of great value. He has now seen numerous cases in which the most severe hæmorrhages have been controlled by this means. It apparently acts by hardening the mucous covering of the tumour. The great objection to this treatment is the necessity for a special and costly plant, its length, and its uncertainty, for it unquestionably often fails. Under favourable circumstances, however, it is well worthy of trial.

(b) Injection of *styptics* into the uterine cavity, such as tincture of iodine, or diluted tincture of the perchloride of iron, is valuable when the hæmorrhage is excessive, but is a plan which should not be tried unless the cervix has been previously dilated.

(c) *Incision of the cervix* is decidedly beneficial when the hæmorrhage is frequent and severe, and is supposed to act by allowing the uterine fibres to contract upon the tumour.

(d) *Incision of the capsule of the tumour* itself is useful in certain sessile tumours projecting into the uterine cavity, certainly diminishing the hæmorrhage, and facilitating subsequent enucleation.

(e) *Removal of as much as possible of the tumour*, with the *écraseur* or galvano-caustic wire, may be undertaken, when it is so situated as to be within reach.

(f) *Enucleation* is very valuable when the tumour is projecting into the uterine cavity, and is already partially separated from its attachments. Under such circumstances it may be shelled out from its capsule *en masse*. The operation, however, is difficult and severe, and must be reserved for very urgent cases.

(g) *Hysterectomy*, with the removal of the mass of the tumour, and even of the entire uterus, has now been brought to such perfection, that it may be resorted to with much more confidence than formerly. The tendency in modern practice is,

perhaps, to adopt this expedient too often, and too early, in cases in which there was no urgent call for so serious a procedure.

(h) The artificial production of the menopause by *removal of the uterine appendages* is an operation which has been highly recommended, and is chiefly valuable when the tumour is of small size.

(2) *Polypus*.—Polypus of the uterus may be considered in connection with this subject, since the large majority of polypi are merely *fibroid* tumours, to a great extent enucleated from their capsules, and attached to the uterus by a narrow pedicle. There are, however, two other varieties described, the *glandular*, and the *cellular* polypi.

ANATOMICAL CHARACTERS.—The *glandular* polypus is a localised hypertrophy of connective tissue, rarely larger than an egg, and generally attached to the cervix; the *cellular* is a hypertrophy of some of the glandular structures of the cervix, either of the Nabothian follicles or the utricular glands, and it is generally of small size. *Fibroid* polypi, like fibroid tumours, may be of any dimensions, but they are commonly met with about the size of a small pear.

SYMPTOMS AND DIAGNOSIS.—Polypi are only important because of the hæmorrhage which so frequently accompanies them. When extruded from the cervix, or growing from it, they offer no difficulty in diagnosis. Nor is there any condition apt to be mistaken for them, except a chronic inversion of the womb, which can be readily differentiated by tracing the pedicle through the os, and finding that the sound enters the uterus to its usual depth. Intra-uterine polypi are much more difficult to discover, and here the only plan is complete dilatation of the cervix, and thorough exploration of the uterine cavity. This procedure is essential in all cases of severe hæmorrhage resisting ordinary hæmostatic treatment.

TREATMENT.—When once a polypus has been detected, the only treatment is its removal. In cases in which the polypus is chiefly in the vagina, this is easy enough, the wire of an *écraseur* being passed round the pedicle, which is separated in this way from its attachment. It is not essential that the wire should touch the base of the pedicle, since the part left, after the bulk of the polypus is removed, always shrivels up and disappears. In intra-uterine polypi it is sometimes difficult to pass the wire round the pedicle, but by thoroughly anæsthetising the patient, and using a single wire, it can generally be managed. No other method of removing polypi is so good. Excision may give rise to hæmorrhage, and the old method of ligature is dangerous from the risk of inducing septicæmia.

(3) *Fibro-cystic and Sarcomatous Tumours*.—The only other uterine growths requiring mention are the fibro-cystic tumours (cysto-fibroma, cysto-sarcoma), and the sarcomatous tumours.

The *fibro-cystic* tumour is specially important on account of its great resemblance to cystic tumours of the ovary, and the extreme difficulty of differential diagnosis, which is so great that probably there is no ovariologist of any experience who has not mistaken the one for the other. The fibro-cystic tumour is a fibroid tumour of the uterus, generally of the sub-peritoneal variety, which has grown to a large size from the development of cysts in its substance. This is most usually effected by degeneration of its tissue, which becomes

liquefied and transformed into an albuminous fluid. Thus we have a tumour partially solid, partially fluctuating—although rarely so distinctly so as an ovarian tumour—from which fluid can be drawn by an exploratory puncture, and which may attain dimensions, and produce constitutional effects, not less marked than those of ovarian cystic disease. The differential diagnosis may well baffle even the most expert gynaecologist. The sound may possibly enable us to ascertain the uterine character of the growth, as it enters for a considerable length, and on moving it the connection of the tumour with the uterus may be demonstrated. Atthill has laid stress on the character of the fluid removed on puncture as diagnostic, since, unlike ovarian fluid, it coagulates spontaneously on standing, and on microscopical examination elongated fibre-cells, similar to those of the uterus itself, are found in it. The prognosis of these growths is unfavourable, since they produce all the evil effects of ovarian tumours, and the risk attending their removal by operation, which is the only available method of treatment, is much greater than that of ovariotomy.

Sarcomatous tumours of the uterus have been but little studied. They are in many respects like fibroid growths, but have a marked tendency to fungate and ulcerate, and to return after removal. Hence, they hold a place midway between the benign fibroid and the malignant cancerous growths, and they generally spring from the uterine tissue, like the sub-mucous fibroids, but without any distinct capsule. The symptoms are chiefly those of fibroid in that situation, namely, hæmorrhage; profuse watery discharges, and sometimes pain, probably the result of uterine contractions. The treatment must consist either in complete hysterectomy, or, under certain circumstances, in the removal of as much as is possible of the tumour by the *écraseur* or galvano-caustic wire; and, if the nature of the tumour be ascertained, its attachment should be thoroughly cauterised with strong nitric acid.

Deciduoma malignum is the name given to a peculiar and very severe form of disease occurring shortly after child-birth or abortion, which has attracted much attention of late years. Pathologically it is of great interest because of its connection with recent pregnancy; clinically it is not different from a very rapidly progressing form of intra-uterine sarcoma (see p. 1314). Its diagnosis requires the dilatation of the uterine cavity, and thorough exploration under an anæsthetic, and this is called for when we meet with profuse hæmorrhage and offensive discharges shortly after labour or abortion. (See p. 1018). The only remedy is immediate vaginal hysterectomy, any merely palliative measures, such as curetting and the like, being worse than useless.

W. S. PLAYFAIR.

UVULA, Diseases of.—SYNON.: Fr. *Maladies de la Lette*; Ger. *Krankheiten des Zäpfchens*.—The uvula consists of a fold of mucous membrane enclosing muscles, aponeuroses, vessels, nerves, and glands. It may be bifid, either partially or completely, in cleft palate; it may be absent or rudimentary; and it may be attached irregularly.

From its intimate relation with the soft palate and other parts of the throat, naso-pharynx, and nose, it is frequently involved in pathological conditions affecting these structures. Indeed, it can scarcely be said to have any disease restricted to itself, but an extremely acute inflammatory oedema has been noted in gout, without coincidental implication of surrounding parts.

It may be affected by (1) Erosion in syphilis (mucous patches) and tuberculosis, including lupus; (2) Congestion and rash in acute specific fevers, e.g. scarlatina, small-pox, chicken-pox, &c.; (3) Oedema in acute pharyngitis, and hydræmia; (4) Membranous exudation in diphtheria, septic tonsillitis, gangrene; (5) Paralysis following diphtheria, or part of a bulbar paralysis; (6) New-growths—papilloma, cancer. See also p. 685.

Enlargement.—The condition of the uvula which most frequently calls for attention is simple hypertrophy or elongation combined with paresis, so that it is very imperfectly retracted when the effort is made.

ÆTIOLOGY.—This condition may be due to (1) nasal obstruction, whether it arise from hypertrophy of turbinates, spurs, deviation of septum, or overgrowth of the naso-pharyngeal tonsil (adenoids); (2) simple congestion of the pharynx from any cause, usually associated with paresis of the palate, so that the uvula not only is elongated, but is permitted to hang too low in the pharynx.

SYMPTOMS.—(1) Constant sensation of the presence of a foreign body in the throat, leading to hawking and coughing, and sometimes to inclination to retching—all worse on lying down; (2) alteration of voice—loss of power, clearness, and range; (3) spasm of glottis: the last is not common, but we have seen it occur where the uvula is greatly elongated.

TREATMENT.—Removal of the cause will cure a slight case of elongated uvula, but we must make the nose, naso-pharynx, and pharynx healthy to do this. Locally, astringent and antiseptic gargles and sprays will help. Where the hypertrophy is really considerable the only proper treatment is removal of a piece of the uvula by means of forceps and scissors after cocaineisation. Care should be taken to remove it obliquely so that the front is longer than the back, as causing less soreness in swallowing; and to leave a piece one-third of an inch in length; in fact we should only remove the redundant mucous membrane, leaving the original muscle intact.

J. BARCLAY BARON.

V

VACCINATION (*vacca*, a cow).—SYNON. : Fr. *Vaccination* ; Ger. *Kuhpockenimpfung*.

DEFINITION.—Inoculation with the material of vaccinia or the cow-pox for the purpose of protecting the person so inoculated or vaccinated from an attack, and especially from a severe or fatal attack, of small-pox. The material is now derived almost exclusively from the results of calf-inoculation and after-admixture with glycerine, in a manner to be presently described ; it is officially called *Glycerinated calf-lymph*, and is here spoken of as *Vaccine*.

The cow-pox, which is a natural, though not a common, disease of the cow and horse, never occurs spontaneously in the human subject. Nor is it communicated to him by effluvia, or in any other way than by the direct inoculation of its own specific virus. Such inoculation, before the time of Jenner, was merely accidental, and occurred with comparative rarity. There was a popular tradition that persons who had thus been accidentally vaccinated enjoyed immunity subsequently from small-pox. It was left for Jenner to demonstrate the facts upon which this tradition was founded, and to explain the deeply significant truth which accounted for their existence.

Relationship of Variola and Vaccinia.—

The title of Jenner's work published in 1798, viz. 'An Inquiry into the Causes and Effects of the Variolæ Vaccinæ,' carried the suggestion of identity of the two diseases, cow-pox and small-pox. It was, indeed, one of his fundamental doctrines that the cow-pox was the product of the same virus as that which produced the small-pox in man. The malignancy and peculiarly infectious character of human variola were not, in his view, any essential part of the effects producible by the variolous poison on the human constitution, but were properties at first accidentally superadded, and, when once acquired, capable of propagation. The author of this article as it first appeared in this Dictionary, Edward Cator Seaton (the father of the present writer), the chief authority of the time, and one who made the organisation of public vaccination in this country his life-work, upheld Jenner's views. The relation of cow-pox to small-pox has, however, until of late been the subject of doubt and conjecture. But now Monckton Copeman sums up the results obtained by numerous observers who, in various parts of the world, during the past century have endeavoured by experimental methods to solve the problem of the true relationship of the two diseases, and he declares without hesitation that : 'As the outcome of this work it may now be definitely stated that small-pox lymph, more especially if obtained from the primary vesicle of a case of the inoculated form of the disease, by passing through the system of the calf, can be so altered in character as to become deprived of its power of causing a generalised eruption, while inducing at the site of inoculation a vesicle indistinguishable from a typical vaccine vesicle ; and, more important still, that when transferred again to man, it has by such treatment completely lost its former infectious character. Such being the case, it may fairly be asserted that cow-pox—or rather that artificially inoculated form

of the disease which we term vaccinia—is nothing more nor less than variola modified by transmission through the bovine animal. An outbreak of small-pox, indeed, may be turned to account for raising, by appropriate experimental methods, a fresh stock of vaccine lymph.'

Vaccine.—Before proceeding to give an account of the phenomena of vaccination, it may be well to describe shortly the process of preparing vaccine, which, by the courtesy of Dr. Blaxall, the present writer has been able to observe for himself both at the Government Calf Vaccination Station at Lamb's Conduit Street, and in the Government laboratories on the Chelsea Embankment.

The material of vaccinia or cow-pox from which the lymph is derived came from various stocks (whose pedigree is recorded, but whose remote origin could not be demonstrated at the present day). It is grown on calves whose bellies are shaven for the purpose of inoculation with the virus, which is done by numerous long incisions. The resulting pocks or vesicles are carefully scooped out on the fifth day with a sterilised Volkmann's spoon, and transferred with aseptic precautions to bottles, and taken to the Government laboratories. The pulpy material is then finely ground up by machine, and subsequently triturated with four times its weight of a 50-per-cent. solution of chemically pure glycerine in distilled water. When the process of attrition and admixture is complete, the compound is a viscid fluid of a creamy consistence and appearance. This emulsion is run into 'stock-tubes,' i.e. miniature test-tubes, each containing 3 to 8 c.c. These, when filled, plugged, and sealed with aseptic precautions, are placed in earthenware jars and put in a dark cool cupboard or ice-chest, the temperature of which is kept at 15° C. the first week and at 10° C. afterwards. The glycerine possesses the peculiar property, which Monckton Copeman was the first to demonstrate in this country, viz. that organisms which might give a septic character to the stuff taken from the calves' bodies are destroyed without impairing the efficiency of the material, *quâ* vaccine, for practical use. After storage for about a month the process of bacteriological purification is found to be complete. How this has been effected is thus explained in simple language by Monckton Copeman :—

'There is much evidence to prove that the results following on vaccination are due to a specific contagium, and, moreover, that the particular micro-organism concerned is capable of existing, during one period of its life-cycle, in a resting or spore form, in which condition it is more resistant to the germicidal effects of glycerine than is the case with non-sporing microbes.'

The retention of the specific quality of the stuff is thus accounted for, while its purification is explained as follows :—

'By thoroughly incorporating the lymph or vesicle pulp with a sterilised 50 per cent. solution in water of chemically pure glycerine, and afterwards storing the mixture for some weeks prior to use, protected from light and air, all the ordinary saprophytes found associated with lymph are

eventually destroyed. This result is proved by the fact that no growth arises in any of the ordinary culture-media inoculated with such glycerinated lymph. This statement applies equally to the bacillus of tubercle and to the streptococcus of erysipelas, should these microbes have been originally present in, or have been added experimentally to, the lymph.'

As soon as the vaccine is proved to be bacteriologically pure by the tests applied week by week, capillary glass tubes of suitable size are charged with it and sent out in large numbers every day, ready for use by public vaccinators.

Performance of Vaccination.—Vaccine of clinical activity and bacteriological purity being thus produced, it becomes necessary for the purpose of efficient vaccination that it should be used directly or within two or three days, the operation being skilfully and thoroughly performed, with every possible attention to cleanliness, and with every practicable aseptic precaution. Non-recognition of the full importance of these details in the past may have contributed in some measure to the unpopularity of vaccination. But, in saying this, it is right to add that much more discredit has been brought on its prophylactic value by its very imperfect performance; that is to say, by private practitioners (not public vaccinators) being content with aiming at only producing one small vesicle. It is only too true that a very considerable part of the vaccination to-day is of this most unsatisfactory kind. On this and other points connected with the protective effects of vaccination, as to which there has been so much controversy, it is well to reproduce, in their own words, the conclusions arrived at by the Royal Commission in their Final Report in 1896, after their very prolonged investigation.

Paragraph 377 of the report (pp. 98-9), reads as follows:—

'We have not disregarded the arguments adduced for the purpose of showing that a belief in vaccination is unsupported by a just view of the facts. We have endeavoured to give full weight to them. Having done so, it has appeared to us impossible to resist the conclusion that vaccination has a protective effect in relation to small-pox. We think :

'1. That it diminishes the liability to be attacked by the disease.

'2. That it modifies the character of the disease, and renders it (a) less fatal and (b) of a milder or less severe type.

'3. That the protection it affords against attacks of the disease is greatest during the years immediately succeeding the operation of vaccination. It is impossible to fix with precision the length of this period of highest protection. Though not in all cases the same, if a period is to be fixed, it might, we think, fairly be said to cover in general a period of nine or ten years.

'4. That after the lapse of the period of highest protective potency, the efficacy of vaccination to protect against attack rapidly diminishes, but that it is still considerable in the next quinquennium, and possibly never altogether ceases.

'5. That its power to modify the character of the disease is also greatest in the period in which its power to protect from attack is greatest, but that its power thus to modify the disease does not diminish as rapidly as its protective influence against attacks, and its efficacy during the later periods of life to modify the disease is still very considerable.

'6. That re-vaccination restores the protection which lapse of time has diminished, but the evidence shows that this protection again diminishes, and that, to ensure the highest degree of protection which vaccination can give, the operation should be at intervals repeated.

'7. That the beneficial effects of vaccination are most experienced by those in whose case it has been most thorough. We think it may fairly be concluded, that where the vaccine matter is inserted in three or four places it is more effectual than when introduced into one or two places only; and that if the vaccination marks are of an area of half a square inch, they indicate a better state of protection than if their area be at all considerably below this.'

The object of the vaccinator should be to ensure the insertion of vaccine-matter in four separate places, so as to produce scars of the requisite size. The methods generally recommended are scarification by 'cross-hatching' or tattooing. The arm should be first washed with soap and warm water, and then carefully dried with a soft towel, gentle friction being employed. Vaccine is put on the surface of the arm, the skin being kept on the stretch by the fingers of the left hand, the operator scarifying through the vaccine, and being careful not to make his insertions too close together. An ordinary bleeding-lancet, the point of which has been slightly blunted, or a spear-pointed surgical needle, are the most suitable instruments. The lancet must, of course, be sterilised immediately before use. The advantage of the needle is that a new one can be employed on each occasion. Complicated instruments are inadvisable on account of the difficulty in keeping them clean.

In dealing with this part of the subject—viz. the performance of the operation—it remains to add a few words as to the age and state of health of the child at the time of vaccination.

The statutory period, after the expiration of which a parent having an unvaccinated child falls into default, has been extended from three to six months.

It is under ordinary circumstances a preliminary condition of the performance of vaccination that the child to be vaccinated should be healthy, and a careful examination to ascertain this is the first duty of the vaccinator. The child should not only be free from any acute febrile disease, but also from diarrhoea and from cutaneous diseases, especially those of the vesicular type. The states of constitution associated with herpes and eczema singularly interfere with the proper course of vaccination, and seem to be the most frequent causes of those spurious results of vaccination just described. They may both—especially intertrigo—without care, be overlooked; hence examination of the scalp, and of the folds of skin behind the ears, in the neck, and in the groins, is indispensable. Vaccination should also be postponed if erysipelas be prevalent in the neighbourhood in which the child is living, or if it has been recently exposed to the infection of measles or scarlatina. There is, however, a state of things under which these conditions must be disregarded—namely, when there may be *immediate* exposure to the infection of small-pox, as when an unvaccinated child is in a house in which the infection exists, or has come into direct contact with an infected person. Under such circumstances, it cannot be too strongly impressed that no age is too early for vaccination, and no state of health, except the presence of acute disease of a serious character, can be held to contra-

indicate it. Life then may depend on the promptitude with which the vaccination is done.

The Phenomena of Vaccination.—These are practically the same with the new vaccine as under the former system of arm-to-arm vaccination. Histologically there is no difference in the phenomena.

Course of Primary Vaccination.—When vaccine is inserted into the skin by puncture, or is applied to a small abraded surface of the skin of an unprotected person, no particular effect is noticeable till about the end of the second day, or early on the third day. By this time, if the vaccination be about to succeed, a slight papular elevation becomes perceptible. This by the fifth or sixth day has become a distinct vesicle of a bluish-white colour, with raised edge and central cup-like depression. By the eighth day (the day-week from that on which the lymph was inserted) it has attained its perfect growth; it is then plump, round, more decidedly pearl-coloured, and distended with clear lymph; its margin is firm and central depression very marked. On this day, or sometimes even by the end of the seventh day, a ring of inflammation, called the areola, begins to form about its base; and the vesicle and areola together continue to spread for the next two days. The areola is circular, and when fully developed has a diameter of from one to three inches, being then often attended by considerable hardness and swelling of the subjacent connective tissue. After the tenth day the areola begins to fade; and in two or three days more it has usually disappeared, along with any hardness or swelling which may have existed. With the decline of the areola the vesicle begins to dry in the centre; the lymph remaining in it becomes opaque and gradually concretes; and by the fourteenth or fifteenth day a hard brown scab is formed, which gradually contracts, dries, and blackens, and from the twentieth to the twenty-fifth day, but usually about the twenty-first day, falls off. There is then left a cicatrix, which is circular, somewhat depressed, foveated, sometimes radiating, and, with rare exceptions, permanent in after-life.

If the lymph has been inserted by two, three, or more punctures set near together about one spot, or by abrasion over a sufficient surface, two or more vesicles may arise at the spot; and in the course of their growth either form a large vesicle of a compound character, with but one central depression, or a crop of vesicles, generally coalescing, but each retaining its own central depression. These compound vesicles and crops are round, oval, or of irregular outline, according to the manner in which the cutis has been penetrated or exposed; and the shape of the resulting cicatrices varies accordingly.

Vaccination which has gone through the course above described is held to be protective against small-pox.

The constitutional symptoms attending these local phenomena are a rise of temperature, sometimes detectable by thermometer as early as the fourth day; more marked, but still often very slight, from the fifth to the seventh day; more obvious feverishness, with restlessness, and frequently derangement of the stomach and bowels, from the eighth to the tenth day—that is, during the stage of areola, subsiding as that subsides. The general symptoms are in most cases quite moderate, and often exceedingly slight. Occasionally, when the areola is at its height, swelling of the axillary glands may be

intense; and occasionally also at that period, in young children of full habit, especially in hot weather, an eruption of roseola (*Vaccinal roseola*) may occur, chiefly on the extremities; or a papular eruption (*Vaccinal lichen*), or a vesicular one—the vesicles, however, differing from vaccine-vesicles in being entirely free from central depression. The duration of any of these forms of eruption, when they do occur, is very transitory, usually not extending beyond a week, and very seldom indeed beyond the falling of the scab.

Deviations.—The above is a description of the regular course of vaccination. There may be some deviations in point of time, the development of the vesicle being somewhat retarded on the one hand or accelerated on the other. But if the phenomena are in all other respects regular, then variations in time do not, as far as known, affect the protective power of vaccination. It is, however, quite otherwise where the irregularity is in the course and character of the vesicle. Papules or vesicles which do not bear the character of the true vaccine-vesicle must be regarded with great suspicion, as not being worthy of reliance for protection against small-pox.

Complications.—The occurrence of complications in the course of primary vaccination should be very much diminished by the introduction of the new system. It is perhaps too early yet to judge of the effects of the substitution of glycerinated vaccine in place of the ‘arm-to-arm’ lymph, and other changes recently introduced into our national system of public vaccination. The present writer has officially seen thousands of vaccinations under the old system, but cannot as yet claim sufficient experience of the new system to make a fair comparison. But the accounts generally given by able and experienced observers and vaccinators are most favourable. We are, indeed, led to hope that the rare but serious risks of vaccination, such as erysipelas and other infective diseases, are things of the past, and that even those troublesome (though to a certain extent necessary) complications, perhaps rather lightly referred to as ‘sore arms,’ are likely to be very sensibly diminished under the new system.

Re-vaccination.—In some persons the regular phenomena of vaccination can only be produced once in the lifetime. But this is not always the case, and vesicles may be produced by a second vaccination not distinguishable in their appearance from primary vesicles, though usually having a smaller and more transitory areola, and leaving only a small cicatrix. Much the most frequently the result of that process is the production of a spurious papule or acuminate vesicle, with hard, irregular areola, reaching its height by the fifth or sixth day, and having by the eighth day an imperfect scab, which soon falls. There is often much itching and more serious local irritation; and the constitutional symptoms are out of all proportion more frequent after re-vaccination than after primary vaccination.

The question whether re-vaccination should be systematically carried out among the population generally, as in the case of primary vaccination, is one on which opinions of responsible officials are divided at the present day. The conclusions of the Royal Commission have already been quoted. The great value of vaccination, and the immense boon it has been to the community, were recognised by all the Commissioners except two. In legislating upon

the subject Parliament has shown a desire to promote the adoption of vaccination and to diminish as far as practicable the number of the unvaccinated infant and child-population, which if allowed to assume very large proportions would constitute a serious menace to the public health. For it must be clearly understood that no medical organisation, however complete, and no system of isolation, sanitation, and general preparedness for dealing with outbreaks, could be safely trusted to in the absence of systematic primary vaccination. Every medical officer of health, however strongly he might believe in the efficiency of the measures which he immediately directs, would shudder at the thought of a large population such as that of Gloucester or Leicester, for example, with organisations of such varying efficiency, being in a largely unprotected state and exposed to the virulent infection of small-pox. There can be no two opinions among such officials as to the desirability of maintaining a well-vaccinated population. And here it may be remarked that by a well-vaccinated population is meant a population with a proportion of infants 'accounted for' of at least 90 per cent. Moreover, it should be stipulated that vaccination is performed with a degree of efficiency nearly approaching that which is absolutely required of public vaccinators. The certificate of vaccination should, in fact, only be given where a defined standard has been attained. Some legislative or administrative order is necessary to secure this end. If at the same time the use of the vaccine manufactured by Government were made obligatory in all vaccinations performed by private practitioners, as well as public vaccinators, much would be done to strengthen our defences in respect of epidemic small-pox. But it is altogether another matter to advocate, as some eminent authorities on the subject have done of late, the re-vaccination of the whole population at stated periods. The inconvenience, to say the least, of the process has to be considered in relation to the risks of small-pox. In a well-vaccinated population small-pox would never be allowed to become generally epidemic if the sanitary organisation and administration were what it should be. The present writer has often directed attention to the achievements of local sanitary authorities in the way of cutting short outbreaks of small-pox and preventing epidemics. One most essential part of this system is that, concurrently with the isolation of the sick, the re-vaccination of all persons brought within the sphere and risk of small-pox is immediately attended to. The advantages of the plan, which only became possible when the system of notification came fully into operation, are obvious. The present writer desires to point out that experience has been steadily accumulating of late years which strongly confirms this view. Re-vaccination is of course an essential precaution for this purpose. It should be immediately resorted to by persons exposed to the risk of infection, and it should be part of the business of every local sanitary authority to warn them of their danger, to provide means of safety, and to enforce as far as possible the adoption of re-vaccination and other measures of precaution. With improvements in the practice of vaccination such as science has made possible, and with steadily improving local sanitary administration, we may reasonably hope that every person in any way brought within the sphere and risk of small-pox will be efficiently protected. The writer strongly

deprecates indiscriminate re-vaccination undertaken because of the fears of the individual, rather than in accordance with the judgment of the practitioner.

Such a scheme ought, in the opinion of the present writer, to be quite practicable in England. The discomfort entailed by the sore arm and a certain amount of constitutional disturbance is absolutely necessary in cases where re-vaccination is specially indicated; but the inconvenience or loss of wages would be confined to a comparatively very small number of persons—at any rate, only a fraction of those who would be incommoded by the larger and, as the present writer thinks, unnecessary scheme of general re-vaccination.

The above remarks apply to populations living under English systems of sanitary and public-health administration. In the case of persons going to the East, or to countries where small-pox is a prevailing disease, subject to no such control as that which has been established in Jenner's country, re-vaccination is recommended to all except young children with good primary vaccination-marks, or persons who have undoubtedly been already successfully re-vaccinated in adult life. EDWARD COX SEATON.

VAGINA, Diseases of.—SYNON.: Fr. *Maladies du Vagin*; Ger. *Krankheiten der Scheide*.

The vagina frequently participates in the morbid processes which affect the uterus and other neighbouring organs. The vaginal affection is then a matter of minor importance, and may not call for special recognition. But this canal is often the seat of independent diseases, the more important of which will now be considered.

1. Atresia.—Imperforate vagina is met with as a congenital or acquired malformation. *Congenital atresia* may occur alone; or it may be complicated with absence, imperfect development, or closure of the orifice of the uterus. Occasionally the vagina is bifid, and the atresia affects only one side, in which the menstrual fluid of the corresponding horn of the uterus may accumulate, producing the condition described as *hematocolpos lateralis*. The occlusion may, first, affect the organ in its entire length; or, secondly, for a half or third of its length, most frequently towards the lower extremity; or, thirdly, it may be simply membranous, as from a too complete hymen. The congenital atresia is usually complete, so that the passage to and from the uterus is perfectly occluded. *Acquired or accidental atresia*, on the other hand, may present any degree of constriction, from a slight and partial narrowing of the canal up to its total obliteration. We find it resulting, first, from sloughing after labour, when it is frequently complicated with vesical or rectal fistulæ; secondly, from sloughing after fever; thirdly, from chronic inflammations and ulcerations; fourthly, from repeated applications of caustics.

SYMPTOMS AND DIAGNOSIS.—There are three stages at which atresia of the vagina may betray itself by symptoms. First, after puberty has set in, the patient has the usual indications that ovulation is taking place, but she suffers from *amenorrhœa*. The uterine hæmorrhage is taking place; but the extravasated blood is detained above the seat of the occlusion, and does not appear externally. Secondly, in some women *dyspareunia* (impossibility of copulation) after marriage leads to the examination which discovers the obstruction. Thirdly, in the acquired variety the difficulty is

often only discovered in consequence of the *dystocia* that results from the resistance offered to the advance of the foetal head by the constriction of the canal. The physical examination may discover, first, on abdominal palpation, a swelling in the hypogastric or inguinal region, due to the accumulation of menstrual fluid in the upper parts of the sexual canals. Secondly, on vaginal exploration being attempted, either the finger is soon arrested within the labia, or a bulging, fluctuating pouch is felt. Thirdly, we then examine *per rectum* or *per vesicam* with sound or finger, or through these cavities simultaneously, combining the exploration by means of the fingers of one hand through the available openings in the pelvic floor, with pressure and palpation with the other hand above the pelvic brim. The exact seat and extent of the occlusion can thus be detected, and at the same time an estimate can be formed of the amount of accumulation that may have taken place above it.

PROGNOSIS.—(1) Where the obstructing membrane is thin, it may give way at a menstrual period, or undergo a gangrenous process. (2) The sac formed by the dilated uterine or Fallopian cavities may burst, and pour its contents into the peritoneal cavity. (3) In a considerable proportion of cases early menopause comes on, and lessens the risk. (4) Patients who suffer from atresia vaginæ, even when they have been relieved by operative measures, are said to show a tendency to die of consumption.

TREATMENT.—In view of the dangers associated with the accumulation of menstrual fluid in the genital canals, the indication usually becomes very clear for its evacuation by perforating the obstructing tissues. But this operation has often been followed by disastrous results. Not to speak of the risks of wounding the bladder or rectum, or of setting up pelvic cellulitis, in cases where there is total absence of the vagina, and a canal needs to be tunnelled to the uterus, emptying of a hæmatometra and hæmatocolpos has been followed by death, sometimes from septicæmia, sometimes from bursting of the sac above when pressure is made on it; or dangerous inflammation has been set up in the pelvic organs. Care must be taken never to empty the sac by pressure from above, but by washing it out with a warm antiseptic fluid through an opening, which must be made under antiseptic precautions. Where the atresia has been extensive, there is a strong tendency to its repeated closure. This must be averted by making the patient wear a glass or vulcanite tube filled with cotton wadding soaked in carbolised oil, through which the uterine cavity can be occasionally washed out until it has collapsed. This must be worn for some months, until the vaginal canal has fully cicatrised around it.

2. Displacements.—When the perinæum has become relaxed or lacerated, hernia of the pelvic contents is apt to occur to a greater or less extent. The descent of the uterus in such cases has commonly been regarded as their most important feature, and they have generally been described as *prolapsus uteri*. When the protrusion or herniation, however, is complete, the walls of the hernial sac are formed chiefly by the walls of the vagina, and we get the most extensive displacement, or *inversion*, of the vagina. The symptoms and treatment of this inversion belong to the history of uterine displacements. But we may have displacement of one or other of the vaginal walls as an

independent mischief, or as the most prominent disturbance, in a case where the retentive power of the pelvic floor is impaired. If the anterior wall of the vagina descend, it carries with it the back wall of the bladder—*cystocele*. If the posterior vaginal wall descend, it brings with it the anterior wall of the rectum—*rectocele*.

TREATMENT.—The treatment of these conditions is either palliative or radical. The palliative treatment is effected by the use of astringent injections, and the application of vaginal pessaries—such as the Hodge pessary with crossbars towards its lower end. The radical treatment implies a plastic operation for repair of the relaxed or ruptured perinæum, or for producing a contraction in the displaced vaginal wall.

3. Foreign Bodies.—The vaginal canal is sometimes found occupied by foreign bodies. Every gynaecologist has met with cases where pessaries have been left in for years, until by their presence and pressure they began to set up ulcerative processes in the vaginal walls. Introduced at first with a useful object, and producing for a time a beneficial effect, their presence has sometimes been forgotten, until the discharges they excited have recalled attention to them. But bodies of quite another kind are sometimes met with, usually introduced by patients with onanistic propensities. Corks, pieces of wood, pomade-pots, fir-tops, dram-glasses, &c., have been met with in such cases. Portions of glass specula and of glass syringes have sometimes broken off in the hands of practitioners or patients. Ascarides and other parasites seem occasionally to make their way from the anus into the vagina.

Some of these foreign bodies are very easy of removal. Others are a source of great difficulty—those more especially which have become embedded to some extent in the vaginal walls. Thus it may become necessary to anaesthetise the patient, to lay hold of the foreign body with a polypus-forceps or vulsellum, and to detach it with the fingers or with a knife from the tissues that have granulated round it, before it can be withdrawn.

4. Inflammation.—**SYNON.**: *Colpitis*; *Vaginitis*.—Apart from gonorrhoeal inflammation of the vagina, we may have colpitis of a non-specific character, either as a primary disease, originating in itself, or spreading to it from the neighbouring structures. The causes of inflammation commencing in the vagina are found in chills (puerperal or menstrual); injuries (as from rude use of obstetric and gynecological instruments); prolonged presence of pessaries; excessive coition; irritants (as in cases where nitrate of silver applied to the cervix has acted on the vaginal mucosa); neoplasms; and some of the fevers. In elderly women we meet with a *colpitis senilis* or *vetularum* (Ruge), the cause of which is not easily traceable, in which the mucous membrane, especially of the upper part of the vaginal tube, sheds its epithelial covering in patches, becomes studded here and there with papillary granulations, and shows a tendency to cicatricial contractions. In other women the colpitis in its acute forms is found as a catarrh of the mucosa, attended by swelling, rapid desquamation of epithelial cells, and exudation of a serous fluid, which, mixed with the granular cells, produces a milky discharge. In the chronic forms the discharge becomes more creamy or purulent as the exudation is less copious, and there is more exfoliation of

degenerated and often unripe epithelial cells; and then the surface is often thickly strewn with red papillæ, over which the epithelium is almost destroyed. The symptoms are local discomfort, and leucorrhœal discharges of various kinds; and the diagnosis is made by examination of the discharge, and exposure of the affected surface by means of the speculum.

TREATMENT.—The treatment in the acute stage is directed to keeping the part at rest, and using sedative injections. In the chronic forms the use of the injection or douche must be steadily persevered in. The canal must be washed out with a stream of hot water, in the last pint of which alum or some other astringent has been dissolved. Where an acute process is likely to become chronic, or in the chronic forms attended by granulations on the surface, it is well to apply with a mop or brush a solution of nitrate of silver containing half a drachm to the ounce. Frequently the use of pessaries of oxide of zinc, bismuth, or iodide of lead proves useful in cases where patients have difficulty in using the syringe or douche. In *colpitis senilis*, the distress which the patient feels from the irritating discharge is best relieved, and the unhealthy surface is most speedily brought to heal, by the application of bismuth-powder, through a speculum or other tube, to the mucous membrane, after washing or wiping away the secretion; or an injection of boric acid with cocaine may be used.

5. Injuries.—It is principally in connection with labour that the vaginal walls are liable to be injured. Not only in operative cases where the walls may get bruised and torn, or in tedious labours where the walls are so long compressed that they may afterwards slough and become the seat of fistulæ, but even in ordinary cases, the vaginal mucous membrane is almost always fissured, or torn more or less deeply, at its lower extremity. These lacerations are mainly important because of their liability to become the channels through which septic matters are absorbed in the puerperal patient. In every case where there is a chance of infection, the canal should be syringed with a solution of creolin, or perchloride of mercury, or carbolic acid; and it is a further safe precaution to keep the raw surface dusted with a powder of several grains of starch combined with one grain of salicylic acid, or with iodoform and bismuth.

6. Neoplasms.—*Fibromata* affect most frequently the anterior wall of the vagina. They may be either sessile or pedunculated. They do not give rise to much distress, except from their pressure on the bladder, or from their protruding through the vulva. Extirpation affords the only cure, and in carrying out the operation care has to be taken to avoid injuring the bladder or urethra when they are seated anteriorly, and the rectum when they spring from the posterior wall. *Sarcomata*, round-celled or spindle-celled, have been in some few cases found springing from the vaginal walls. They have sometimes been described as growing from the submucous tissue; and the writer has seen them in two instances develop from the submucous tissue of the back wall. In other cases the growths arose from the mucous membrane. Early extirpation is indicated. These growths tend to recur. *Carcinoma*, more markedly even than the other neoplasms, is oftener a secondary than a primary affection in the vaginal walls. It may, however, originate in the vagina itself, running a course at least as rapid

as in the uterus, and usually leading early to infiltration of the inguinal glands. It only admits of palliative treatment. *Cystomata*, like the simple solid tumours, are most frequent on the anterior wall, and arise in many cases from accumulation of fluid in portions of the duct of Gaertner that have remained unobliterated. The contents are usually pale, and, where they have attained the size of a walnut, watery. In the smaller cysts the contents are more viscid. Some seem to result from cavities into which blood has been extravasated, and then the contents are brownish. They must be freely evacuated, and iodine or nitrate of silver applied to their lining membrane; otherwise they are apt to refill.

7. Vaginismus.—Under this designation has been described an affection of the vaginal orifice which is not infrequent among recently married women, and which utterly unfits the subjects of it for enduring coition. In some of them the hymen is unruptured, and there are excoriations at its base, towards the navicular fossa. More frequently the hymen has been infringed, but the lacerations have not healed, or fissures have formed at the roots of the hymeneal flaps, and a chronic inflammation is set up in the tissues, which renders them exquisitely sensitive. In such a condition any touch, even of the finger, causes intense pain, and when an attempt is made to pass through the orifice, the constrictor vaginæ and the lower fibres of the levator ani are thrown into a tenesmic state, which prolongs the suffering. The leading symptom is the distressing dyspareunia; and the diagnosis is made by the touch of the finger, supplemented by inspection. An examination can often be effected only when the patient is placed under an anæsthetic.

TREATMENT.—Treatment of a palliative kind may be attempted, making the patient use sitz-baths and apply emollients and sedatives. But it is far more satisfactory to have recourse to radical measures. The patient being under the influence of chloroform, the fragments of the hymen should be pared or clipped off. An incision should be made on each side of the vaginal opening towards its posterior aspect, running in a direction outwards and backwards, and passing through the whole thickness of the mucous membrane and some portion of the thickness of the constrictor muscle. The points of four fingers of the hand, gathered together and well greased, should then be passed through the dilated opening, so as fully to distend it, and produce complete relaxation of the sphincter. With due care the bleeding is trifling; the wound heals kindly; and undue contraction is prevented by making the patient wear for half an hour or longer, twice a day, a thick vaginal bougie. For a time the introduction of the bougie is resented, but the pain passes off when it is kept in position; and after a few days its passage ceases to be painful. This operation can be carried out with a very confident expectation that the dyspareunia will disappear; and if no other complication be present, the probability is that conception will ensue.

ALEXANDER RUSSELL SIMPSON.

VALENCIA, on the East Coast of Spain.—A dry, variable, mild, winter climate; and important sea-bathing station. Mean winter temperature, 57° F. Prevailing winds E. (moist), W. and S.W. (rough). See CLIMATE, Treatment of Disease by.

VALS, in *Ardèche*, *France*. — Alkaline waters. See MINERAL WATERS.

VARICELLA (dim. of *Variola*).—A synonym for chicken-pox. See CHICKEN-POX.

VARICOCELE (*varix*, a dilated vein; and *κῆλη*, a tumour).—**SYNON.** : Fr. *Varicocèle*; Ger. *Krampfaderbruch*.

DEFINITION.—A dilated, elongated, and tortuous condition of the veins of the spermatic cord, due either to increased pressure within the vessels, or to diminished resistance in the walls of the vessels and the surrounding structures, or to overgrowth of Wolffian veins.

PATHOLOGY.—The testicle, probably, like other glands, receives supplies of blood varying with its activity; and the veins are numerous and tortuous, freely anastomose, are liable to intermittent compression in their passage through the inguinal canal from muscular contraction, and terminate on each side in a single vein, which, like the companion artery, is remarkable for its great length and small size. These conditions are favourable to the production of dilatation and varicosity. Diminished resistance in the walls of the vessels and surrounding structures is, however, probably the chief cause. Varicocele is so much more frequent in the left than in the right spermatic cord, and when present in both is so much larger in the left, that the inferior muscular development of the left side of the body from predominant use of the right is very possibly a predisposing cause. The termination of the left spermatic vein at right angles in the renal vein, as compared with the termination of the right vein at an acute angle in the inferior vena cava, and the relation of the left vein to the sigmoid flexure, have been suggested as possible exciting causes; but their influence, if any, must be slight. The epididymis and organ of Giralde's are developed from a highly vascular organ, the Wolffian body. It is probable that varicocele is sometimes dependent upon the non-disappearance and overgrowth of persistent Wolffian veins. Not infrequently the veins of the spermatic cord become varicose where they lie in the inguinal canal (*inguinal varicocele*). In the absence of a scrotal varicocele the tumour caused by the dilated veins is easily mistaken for an incomplete inguinal hernia.

SYMPTOMS.—Varicocele is generally painless, but is sometimes associated with neuralgia or hyperæsthesia of the testicle. The subjects of it sometimes complain of a feeling of weight or uneasiness in the part after standing or prolonged exercise; and in extreme cases, when the scrotum is very much relaxed, labouring men have found it a mechanical hindrance in their work. In the tropics a varicocele is nearly always painful, and the pain is aggravated by the fatigue of marching. The testicle is in many cases normal, but is sometimes soft and even atrophied, but these conditions of the testicle are probably the result of other causes, and not of the varicocele. In such cases the patient is generally very hypochondriacal. An *inguinal varicocele* may cause pain, appears when the patient stands up, disappears when he lies down, and has an impulse in coughing. But a scrotal varicocele is often present, and sometimes the dilated veins can be felt when the cord is pulled down.

DIAGNOSIS.—The diagnosis of scrotal varicocele is easy. The veins can be readily felt, and have

been aptly compared to a bag filled with worms. The position of the varicocele is usually above and behind the testicle; but it may vary and the tumour lie below the testis, under which circumstance it is apt to be overlooked. Varicocele may complicate inguinal hernia and hydrocele.

TREATMENT.—In slight cases of varicocele no treatment is required. The use of a light truss, with pressure sufficient to take off the weight of the superincumbent column of blood from the spermatic veins, without interfering with the current of blood through the spermatic artery, has been recommended with advantage. A well-fitting suspensory bandage, cold bathing, avoidance of constipation, and tonics, will suffice for most cases; but if operative interference be requisite, the writer (C. B. L.) has found excision of the veins most satisfactory. The bundles of veins should be transfixed, and tied so as to avoid slipping of the ligature. The latter may consist of silk or catgut. It is safest to drain the loose tissues of the scrotum for the first twenty-four hours. Subcutaneous ligature and division of the veins have been recommended; but the result is always uncertain, and sometimes unsuccessful. The treatment of inguinal varicocele consists in opening the inguinal canal, after which the veins can be isolated, transfixed, and tied, and the canal closed again.

JEREMIAH MCCARTHY.
C. B. LOCKWOOD.

'VARICOSE' GLANDS.—See FILARIASIS, p. 545.

VARICOSE VEINS.—See VEINS, Diseases of; and VARICOCELE.

VARIOLA (*varius*, spotted).—A synonym for small-pox. See SMALL-POX.

VARIOLOID (*variola*, small-pox; and *εἶδος*, form).—This term has been applied to a mild form of variola, the disease being modified by previous vaccination or inoculation. See SMALL-POX.

VEGETATIONS.—In modern pathology this term is generally applied to growths and deposits connected with the valves of the heart (see HEART, Inflammation of). The name is also given to excessive granulations on wounds, and to warty growths in any situation.

VEINS, Diseases of.—**SYNON.** : Fr. *Maladies des Veines*; Ger. *Krankheiten der Adern*.

The diseases of veins will be described in the following order: (1) Inflammation; (2) Varix; (3) Hypertrophy; (4) Atrophy; (5) Degenerations; (6) Phleboliths; (7) Wounds; (8) Air in Veins; (9) Parasites; and (10) New-Growths. Neither thrombosis nor pyæmia, except in so far as they affect the vessel-walls, will be discussed here. See PYÆMIA; THROMBOSIS; and VEINS, Entrance of Air into.

1. Inflammation.—**SYNON.** : Phlebitis; Fr. *Phlébite*; Ger. *Venenentzündung*.

DEFINITION.—Inflammation of the coats of a vein.

CLASSIFICATION.—Cases of phlebitis may be classified: (1) according to the *intensity* of the inflammation—acute, subacute, or chronic; (2) according to the *result* of the inflammation—whether the formation of new tissue (plastic) or suppuration (suppurative); (3) according to the

layer of the venous wall primarily or chiefly affected—endo-, meso-, and exo-, to which may be added as closely associated peri-phlebitis; or (4) according to the cause of the phlebitis, e.g. septic. Practically, however, we may discuss the subject under two heads, namely, *endophlebitis* and *periphlebitis*.

ÆTIOLOGY.—The following are more or less well-established causes of phlebitis:—

Mechanical injury.—This frequently, but not necessarily, leads to the formation of a thrombus—a further source of mechanical irritation. A wound of a vein is generally lost sight of in the injury of surrounding parts; but the degree of inflammation resulting in the vein-wall, like that in the wound at large, will depend upon whether the injury is or is not accompanied by infection with pyogenic organisms, or whether these subsequently gain access to the injured spot. The effect of chronic strain is shown in the thickening and sclerosis of the wall of a varicose vein.

The formation of a thrombus.—For the causes of this see THROMBOSIS. Here it will suffice to say that a certain unknown degree of alteration, by injury or disease, of the endothelial layer of a vein will induce the formation of a clot, and that this is favoured by slowness of the circulation and by some blood-states. The clot is an irritant, slight or intense. When the thrombus quickly clears up, and the vein becomes patent, we may presume that the changes in the vein-wall have been but slight; when the thrombus is the seat of infective softening, the wall of the vein may suppurate or necrose. Between these two extremes come the changes accompanying the 'organisation of a clot,' and the conversion of it and the vein-wall into a mass of fibrous tissue.

The existence of an inflammation in the tissues through which the vein passes.—When a periphlebitis exists, whether acute or chronic, it tends to spread to the wall of the vein, involving first the adventitia, and extending inwards until, perhaps, sufficient change of the intima is produced to cause thrombosis. The intensity of the phlebitis varies with that of the surrounding inflammation, but it does not follow that a venous wall exposed in an abscess will become the seat of abscess, nor even that it will be thrombosed, for the vein is not one with the tissue in which it lies. Still, it is not difficult for organisms in tissues round about a vein to invade the wall of the vein, to excite in it a process similar to that going on around it, and to penetrate to any thrombus which may form within it, causing it to undergo infective softening. In organs and parts which are the seats of sclerosis the veins undergo fibroid thickening, and contraction of their lumina. Gummatus and tubercular infiltrations of veins passing through parts which are the seats of late syphilitic or tubercular lesions occur; and softening of a tubercular lesion of a vein-wall may lead to discharge of the contents of the focus into the circulation, and to a more or less widespread outbreak of tuberculosis.

But *syphilis* and *tuberculosis* may affect the walls of veins directly, giving rise to small gummata and discrete tubercles in the walls. The former lead to changes similar to those in syphilitic arteritis. Either syphilitic or tubercular inflammation may lead to sclerosis of the wall with contraction of the lumen, and, very likely, thrombosis.

A hyperplastic phlebitis is described, correspond-

ing to endarteritis obliterans, but it is even less common, and the subendothelial thickenings are much less marked. The cause is unknown.

There is no *a priori* reason why acute inflammation excited by the presence of organisms should not start in the external and middle coats of veins, which are vascular; but there seems to be no pathological evidence of its occurrence. On the other hand, it seems probable that blood-borne germs do settle in the intima of veins in acute necrosis and in pyæmia, and induce such changes as lead to thrombosis. Again, if the changes in acute rheumatism in the non-vascular cardiac valves are not always due to organisms settling upon them, but are caused by some irritant in the blood, the vessels may be similarly affected; there is, however, nothing but theory to support this view. The recurrent phlebitis to which the gouty are liable may possibly own a pathology of this kind.

To sum up: the great causes of phlebitis are injury, the irritation of a thrombus, and infection from surrounding tissues. The settlement of germs in the endothelium from the blood seems probable.

MORBID ANATOMY AND HISTOLOGY.—When a thrombus forms, contraction of the vessel-wall and uniform reddish staining of the intima occur, exactly corresponding to the clot. The inner wall presents longitudinal folds, easily obliterated by distension. More or less injection of the vasa vasorum, more or less fluid and cellular infiltration, and consequent swelling and softening of the vein-wall, ensue, in proportion as the clot is more or less irritant. If the clot soon disappears, return to the normal is easy. If the clot organises, contraction of the vein upon the clot goes on; the clot is freely infiltrated by leucocytes from the vasa vasorum, and proportionately decolourised; new vessels form; fibrous tissue develops; and wall and clot are converted into a cord of connective tissue, in which the structure of the vein may for a long time remain more or less distinct. If the clot undergoes infective softening or putrefaction, the swelling and softening of the wall reach their greatest height; hæmorrhagic points and small collections of pus may be visible to the naked eye; under the microscope the wall is densely infiltrated with white and red corpuscles; and, finally, loss of fine structure and imperfect staining may indicate death of the part. The thrombus which has undergone infective softening may thus give rise to an abscess about the vein, and may burst through the venous wall—the most favourable termination; for it may ward off rupture of the central end of the clot into the circulation, and consequent septic embolism. These changes are well seen in cases of pyæmia, and in thrombosed veins starting from septic ulcers or wounds.

Exactly the same state of matters may be produced by a septic inflammation extending from without to the venous wall, and leading to thrombosis and infective softening of the thrombus, e.g. in thrombosis of the petrosal and lateral sinuses in middle-ear disease.

SYMPTOMS.—Thrombosis of a vein—generally of the leg—is usually spoken of as 'phlebitis.' The patient complains of pain in the part, either dull aching or sharp shooting; and on examination one feels a firm rounded cord, if the affected vein is superficial. The part is somewhat tender, there is usually slight œdema around the cord, and the

skin over it may be slightly or markedly reddened; these symptoms being due, apparently, to thrombosis causing a phlebitis and periphlebitis. Some, however, believe that these symptoms may arise from phlebitis without thrombosis, an inflammation spreading outwards from the wall of the vein. In the case of deep veins of no great size there may be no symptoms at all to indicate the occurrence of simple thrombosis, and it is evident from what we see in superficial veins that thrombi may cause very little irritation. When the vein thrombosed is a main one, more or less widespread oedema results, but this is a symptom of thrombosis, not of phlebitis.

When the thrombus undergoes infective softening, the vein-wall and the tissues for some distance round about it become the seat of an intense inflammation, the signs of which are obvious in the case of superficial veins; and in deep veins, like the jugular, fullness and tenderness along its course may be discovered. On the other hand, nothing used to be commoner than the occurrence of pyæmia, without any symptoms to guide the surgeon to the vein which was occupied by the breaking-down clot, unless a characteristic oedema was present.

No fresh symptoms accompany the spread of inflammation to the wall of a vein passing through a focus of inflammation, unless, again, thrombosis of it occurs and induces oedema.

Formerly, when almost all wounds suppurated, the thrombi which formed in veins, cut across in operations, were frequently infected with pyogenic and septic organisms, and the veins of bones which did not collapse on section were more liable than those of soft parts to infection. The result of the infection was sometimes a continued thrombosis of the vein, with infective softening of the clot, and thus arose a progressive phlebitis and a progressive inflammation of the tissues about the inflamed vein which, perhaps, ended in abscess. On the other hand, a very similar clinical result was produced by a septic inflammation of the lymphatics around the vein, leading to abscess in their course and, perhaps, to phlebitis by extension, and thrombosis with infective softening. These two conditions, forerunners of pyæmia, went by the name of *suppurative phlebitis*, and ranked high among the septic diseases of wounds.

PROGNOSIS.—In a simple phlebitis, not connected with a septic wound or an inflamed mucous membrane, the prognosis is good, as regards life. Serious embolism is the danger, but with ordinary care the probability is that the clot will completely disappear, and the vein become again pervious, or that it will become organised, and the vessels of the new connective tissue will establish a more or less complete communication between the parts above and below the obstruction. Thus oedema will be more or less completely removed. In infective phlebitis and thrombosis the prognosis is almost as serious as in former days.

TREATMENT.—In all forms of phlebitis we must ensure absolute rest by confining the patient to bed, and by fixing the whole limb between sand-bags, or by means of splints. This is essential to procure diminution of pain, and to lessen the chance of breaking off a fragment of the clot, whereby fatal embolism might be caused. Glycerine and belladonna smeared on the part, and hot fomentations or linseed poultices, are by far the most agreeable

and soothing application. When abscesses form, they should be incised and dressed with fomentations wrung out of hot perchloride-of-mercury lotion (1 : 2000). Any oedema or general thickening that may remain must be combated by Martin's elastic bandages and regular massage, after all danger of embolism is over. Medicines, except those given to support the patient's strength, such as cinchona bark, ammonia and the like, are not indicated. Opium is given only to allay pain, and the less the drug is used for that purpose the better. The treatment of infective thrombosis and phlebitis is to be conducted at first on the same principles; the further treatment is discussed under PYÆMIA. See PYÆMIA; and THROMBOSIS.

2. Varicose Veins.—SYNON.: Varix; Phlebectasis; Fr. *Varice*; Ger. *Krampfadern*.

DEFINITION.—Veins which are dilated out of proportion to the quantity of blood which should pass through them; wherefore the current in them is slowed.

ÆTIOLOGY.—It is conceivable (1) that the wall of a vein may yield under normal intravenous pressure; (2) that it may be dilated by increased intravenous pressure; or (3) that it may be dragged open. The last cause is probably at work when dilated veins are found traversing cicatricial tissue—e.g. in an organising thrombus—but it is of little importance as compared with the others mentioned.

(1) Although varicose veins are not inherited, the tendency to them appears to be hereditary. The walls of any given vein vary markedly in strength in different individuals, and at different spots in the same individual. Sabourroff has demonstrated these variations in strength and thickness of wall for the saphenous system. Weakness of venous walls may probably be acquired. Although we have no very certain knowledge about it, it is probable that from impaired circulation in a part malnutrition and degeneration of the walls of the veins in it will result, and that this degeneration will chiefly affect the contractile element, the loss of which is not compensated by increase in the inelastic, non-contractile fibrous element. Again, small varicose veins are common on mucosæ which are the seats of chronic catarrh, but their ætiology is complex. It is well known that under conditions of fatigue and exposure to heat, especially in air containing much moisture, the superficial veins dilate and form prominent objects on the surface; also, that in some persons this effect of 'relaxing' conditions is felt much sooner than in others. Thus a temporary weakness of the venous walls is produced; and if the conditions of life bring about this effect frequently, normal intravenous pressure may lead to permanent dilatation of veins—those which are weakest congenitally or owing to degeneration of muscle yielding first.

The 'normal intravenous pressure' is the sum of or difference between the driving force of the heart, the aspirating force of the thorax, and gravity. These may coincide in their action, or gravity may oppose the other two, and does so especially in the lower limbs and lower parts of the trunk, where the veins are thicker-walled in proportion to the strain which they have to bear. The effect of gravity on a vein-wall is proportionate to the height of the column of blood in the vein, and is therefore greater in the lower limbs of tall than of short people; its effect is constant as long as the height of the column of blood in the vein and the lumen of the vein are unaltered.

The element of *time* is a most important one in considering the dilating action of the normal pressure. No tissue in the body is able to bear, continuously or repeatedly, for long periods the maximum strain which it is capable of bearing without at once yielding. The more perfectly contractile, the more perfectly elastic it is, the longer will it withstand such trials; but, sooner or later, it will fail to recover perfectly—that is, permanent dilatation will begin. The veins are neither highly muscular nor elastic, yet they may recover from considerable and repeated dilatation, lasting even for months, as we see frequently in childbearing women.

The withdrawal of support which is usual may lead to dilatation of veins under normal pressure; thus a lax sphincter may encourage the development of piles.

(2) That heart- and lung-disease may cause accumulation of blood in the veins, and that these, especially the abdominal veins, dilate to accommodate it is certain; but such general obstructions to the venous return are not causes of varix. There seems some reason to doubt the correctness of the view, held by many, that cirrhosis of the liver is a direct cause of piles. When a main venous trunk becomes thrombosed or is compressed by the gravid uterus, full rectum, aneurysm, tumour, &c., dilatation of its tributaries and œdema may result; or a collateral circulation may open up through neighbouring veins, the walls of which may simply hypertrophy; or certain veins may become varicose. As Sabouroff says, the vein behaves in response to increased pressure like the bladder or heart: at first the muscle-cells hypertrophy, and then, if new vasa vasorum are developed and fuller nourishment is granted, the adventitia increases in strength; but if nourishment fails, the vein atrophies and dilates progressively. In aneurysmal varix and varicose aneurysm intravenous pressure approximates to arterial; the veins dilate and thicken greatly. It is believed by many that frequent and powerful muscular contractions, and the accompanying great afflux of blood to the muscles, lead to the throwing into the veins of quantities of blood larger than they can accommodate, and thus to their permanent dilatation. Even the effect of long standing on the leg-veins has been explained thus, the calf-muscles being specially active; this, at least, seems very doubtful. Walking, short of excessive fatigue, probably promotes the nourishment of all tissues in the leg; but when it and such exercises as cycling are carried to excess—that is, to great fatigue—they may, perhaps, lead to dilatation of veins.

ANATOMICAL CHARACTERS.—The principal seats of varix are the lower extremities; the trunk, when collateral circulation is set up as the result of blocking of the venous trunks; the rectum (*see HÆMORRHOIDS*); the spermatic plexus (*see VARICOCELE*); and the ovarian veins. But almost all veins have occasionally been found varicose—large and small, deep and superficial, a single vein or venule, or almost all in the body.

The following changes occur in the development of a varicose vein:—

(a) Simple dilatation of a vein occurs when unusual strain is thrown on its walls.

(b) If the strain endures, and increased blood-supply be sent to the vein-wall, hypertrophy of the muscle-cells in the middle coat, and hyperplasia of the connective tissue in all the coats, ensues. So far the vein is merely hypertrophied in proportion to the demands made upon it.

(c) Should the excessive strain continue, the vessel yields in all directions, becoming wider and longer, but not regularly; thus it becomes tortuous and irregular in its outline and calibre. Its wall is abnormally thick at some spots, very thin at others, especially in the neighbourhood of valves and towards the free surface.

The valves, too, become hypertrophied, and for a time perform their function; but by-and-by they fail to span the widening stream, and waste to fibrous cords. In the sac-like or spindle-shaped dilatations behind the valves the blood frequently coagulates, and the thrombus may remain small and parietal, occasionally calcifying (phlebolith), or may grow and become obstructive.

(d) A sac-like dilatation of the vein, as it approaches the surface, may by its pressure cause thinning of the superficial tissues; and these, together with its own walls, may finally rupture.

(e) The tissues round a varicose vein may appear normal; they are frequently slightly œdematous, or hard and fibroid; and perhaps there is evidence of shrinking of the new fibrous tissue. In this dense tissue the veins seem to lie in definite channels. The explanation is that the circulation is slow in proportion to the dilatation of the veins, and the tissues are under-nourished, yet are kept soaked in a transudate of poor quality, which leads to thickening of the connective tissue. Such tissues offer little resistance to the causes—especially infective—of inflammation. Thus spontaneously, or as the result of injury or of rupture of a vein, ulcers develop which show little tendency to heal. *See ULCER AND ULCERATION.*

SYMPTOMS.—It is not until veins are seen or felt to be varicose that the disease can be known to exist. When first seen a small part of a superficial vein, usually about the calf or ankle, looks slightly bluer and larger than usual. This may disappear for some time—only, however, to recur; and by-and-by the condition will become permanent, and may spread to other veins. There may be no pain with very large veins; but patches of very small varices are often very painful—probably from pressure on nerve-endings.

A limb may be somewhat swollen, and pit on pressure; or it may be hard from fibroid thickening. Here and there venous saccules may cause localised soft prominences. Signs of old or present inflammation are common; and ulcers often form in connection with varicose veins.

When a varicose vein bursts, hæmorrhage is likely to be excessive, more blood pouring from the upper than from the lower end of the vessel, the valves between the rupture and the heart being incompetent.

DIAGNOSIS.—Varicose veins, as usually found, are unmistakable in their appearance. A saccular dilatation of the internal saphenous vein, just below Poupart's ligament, has been mistaken for a femoral hernia; but there is no excuse for the error unless the sac be thrombosed, when the diagnosis from irreducible hernia may be impossible.

PROGNOSIS.—The dangers of varicose veins are: Dermatitis; ulceration; thrombosis; phlebitis, simple or infective; embolism; rupture and hæmorrhage. Much relief can be given by treatment, but cure can hardly be spoken of, except in limited cases.

TREATMENT.—The treatment in any particular instance is to remove, if possible, the cause of the

veins becoming varicose. The circulation in the dilated vessel must be encouraged—by obtaining a good cardiac and vascular tone; by support of the vein; and by particular attention to dietary and hygienic rules for some time. The vein is best supported by a well-fitting knitted stocking, by an elastic stocking, or by Martin's elastic bandage. To help the venous return, the patient when sitting should have the feet raised on another chair, and at night should sleep with the lower end of the bed slightly raised. Cold-water bathing, followed by firm rubbing with a towel upwards towards the heart, is useful. Treatment such as this no doubt promotes recovery after removal of a definite cause, e.g. gravid uterus.

It is desirable to operate in most cases in which the larger trunks and their main branches are affected, yet not so widely but that their removal can be effected by operations of reasonable extent. Operation is specially desirable (1) when the veins give rise to pain and inconvenience; (2) when hæmorrhage is imminent; (3) when ulceration threatens or is present; (4) when a patient wishes to enter the public services.

The operation usually practised is that of excising long pieces or the whole of the varicose trunks and branches, and especially all obvious points of anastomosis, through one long or a series of shorter cuts. The wounds almost always heal by first intention. The operation is easily done under eucaine, either in the leg or in the spermatic cord. Embolism is the danger, but rarely occurs. Other veins may dilate sooner or later after the operation.

3. **Hypertrophy of Walls.**—This takes place when extra work is thrown on the walls of the vessel, and is accompanied by increased blood-supply. See 2. Varicose Veins, p. 1831.

4. **Atrophy.**—When from any cause a vein, or part of a vein, falls into disuse, as after an amputation, its calibre diminishes and its coats atrophy, until it finally disappears.

5. **Degeneration.**—Degenerations in veins are probably similar to those occurring in arteries; but less is known about them. Calcareous plates are found at times in the saphenous veins, inferior vena cava, and uterine veins.

6. **Phleboliths.**—Phleboliths, or venous calculi, tend to form in veins in which circulation is slow, as in the veins of the prostate and bladder, and in varicose veins anywhere. They commence, no doubt, as precipitated fibrin, which becomes infiltrated with the less soluble salts of the blood—chiefly phosphate of calcium, and in less quantity sulphate of calcium and sulphate of potassium. Phleboliths are harmless, and require no treatment.

7. **Wounds, and Process of Healing.**—*Wounds.*—When a healthy superficial vein is wounded, dark venous blood flows in a uniform stream from the distal end; in the case of a varicose vein the blood flows from both ends, but chiefly from the cardiac. At the same time a quantity of blood escapes into the subcutaneous areolar tissue and around the sheath of the vein. When a deep vein is torn by a broken bone, without breach of surface, the part around swells, and becomes dark in colour; the part below swells and its circulation is more or less impeded, but it recovers in the great majority of cases, even when the extravasation is very extensive.

Healing process.—When gentle pressure is applied over the wound after venesection, and the limb is kept at rest, union takes place in a few days, so that no scar even can be found in the injured vein. The coats of a vein contract and retract only to a slight extent within the sheath, but still sufficiently to help in the arrest of the hæmorrhage and the formation of the clot. The extravasated blood coagulates, extends through the opening in the vein, and projects like a button into the blood-stream. The whole coagulum now contracts; the part projecting into the vein becomes 'organised,' and thus helps to close the wound. The vessel may not become obstructed, or, if it does, is soon opened up again. Instead of this favourable ending, numerous troubles may arise, such as spreading thrombosis and phlebitis; infective softening of the clot; local suppuration; embolism, simple or infective.

TREATMENT.—Hæmorrhage from a superficial vein is readily arrested by pressure over the wound and elevation of the limb. In the event of persistent hæmorrhage occurring from a deep vein after the employment of pressure and elevation, the vessel must be cut down upon and ligatured. When a large vein is pricked, and bleeds, the margins of the opening in the vein may be seized with a forceps, and tied with catgut; a larger opening, even in the inferior cava, has several times been closed by suture, or by clamp-forceps left on twelve to twenty-four hours.

8. **Air in Veins.**—See VEINS, Entrance of Air into.

9. **Parasites.**—The embryos of the *Tæniæ* and of the *Bilharzia hæmatobia* are occasionally found in the blood of the portal vein; the latter are also found in the veins of the bladder. See ENTOZOA.

10. **New-Growths.**—Tumours are not known to originate in connection with veins, but they often compress veins or grow into their lumina, and their cells are disseminated by the passing current. Often these protrusions cause thrombosis, local or spreading. For an account of venous nævi, see TUMOURS: Angiomata.

STANLEY BOYD.

VEINS, Entrance of Air into.—SYNON.: Fr. *Aérhémotomie*; Ger. *Luft Eintritt in die Venen*.

The result of the investigations respecting the entrance of air into veins may be summed up briefly as follows:—

1. **Amount of Air necessary to Cause Death.**—This varies with the size of the animal experimented on, and the mode of injection of the air. A small animal requires a smaller amount of air to cause death than a large one. If slowly injected, enormous quantities may be pumped into the veins with impunity; while a quantity sufficient to fill the auricle, injected suddenly, is certainly fatal. Recovery may take place after the occurrence of very serious symptoms, and on the other hand death may occur after an interval of some hours or even days.

2. **Causes of the Spontaneous Entry of Air into a Wounded Vein.**—In inspiration, the diminished pressure within the thorax causes just the same tendency for the blood in the large veins at the root of the neck and in the axilla to rush into the right auricle, as there is for the air to enter the lungs

by the trachea. This aspiratory force rarely extends beyond the veins mentioned, and the region in which they lie is often called the 'dangerous region.' If the vein be completely divided, its lax walls fall together, and thus offer a valve-like resistance to the entrance of air; but if in any way the opening be kept patent, air will rush in at each inspiration. The opening may be kept patent by a diseased condition of the walls of the vein, as when it passes through a tumour or is embedded in inflammatory products; or the surgeon may pull open a half-divided vein by traction on the parts he may be removing; or the aperture may be circular, as when a small piece is cut out of the wall of the vein, or a branch is cut off close to the main trunk. The external jugular, if divided low in the neck, remains open, on account of its connection with the cervical fascia.

The evidence that air can enter the veins of any other region and cause serious results is not altogether satisfactory, but the accident is believed to have caused sudden death during parturition, and to have been induced by intra-uterine manipulations, such as version in the treatment of placenta prævia.

After death the right side of the heart has been found distended with a frothy mixture of blood and air, and bubbles of air have been found in the pulmonary artery even as far as the smaller subdivisions.

SYMPTOMS.—As the air enters the vein, it gives rise to a noise variously described as hissing, whistling, or sucking. If the patient be not under the influence of an anæsthetic, he cries out that he is dying, or makes use of some expression indicative of great distress. He becomes immediately pale and faint. There is intense anxiety, and the most severe dyspnoea. The dyspnoea is purely cardiac in origin, the air entering the lungs freely, with violent and hurried inspirations. The sense of want of breath is due to an interruption of the flow of blood through the lungs. The pupils are usually widely dilated. Although the patient is pale and faint, the action of the heart may at first be felt through the chest-walls to be violent and irregular, and it is said that on auscultation a peculiar churning sound may be heard. The pulse rapidly becomes weak. Tetanic convulsions have occurred in some cases; in some instances violent coughing has also been noted. If a large quantity of air has entered, death may be almost instantaneous; but if a small quantity only has been sucked in, the patient may recover, occasionally after some hours of distress. In rare instances in which death has occurred some days after the accident, bronchitis was present, and possibly the entrance of air may not have been the real cause of death.

There can be no doubt that death results from arrest of the pulmonary circulation, and not from paralysis of the heart, for the cardiac action continues long after the air has entered. The want of blood in the lungs causes the sense of dyspnoea; and, the flow through the lungs having ceased, the left side of the heart will become empty, and, no blood reaching the brain, faintness, followed quickly by death, naturally occurs. Supposing the patient to recover, the air which may have got into the circulation is absorbed by the blood.

TREATMENT.—The accidental entrance of air into the veins must be prevented by careful operating. If a vein can be seen to be in danger it is advisable to compress it on the proximal side, and if it is

necessary to divide it, a double ligature must first be applied. In removing a tumour from the 'dangerous region' traction upon it should as far as possible be avoided.

If the symptoms described should appear, the further entry of air into the wounded vein is best prevented, as suggested by Treves, by at once filling the cavity of the wound with fluid, while an attempt may be made to expel the air from the right side of the heart by applying forcible compression to the front of the chest during expiration. The wounded vein should then as quickly as possible be secured and ligatured. Treatment should further be directed to the prevention of syncope by maintaining the circulation of blood to the brain. With this object the head should be lowered, pressure applied to the large arteries of the limbs, and stimulants administered hypodermically and by the rectum.

MARCUS BECK.

RAYMOND JOHNSON.

VENEREAL DISEASES.—A common term for all forms of contagious disease usually contracted and transmitted by impure sexual intercourse. There are three principal kinds of venereal disease: namely, *gonorrhœa*, *syphilis*, and the *local venereal sore* or *chancere*. See GONORRHEA; SYPHILIS; and VENEREAL SORE.

VENEREAL SORE.—SYNON.: Local, Soft, Non-infecting Chancre or Sore; Fr. *Chancre Mou*; Ger. *Weicher Schanker*. The ambiguous term 'chancroid' has been adopted by many American authors.

DEFINITION.—A virulent, local, infectious ulcer, communicable by contact of its secretion with a breach of surface.

ÆTIOLOGY.—The ætiology of the local chancre is still a subject of dispute. A few maintain that it is connected with syphilis. Others affirm that it may be caused by the products of simple inflammation. But the view which is most in accord with the present state of knowledge on the subject is that the local chancre is due to a specific virus distinct from that of syphilis; that it never gives rise to any special constitutional symptoms; and that its effects are limited to the neighbourhood of the sore itself and the nearest lymphatic glands.

In 1889 Ducrey, of Naples, announced that he had succeeded in isolating on the human skin the pathogenic microbe of soft chancre, which he described as a short thick bacillus 1·48μ long and 0·50μ broad, with rounded ends and usually notched laterally. He had not been able to cultivate it outside the body. It seems now to be pretty generally agreed that this strepto-bacillus is peculiar to the soft chancre, but whether it is the sole causal agent or not is still disputed. Some observers claim to have isolated and cultivated it artificially, while others have failed, so that at present the question must be considered unsettled.

INFECTION.—The local chancre, like syphilis, may be communicated by direct or by mediate infection; but it is of course never transmitted by inheritance. Syphilis is not infrequently conveyed in various ways independent of sexual intercourse (see SYPHILIS). The local chancre, on the other hand, is very rarely other than a venereal disorder; chiefly because, not being part of a general disease, it does not give rise to infectious lesions on distant parts of the body.

The local chancre, like syphilis, may be conveyed from one person to another, through the medium of a third, whose cutaneous or mucous surface happens to be intact, and who thus escapes infection. One attack of the local chancre, unlike syphilis, affords no protection for the future.

DESCRIPTION.—When chancrous pus is inoculated artificially, the puncture within twenty-four hours becomes surrounded by a faint red blush; on the second day the redness extends, and the site of inoculation becomes swollen. On the third day a vesicle appears, and rapidly becomes a pustule. About the fifth day the pustule bursts, leaving a circular ulcer, with well-defined, sharply-cut edges, surrounded by a pink areola. The surface of the ulcer is uneven and spongy, the discharge is purulent, and as time goes on the borders become irregular and undermined.

When the local chancre is due to venereal infection the pustular stage is rarely, if ever, seen in practice, and it usually comes under observation as an ulcer which resembles that produced by experimental inoculation more or less closely, according to the circumstances of the particular case.

The base of the local chancre is supple, unless inflammation be present, in which case there is more or less thickening of the surrounding parts.

When the sore is in such a position that the urine frequently comes in contact with it, or when it is irritated in any other way, the thickening of its base may be sufficient to raise the sore above the surrounding parts, so that the surface, instead of being depressed, becomes more or less prominent, in which case the term *ulcus elevatum* is sometimes applied to it. The discharge is readily and repeatedly auto-inoculable; hence a plurality of sores is very common.

The *seat* of chancre is nearly always the skin covering the genital organs or their immediate neighbourhood. A primary sore on the body of the penis is much more likely to be syphilitic than local.

The *form* and *aspect* of the chancre vary in some degree according to its position. Thus in the furrow behind the glans penis the sore may be elongated; about the frænum, in the folds of mucous membrane around the anus, and about the female genitals it is often fissure-like. Again, when exposed to the air and neglected, it becomes covered by a scab. If chancrous pus gain entrance to a follicle (*follicular chancre*) the follicle may become distended, and temporarily simulate a boil or small abscess.

As regards *size*, chancres rarely exceed half an inch in diameter, unless two or more run together, in which case they form a large irregular ulcer. Such confluent chancres are more common in women.

COURSE, DURATION, AND TERMINATIONS.—

When a typical chancre is allowed to run its course, it lasts from four to eight weeks. This course is divided into three stages: (1) an increasing, (2) a stationary, and (3) a healing stage. The length of each is liable to vary from many causes. Roughly speaking, however, it may be said that the first period, during which the sore sensibly increases in size, occupies from a week to a fortnight; that the second lasts about a fortnight; and that at the end of from three to five weeks the stage of repair is reached.

By appropriate treatment the duration can be greatly shortened, but it is also influenced by the position of the sore. Thus, at the orifice of the prepuce or urethra, the irritation of the urine retards

healing, and phimosis acts in a similar manner. Chancres of the frænum, again, often continue to spread until they have perforated or destroyed it. In fact, the more mobile and exposed to irritation the part, and the greater the difficulty of keeping the dressings in place, the longer will be the duration of the sore.

If the syphilitic virus have been absorbed as well as chancrous pus, the course of events will remain uninfluenced until the incubation-period of syphilis has elapsed; when, if the sore be still unhealed, it will gradually change in appearance by the development of induration at its base, until finally it assumes the characters of the initial manifestation (*see* SYPHILIS). If, on the other hand, the local sore has healed before the end of the period of incubation proper to syphilis, the scar will become indurated, and erosion or ulceration will probably, though not necessarily, follow.

COMPLICATIONS.—The less serious complications of the local chancre include *inflammation*, *phimosis*, and *paraphimosis*. These are dealt with under their respective headings.

Phagedæna.—This graver complication of chancre may be either acute or chronic; and may attack the original sore or the consecutive bubo, or both.

In a typical case of *acute sloughing phagedæna* the patient is usually much depressed. He soon becomes feverish, with a dry, brown tongue, quick pulse, and other signs of constitutional disturbance. The discharge from the sore diminishes, and is thin, sanious and shreddy, and very offensive. The margins of the ulcer are puffy and livid at first, but soon become black and ragged, presenting a ‘gnawed’ appearance. As the process goes on, the dead tissues separate in sloughs, which vary in size according to the rapidity of the destruction. In the worst cases necrosis is very rapid, and attended by severe pain. The whole of the genital organs in either sex may thus be destroyed; while, if the groin be the seat of phagedæna, the great vessels and nerves are quickly exposed at the bottom of a deep ragged cavity. If the process be not soon checked, death may occur from hæmorrhage, from exhaustion, or from some acute intercurrent inflammation.

The above description applies to a form of phagedæna which is now fortunately rare; but less severe examples, ranging in various degrees between that described and those where a sore simply becomes inclined to spread, looks unhealthy, and has ‘gnawed’ edges, are common enough in venereal practice.

In the *chronic form* of phagedæna the morbid process is much less active, and is not usually attended by much pain or constitutional disturbance. The sore spreads gradually, but the tendency is rather to extend widely and superficially than deeply. The groin is the most usual seat of the ulceration, whence it may extend upwards along the abdominal wall or down the thigh, laying bare the deep fascia, and dissecting out the superficial vessels and nerves. It often also undermines the skin extensively before destroying it; hence the loose and irregular margins of the ulcer are detached from the deeper parts for a considerable distance. The duration of this form of ulceration is very variable. It sometimes lasts for years; at one time appearing to be stationary, while at other times it spreads in one direction and heals in another. In such cases the patient’s health suffers more or less severely, and finally he may

become exhausted by the constant and prolonged irritation and discharge. If he recover, he may be permanently crippled by the contraction of the resulting cicatrices.

Bubo.—This complication, which is less frequent in women than in men, and in private than in hospital practice, is said to occur in about 20 to 30 per cent. of the total number of cases of chancre. Bubo may be either *simple* or *virulent*, the former being most common. See BUBO, VENEREAL.

Simple or *sympathetic bubo* arises from the absorption of ordinary pyogenic material, and is similar to that which may accompany a suppurating focus of any kind.

Virulent (chancreous) bubo may be due to the inoculation of a simple abscess by chancrous pus, or to virulent matter conveyed from the sore by the lymphatics to the gland. The latter mode of production has been doubted by some observers since Ducrey failed to find the bacillus known by his name in the pus of any bubo when strict precautions had been taken to prevent inoculation from the outside.

Bubon d'emblée.—This term has been applied to

Local Chancre.

1. A local and nearly always venereal disorder, produced by the pus of a similar ulcer.
2. Irritation begins within a few hours after infection.
3. Begins as a pustule which soon bursts, leaving an excavated ulcer with sharply cut, loose, often undermined edges, and an irregular spongy floor of a dirty yellow colour.
4. Base supple unless inflamed, in which case it becomes firm like that of a boil; the firmness is diffused, resistant to the touch, ill-defined, and fades gradually into the surrounding tissues.
5. Discharge abundant, purulent, and freely and repeatedly inoculable, on the bearer as well as on others.
6. Usually multiple.
7. Very rarely seen far away from the genital organs.
8. Course acute, and attended by pain or soreness.
9. Duration greatly influenced by local treatment.
10. Inflammation and phagedæna not very uncommon.
11. Glands remain unaffected or become acutely inflamed. Suppuration common. Bubo may be simple or virulent. Only one or two glands suffer.
12. Does not cause general infection of the system.
13. Repeated attacks common.

While the characters given in the foregoing table are amply sufficient for the diagnosis of the two lesions in uncomplicated cases, it must be mentioned that the appearance of either sore may be altered in various ways, for example, by neglect of cleanliness, or by the application of irritants. Thus the local chancre, especially about the margin of the prepuce, may develop an amount of inflamma-

a variety of bubo, believed by some authors to result from the absorption of chancrous pus without the production of any lesion at the point of inoculation. The existence of such a bubo is not established.

Lymphangitis.—This, like bubo, may be simple or virulent, but is a less frequent complication of the local chancre. Bubo of either kind may exist without any perceptible change in the lymphatics leading to it; but when the vessels are affected, the glands are usually inflamed also. The thickened lymphatics can be felt as tender and often irregular cords, and their course is generally marked out by red streaks along the surface.

Simple lymphangitis may end in resolution, or one or more abscesses may form along the course of the vessel. The virulent form probably always goes on to suppuration, and the resulting sores become chancres similar to the original one.

DIAGNOSIS.—The local chancre is recognised by the characters which have been already mentioned, and which are recapitulated in the following table, where also they are contrasted with those of the initial manifestation of syphilis.

Initial Manifestation of Syphilis.

1. The first sign of a general and not necessarily venereal disease; it may be produced by the secretion of any syphilitic lesion or by the blood during the earlier stages of the disease.
2. Always a period of incubation, which averages 24 days.
3. Begins as a papule. Ulceration may be absent throughout. Edges raised, adherent, and rounded. Surface smooth and often of a ham-red colour.
4. Base more or less indurated. The hardness is sharply circumscribed, somewhat elastic to the touch, and independent of acute inflammatory action; it varies much in amount, being sometimes superficial and scanty, and feeling like a thin layer of parchment or paper; sometimes abundant, and feeling like a mass of cartilage.
5. Discharge scanty, serous, and not readily auto-inoculable.
6. Usually single.
7. Not very infrequent on the lip or finger, and on the breast in women.
8. Course indolent. Pain generally absent.
9. Duration greatly influenced by general specific treatment.
10. Inflammation and phagedæna rare.
11. Adenopathy constant, indolent, and generally multiple. Suppuration rare.
12. Is followed by constitutional symptoms.
13. A second attack rare.

tory thickening which cannot for a time be distinguished from that produced by similar causes in the syphilitic initial lesion; for the specific induration may become masked by inflammation. In such cases a positive diagnosis must be postponed until the irritation has subsided. Again, even if a patient present himself with a typical local chancre, it is of course not certain that the syphilitic poison

has not been imbibed as well ; and the incubation-period of syphilis must be allowed to elapse before the patient can be assured that his trouble is only local. Further, as regards the two most characteristic signs of primary syphilis, namely, induration of the base of the sore, and multiple enlargement of the nearest lymphatic glands, one or other may be ill-marked, or in rare instances inappreciable. Then, as regards number—the initial lesion of syphilis may be multiple if several places happen to be inoculated, as in the case of herpes for example ; and the local chancre may be single, especially in persons of careful and cleanly habits. Inflammatory action also may mask the usually separate indolent glands of syphilis ; but, apart from this, sometimes only one or two glands can be felt in the groins, in which case there may or may not be evidence that some of the glands have been spoiled previously. Absence of enlargement also appears to be sometimes due to the pressure of a truss. In very fat people, again, the glands cannot always be felt.

On the other hand, the multiple adenopathy of primary syphilis is occasionally closely simulated in some other affections — irregular herpes and gonorrhœa for example. In making a diagnosis the gradual and progressive character of syphilitic adenopathy is quite as important as its extent. Thus not one but all of the signs that may be present, together with the history of the case, must be taken into consideration ; and if the diagnosis still remains doubtful, the case must be watched until conclusive evidence is forthcoming.

Auto-inoculation is sometimes of service in diagnosis, but in the present instance would not be of much value ; for even if a typical local chancre were the result, syphilis could not be excluded until the incubation-period had elapsed. Care is always necessary in interpreting the results of inoculation ; for though it may be reasonably concluded that an active sore, the discharge from which is not auto-inoculable, is not a local chancre, yet the converse by no means always holds good. It must be remembered that matter from various lesions is inoculable on the bearer. The important point is not that inoculation produces something, but the character of the lesion which it produces.

When an immediate diagnosis is imperative, *confrontation*, or comparison of the patient with the source of his disease, may set the question at rest ; but many precautions are necessary in drawing conclusions from such evidence.

Ulcerating syphilides, especially mucous patches of the female genitals, occasionally resemble chancres, but the presence or history of other signs of syphilis would lead to a correct diagnosis.

Gummata of the genital organs and groins, after breaking down, leave ulcers which sometimes resemble local chancres or virulent buboes, but which as a rule are not auto-inoculable.

Besides syphilitic affections, there are some others which require to be mentioned in connection with the diagnosis of the local chancre. *Herpes* is usually seen as a group of vesicles or small superficial erosions on an inflamed area, but it must not be forgotten that occasionally there is only a single spot. Itching or smarting often precedes an attack of herpes, and there is frequently a history of previous attacks, which, again, are often independent of any suspicious sexual exposure, and are liable to recur at regular intervals, or in connection with diges-

tive disturbance. Herpes also usually heals in a few days under measures of simple cleanliness. See *HERPES PROGENITALIS*, p. 685.

Abrasions are irregular in form, are usually noticed by the patient at the time of their production or very soon afterwards, and heal readily in a few days if they are not irritated. Both herpes and abrasions, however, as well as the erosions due to balanoposthitis, may, under irritation of various kinds, become suppurating and inflamed ulcers, which for a time it is difficult to distinguish from chancres.

When phimosis prevents exposure of the parts, a discharge from beneath the prepuce may be due to several other causes besides the local chancre, for example, syphilis, gonorrhœa, balanitis, or warts. If the local chancre be present, its site is usually indicated by the presence of a tender spot in that situation, and pressure often causes a slight oozing of blood. Consecutive sores also quickly appear at the margin of the prepuce. In the case of *syphilis*, the presence of induration, and the multiple indolent enlargement of the inguinal glands, will usually render the diagnosis clear. In *gonorrhœa*, soreness of the deeper urethra, scalding during micturition, the presence of chordee and other signs of urethritis, and the absence of localised tenderness beneath the swollen prepuce, are points that will determine the nature of the case. In *balanitis* there will be an absence of circumscribed tenderness and of signs of urethritis. *Warts* can be felt through the prepuce, and a portion of the growth can usually be seen by putting the parts on the stretch. A small speculum is sometimes of use for diagnostic purposes in cases of phimosis.

PROGNOSIS.—The prognosis of the uncomplicated chancre is always favourable. If any complication arise, the prognosis will depend upon its nature and severity.

TREATMENT.—The treatment of chancre consists chiefly in the employment of local remedies. The general treatment at the same time is directed, on ordinary principles, to the maintenance of the patient's health, by tonics, regulation of the diet, moderation in, or abstinence from, alcohol, and as much rest as possible, in order to diminish the risk of complications.

A local chancre of only a few days' duration can generally be destroyed by one thorough application of heat or caustic. From a purely therapeutic point of view, however, destructive measures are not often required ; and as regards the prevention of syphilis, supposing the virus of that disease to have been inoculated, the results of observation so far seem to give but little hope of success.

In nearly all cases the best application is iodoform, of which the *powdered* crystals, either alone or mixed with boric acid according to circumstances, may be sprinkled on the sore by means of a quill, or applied with a moistened camel's-hair brush twice or thrice daily, according to the amount of discharge. The sore should then be covered with a piece of lint or wool, and if the dressing cannot be kept in place by the natural conformation of the parts, a narrow strip of bandage or plaster should be applied. Iodoform may also be applied as an ointment with vaseline, or an ethereal solution may be painted on the part, a thin coating of iodoform being left after the evaporation of the ether.

When for any reason the use of iodoform is

impracticable, the writer has found airol (an iodo-gallate of bismuth), which has no odour, a fairly satisfactory substitute ; or salicylate of bismuth may be used. When the healing stage is reached some preparation of boric acid or zinc usually answers best. Whatever dressing is employed, care must be taken to change it frequently, without making the sore bleed, to prevent the urine from coming in contact with it, and to arrange it so that opposed surfaces are kept apart. Chancres with phimosis must be treated by frequent injections, with a syringe having a long nozzle, of a lotion of carbolic acid (1 in 40), or of boric acid and glycerine. Any of the sores that are within reach should be dressed with iodoform, and a piece of absorbent wool placed within the preputial orifice.

In certain cases, especially in hospital practice, it may be desirable to begin treatment by thoroughly disinfecting the sores ; and for this purpose strong carbolic acid is usually effectual and gives but little pain. It is well to avoid the use of nitric acid for doubtful sores on account of the inflammatory hardness it is liable to produce. Nitrate of silver and sulphate of copper should never be used in such circumstances, not only because they are ineffectual but also because they set up an amount of hardness which may be sufficiently persistent to interfere with the diagnosis of the case if syphilis have been contracted. The actual cautery is rarely, if ever, required in uncomplicated cases. Before using either caustic or cautery the following points should be borne in mind : (1) No sore should be cauterised unless the whole of the diseased surface can be acted on. (2) The surrounding parts must be thoroughly cleansed and disinfected.

Treatment of complications.—Inflamed chancres should be treated by keeping the patient at rest, on simple diet ; by the administration of a purge ; and by the application of lead or warm boric-acid lotion. In phimosis, if the swelling is so great as to prevent the use of the syringe, or if sloughing is threatened, the prepuce must be slit up or removed altogether, and the case treated according to the directions given for the treatment of phagedæna.

If in paraphimosis the prepuce be naturally too narrow, or if strangulation occur, reduction should be effected.

On the first appearance of signs of acute *phagedæna*, the affected part should be immersed for nine or ten hours a day in water at a temperature of about 98° F. This can be accomplished by keeping the patient in a hip-bath, and alternately adding and removing small quantities of water, so that the requisite temperature is maintained. Care must of course be taken to protect the patient from cold, by placing the bath in a warm room, and by wrapping the exposed parts of the body in blankets. If this plan be adopted at an early period the sore often becomes healthy in a few days ; immersion, however, should always be continued for at least a day or two after this has occurred, to guard against relapse. The patient may generally be allowed to go to bed during the night, iodoform or some other suitable dressing being applied ; but if the diseased action continue to extend, the duration of the bath must be prolonged, or even be made continuous ; but in that case, as well as in the cases where the groin is the seat of the disease, a full-sized bath in which the patient can lie down will be necessary. In all cases the whole of the diseased surface must be fully exposed and thoroughly submerged.

If iodoform and immersion fail, or if immersion cannot be carried out, a lotion of tartarated iron (10 to 60 grains to the ounce), or a saturated solution of permanganate of potassium, should be tried.

If milder measures fail to arrest the phagedænic action, strong nitric acid or the thermo-cautery may have to be resorted to. When the surface to be cauterised is small, a solution of cocaine may be applied beforehand, but when it is extensive general anaesthesia will be advisable.

Hæmorrhage from a phagedænic sore should always be checked as soon as possible. If the bleeding is slight, the surface should be cleaned, and pellets of cotton wool, soaked in solution of persulphate of iron, pressed on each bleeding spot, and retained in position by a bandage applied as tightly as the patient can bear. In severe cases the actual cautery may be necessary ; and in extreme instances ligation of the larger arterial trunks above the seat of disease may be required.

The general treatment of phagedæna consists in the administration of good food, tonics, and opium in sufficient quantity to relieve pain ; but under the immersion-plan of treatment, pain usually quickly ceases, and little or no opium is required. Fresh air and good ventilation are also most important.

The treatment of chronic phagedæna is similar to that of the acute form, but of course more time is allowed for the trial of palliative measures before having recourse to the cautery.

For the treatment of simple bubo, see BUBO. It need only be remarked here that it is as important to avoid the application of irritants in the case of bubo as in the case of the sore.

The management of the *virulent bubo*, after evacuation of the pus, is similar to that of the local chancre, which has been described ; and the treatment already recommended for phagedæna applies equally to that morbid process, as a complication of the local chancre, of bubo, or of syphilitic ulcers, whether primary, secondary, or tertiary ; but in the case of syphilis the administration of mercury or iodides, or both, according to circumstances, forms an important element in the management. In fact, in every case of obstinate phagedæna, especially of the chronic form, most careful search should be made for signs or a history of syphilis ; for, if that taint be present, it not infrequently happens that all local applications fail until the constitutional malady is attacked.

ARTHUR COOPER.

VENESECTION (*vena*, a vein ; and *seco*, I cut). **SYNON.** : Bleeding ; Blood-letting ; Abstraction of blood by opening a vein ; *Fr.* *Vénéssection* ; *Ger.* *Aderlass*.—Venesection is performed at the level of the elbow. In practice the most prominent vein is selected ; for anatomical reasons the median cephalic is preferable, although the brachial artery can hardly be punctured except by a very bungling operator.

The skin at the level of the elbow is carefully sterilised. A bandage is tied firmly round the arm. The patient grasps some substance in the corresponding hand, as a stick or piece of bandage. A fine and very sharp sterilised knife is in readiness. The hands and nails of the operator should be cleaned with all the care he would take in a major operation (*see* ASEPTIC SURGERY). A large and prominent vein is selected and fixed by the thumb of the left hand of the operator, who grasps the limb by placing the

fingers of the same hand behind the elbow. The knife is then inserted by the side of the vein, turned across the vein, and brought out smartly so as to make an *oblique incision* across the vessel—not in its longitudinal axis. The blood flows in a continuous dark stream, and is received in a measured basin until a sufficient quantity is withdrawn. The operator checks the flow by placing the thumb on the aperture, removing the constricting bandage above, and directing the patient to drop the bandage or stick out of his hand. The puncture is then dressed with a pledget of iodoform gauze and covered with collodion. Some mercuric wool and a firmly applied 'figure of eight' gauze bandage completes the dressing, and the arm is placed in a sling. By the fourth day healing should be complete, and the puncture merely needs the protection of a little collodion and wool. The conditions in which venesection is now employed are discussed in the article on BLOOD, Abstraction of.

A. MARMADUKE SHEILD.

VENOMOUS ANIMALS.—SYNON. : Fr. *Animaux Vénéneux*; Ger. *Giftige Thiere*.

DEFINITION.—Animals which possess the power of secreting and ejecting a poison, which, when inoculated in man or other animals, produces toxic or even fatal effects.

Venomous animals are found in many classes of the animal kingdom.

1. **Reptilia.**—Reptilia furnish the most numerous and important kinds of venomous animals, and these are limited almost entirely to the order *Ophidia* or snakes.

The statement that no lizard is poisonous is not strictly correct. The heloderm (*Heloderma suspectum*) of Mexico possesses venomous properties, destructive to small animals, and injurious to man himself.

DESCRIPTION.—The poison-apparatus of a snake consists of a composite racemose gland, situated in the temporal region, secreting a clear, slightly viscid, acid fluid, which is poured through a duct into a grooved fang situated on a movable maxillary bone. The fangs are longer, more curved, more movable, and more formidable in viperine (viper; rattlesnake, &c.) than in colubrine snakes (cobra; bungarus, &c.).

Snake-poison is very deadly; more active in some snakes, quantity for quantity, than in others; and varying in activity in the same species or individual, according to season, temperature, and state of health. It acts most rapidly when injected into the blood; but it can be absorbed through mucous and serous membranes, as seen by its poisonous effects when applied to the conjunctiva, the stomach, and the peritoneum. It may neither be applied to the lips nor taken into the stomach with impunity; and sucking a snake-bite is by no means free from danger, though if the saliva be quickly ejected and the mouth washed, the danger is probably small. It may be noted here that the poison of viperine forms differs considerably from the colubrine. They both contain active principles, two of which, according to Drs. Weir Mitchell and Reichert, are proteids, one belonging to the globulins, the other to the proteins; they attribute the difference of the physiological effects produced by different species to the varying proportions of these bodies. Analysis has shown the poison to be very

nearly allied to albumen in composition: according to recent observers, one very toxic body is of the nature of an albumose. The composite nature of venom is proved by the results of heating the poison of the *pseudechis*: thus treated it retains its lethal properties, but loses the power of producing hæmorrhages and clotting of blood within the vessels. Venom is most active on warm-blooded creatures. Poisonous snakes are very insensible to the venom of other poisonous snakes, and absolutely so to that of their own species.

EFFECTS.—The action of the poison is *local* and *general*.

The *local* effects of snake-bite comprise pain; partial paralysis of the bitten part; ecchymosis; swelling; and, if death does not rapidly follow, infiltration of other and distant parts, cellulitis, and sloughing.

Associated with these local effects are many severe *general* phenomena, such as depression, fainting, nausea, hurried respiration, vomiting, exhaustion, hæmorrhagic discharges, lethargy, loss of co-ordinating power, paralysis, loss of consciousness, relaxation of sphincters, coma, and convulsions. If the quantity of poison injected be small or its nature feeble, the earlier symptoms may give way, and recovery take place. The poison is probably eliminated by the kidneys, and in the case of the venom of viperine snakes nephritis may thus be produced.

Snake-poison acts by paralysing the nerve-centres, or sometimes the peripheral distribution of the nerves; and by altering the constitution of the blood. It takes effect through the circulation; and if inserted into a large vessel, such as the jugular, humeral, axillary or other large vein, it will cause almost instant death, the heart's action stopping in systolic spasm. The respiratory centres, the spinal cord, and the peripheral nerves, may all be affected. In ordinary cases death seems to take place by arrest of the respiration, the heart's action continuing for some time after apparent death. The muscular fibre itself would appear in some cases to have its contractility impaired or destroyed. The poison also acts septicly, producing at a later period sloughing and hæmorrhage. Extravasation of blood appears to be due to a direct action of the poison upon the vessel-walls (Weir Mitchell).

There are certain points of difference in the action of viperine and colubrine venom. The poison of viperine snakes effects a direct destruction of the red corpuscles. There is greater tendency to hæmorrhage, extravasation, and fluidity of the blood. In the case of colubrine venom, the effect seems to be more directly upon the nervous system, the blood being less affected. Experiments on animals show that, generally, after death from cobra-poisoning the blood coagulates firmly, while after death from viper-poisoning the blood remains permanently fluid. In most cases of death in man the blood has been found fluid even after cobra-poisoning. It is said that the normal bactericidal power of the blood is destroyed by the action of snake-poison (Ewing).

PROGNOSIS.—In cases of moderate severity, remedies, with careful nursing and tending, may prove successful; but where the bite has been thoroughly effected by the ophiophagus, cobra, daboia, echis, rattlesnake, crotalocephalus, cerastes, and others, the prognosis is very unfavourable; in no case, however, should efforts be

relaxed until the last. The bite of the European viper is not often fatal to healthy adults.

There is often uncertainty as to the kind of snake, its condition, and the extent to which its fangs were used. The great shock or depression which follows a snake-bite may be in a measure due to fright, and will, on reassurance, pass away. The marks of two well-defined punctures attest the insertion of two fangs, and, if the snake has not been seen, may enable one to form an opinion as to its character. Many of the innocuous snakes are fierce, and bite vigorously, but their numerous teeth leave different marks from those of the poison-fangs. There are exceptions to this rule, however; a few innocent snakes have the anterior maxillary teeth developed like poison-fangs, but bites from them are not very likely to occur.

It may be well to note some of the characters that distinguish the venomous snakes, such as the form and arrangement of the teeth; an examination of the wound will often reveal the true character of the bite, and serve to indicate a correct prognosis. On opening the mouth of a venomous colubrine snake, such as *naja* or *bungarus*, two slightly movable fangs will be observed, one on either side, as well as several loose reserve fangs in various stages of development; and close behind them there may be seen one or two smaller teeth. There is no row of teeth along the outer side of the mouth, but a double row of palatine teeth will be found on either side. In the viperine and crotaline snakes, a large fang only is found on either side, and a palatine row as in the colubrine. There are no small fixed teeth behind the fangs as in colubrines, but in a fold of mucous membrane at the base of the fangs, both in vipers and colubrines, several loose reserve fangs will be found in various stages of development, one of which takes the place of the ordinary fang when it is shed, by becoming ankylosed to the maxillary bone. In *hydrophide* the fangs are arranged like those of the cobra, but are very minute, and no reliance can be placed on any mark made by them. The circumstances under which a bite is inflicted will generally help to indicate the kind of snake.

Harmless snakes have a double row of equal or nearly equal-sized teeth in the maxillary and palatine bones. But, as before stated, there are certain innocent snakes that have long anterior maxillary teeth, which might cause doubt as to the nature of the bite.

TREATMENT.—There is reason to believe that the numerous agents that have been recommended from the earliest times as antidotes of snake-poison are useless, and have no such properties as those ascribed to them.

The rational treatment of snake-poisoning is to endeavour to prevent the entry of the virus into the circulation; to neutralise it in the wound before it is absorbed; to support the failing nervous force if it have entered; and to favour its elimination.

The application of a tight ligature between the bite and the heart, and the immediate excision or destruction of the bitten spot, by cautery or caustic, are essential; and other local measures may appear necessary. The injection of a solution (5 to 10 per cent.) of permanganate of potassium into the bitten part has for its object the neutralising of the poison retained there by the ligature, and there is reason to believe that this is sometimes effected. The ligature may then be removed, thus obviating

the risk of gangrene in the part below the constriction. Calmette advises the local injection of a fresh solution (1 in 60) of calcium hypochlorite, or a solution of chloride of gold (1 in 200).

The constitutional treatment requires that the strength should be supported by stimulants, such as alcohol and ammonia. Next, if the respiration be failing, artificial respiration should be resorted to. Elimination should be promoted by stimulating diuretics. The patient should be kept warm, and must not exhaust himself by walking about. Ammonia has always held a high place among remedies in snake-poisoning. Its injection into the veins has been warmly advocated in Australia, and is said to have met with success there, which it certainly had not in India.

Dr. Mueller in Australia strongly advocates the injection of strychnine in repeated doses, and cases are cited which seem to confirm its utility; but there is not yet sufficient evidence to warrant the certainty of its efficacy. Very promising results have been obtained (Calmette; Fraser) experimentally and confirmed in a number of instances of snake-bite, by means of injection of an antitoxic serum or antivenene. This is prepared by injecting a large animal (horse) with gradually increasing doses of cobra-venom, and when immunity is established, collecting the serum for therapeutic purposes. Doses of 10 c.c. are recommended for human use, repeated if necessary. The action of the remedy is probably similar to that of antidiatheritic serum (antitoxin) (*see* ANTITOXINS). A transient immunity may be conferred by doses of antivenene. The remedy is applicable to bites from almost all poisonous snakes. Its efficacy is destroyed by heating to 70° C., but the power of venom itself is not thus affected. The serum retains its activity for at least a year (Calmette). *See also* p. 1485.

2. Amphibia.—None of the amphibia are known to possess a poison-apparatus like that of ophidia; but toads and salamanders secrete a fluid in glands along the back, connected with the integument, which yields an actively venomous principle, capable of causing local irritation, and, when injected into the blood, death, preceded by symptoms indicating action on the cerebro-spinal nerve-centres. Dogs seizing the toad *Bufo vulgaris* are known to suffer from swelling of the lips and salivation; and a case of death was related in France, in 1865, of a child in whom an abrasion of the hand came in contact with the secretion of a toad; death was preceded by vertigo, vomiting, and fainting. When this poison is injected into guinea-pigs, small birds, and other animals, violent symptoms and death soon follow. It is a viscid, milky fluid, with a slightly yellow tint and peculiar odour; it is exuded, and may be pressed, from glands behind the orbits. Zalesky has shown that the land and water salamanders, *S. maculatus* and *Triton cristatus*, and probably others, have also the power of secreting venom; and his experiments prove that it contains a very active principle—*salamandrine*—and that its action on the cerebro-spinal nerve-centres is energetic. It appears that these poisons, like those of ophidia, though effective on others, have no action on their own species.

3. Pisces.—**DESCRIPTION.**—Several fishes are provided with an apparatus consisting of a cavity at the base of, or a sac and duct leading to, a channelled spine, through which an irritating secretion is ejected. No true poison-gland, however, has as

yet been certainly made out. This secretion is apparently connected with the secreting mucous system; and in certain species it produces marked symptoms of poisoning, though never to the same extent as in venomous snakes. Fish armed with sharp or serrated opercular or fin-spines can inflict severe injuries, liable to cause great pain, and to be followed by the grave symptoms attributable to the lacerated or punctured nature of the wounds; and these may be aggravated by the irritating nature of the mucus with which they are contaminated. In several, however, in addition to the spine, there is a distinct receptacle in connection with it, either in the form of a sac or duct, as in the *thalassophryne*, or in a cavity in the spine itself, as in the *trachinus* or weever.

In the case of others, such as the sting-rays, which may produce severe wounds by their pointed and serrated spines, there is no distinct receptacle for the poisons in connection with them. While it is well known that many spiny fish are capable of inflicting wounds that are dangerous from their lacerated and punctured character, it is recognised that others increase the danger by the inoculation of an irritating fluid, as just stated.

EFFECTS.—The effect of fish-poisoning is to produce severe burning pain at and beyond the injured part, and fever. The intensity, no doubt, depends upon the quantity of the poison injected, and the state of health and constitution of the person at the time. The wound alone, even without the poison, is likely to be painful and severe from its punctured character.

TREATMENT.—Ipecacuanha, tobacco, alkalis, alum, and ammonia have all been recommended as useful local applications to allay the irritating action of such poisons. Poultices of onions, or warm applications of opium or other sedative fomentations are likely to be useful; and prompt surgical relief is necessary, if suppuration or cellulitis occurs, to relieve tension, evacuate pus, or give exit to sloughs.

The constitutional treatment is such as would be indicated by the condition and progress of any other inflamed punctured wound. In cases of depression of the heart's action, alcohol or ammonia would be indicated. Rest, quiet, and due attention to the state of the bowels, and elimination by the skin and kidneys, with careful regulation of the diet, should be observed. *See* SAPRÆMIA.

4. **Mollusca.**—*Aphysia punctata*, the sea-hare, a gasteropod, is said by some to produce an irritating secretion capable of causing urticaria and even severe inflammation, and of causing the hair to fall off.

5. **Arthropoda; Myriapoda**, family *Scolopendridæ*.—The centipedes possess mandibles, formed by a pair of dilated feet, joined at their origin, with perforated, hook-like points, and with an aperture near the apex, through which a poisonous fluid, secreted in a poison-gland, with sac and duct, is ejected when they bite, which they can severely. In the case of the larger tropical species the bite is sometimes very painful, and causes considerable local irritation, and even constitutional disturbance—fever and delirium. That of the smaller kind generally causes only local and transient irritation. Centipedes are found nearly all over the world, in Europe, Africa, America, the East and West Indies and Islands, and in the

tropics generally. Those of warm climates are the largest and most dangerous.

6. **Arachnoidea.**—*Scorpionidæ* or *Pedipalps*. **DESCRIPTION.**—Scorpions have a segmented abdomen, the last six joints of which are narrowed into a tail, terminated by a curved perforated spine or hook, with which they strike and wound. At its extremity are two small orifices, through which venom is injected from a gland-receptacle and duct at its base. Scorpions run about quickly, carrying the tail curved over the body. They live in holes in the ground, and under stones or logs of wood, in dark places. The tail is used as an offensive weapon. They seize small creatures with their palpi, and then pierce them with the sting. The venom is so active that it quickly destroys life in these animals. Those of tropical climates are most active and poisonous. They attain to the length of from two to three, four and six inches. The European genera are smaller and less active.

Scorpions exist in all tropical countries, but extend also into the warmer regions beyond the tropics. They are found in the East and West Indies, Ceylon, and other islands, Australia, Africa, Egypt, South of Europe, and America. There are several genera, and *Buthus afer*, *Androctonus*, and *Buthus Caesar*, are good examples of the active kinds. *Europæus* and *Occitanus* are also venomous, but those of Europe are less active than the tropical forms.

EFFECTS.—The effects of the sting of the scorpion and of the bite of the centipede have no doubt been exaggerated; but they may produce very painful, and in the case of the larger species, severe and serious symptoms, in their character not unlike, or even more severe than, those of the sting of the wasp, namely pain, swelling, in some cases numbness, vertigo, nausea, vomiting, temporary loss of vision, swelling of the tongue, and fever. Death may occur in delicate or sickly subjects. The local and constitutional symptoms may be severe in persons of irritable constitution, or otherwise out of health; but generally in the case of bites of ordinary scorpions or centipedes inflicted on healthy subjects, the suffering is local and soon passes away.

TREATMENT.—A variety of remedies have been recommended for scorpion-poisoning. Probably the application of a ligature above the bitten part, or a cupping-glass, or suction of the wound, as in snake-bite, might be useful. Some authorities recommend that the wound should be scarified, and emollient ointments and poultices applied. Suction of the wound, and the application of salt water, vinegar, ammonia, alum, ipecacuanha, spirit of camphor, eau de Cologne, tobacco-water, turpentine, tincture of iodine, alcohol, the leaves of cruciferous plants made into poultices, solutions of opium and lead, or other sedatives, will lessen pain and irritation. The use of diffusible stimulants, opiates, or other sedatives may be necessary, and such surgical interference as suppuration or cellulitis may require.

7. **Arachnida.**—**DESCRIPTION.**—Some spiders are venomous, and certain of the larger tropical forms are capable of inflicting painful bites. The poison-apparatus of spiders consists of falcæ or modified mandibles or jaws, the last joint of which is a hard curved fang, with a fissure near the point; there is an elongated poison-sac and duct in which the venom is elaborated and thence transmitted to the

fang, by which it is inoculated into the flesh of its prey.

EFFECTS.—The venom of spiders is a very active principle, and apparently is capable of rapidly destroying the life of the small creatures on which the spider feeds. It also causes symptoms of poisoning in man and the lower animals. Probably all the species have some venomous secretion, but it is only the larger kinds that are obnoxious to man. It may be noted that while the fangs of one section of spiders move laterally, those of the Mygalidæ move vertically. There are several species. Those reputed venomous are tropical.

Lycosa tarantula is reputed to cause extraordinary symptoms. It is poisonous, but there is no reason to believe that its effects exceed a certain amount of local irritation. See TARANTISM.

There are numerous families, genera, and species of spiders, all probably possessing an irritating fluid; but it is only the larger kinds that do so to any extent, and there is no very positive proof that even in tropical climates they inflict the grievous injuries ascribed to them, though the venom is very fatal to the creatures on which they prey.

The popular notions that the spider is very poisonous when swallowed, and that its web possesses medicinal properties, are probably exaggerated, if not altogether untrue. One species of red spider, however—perhaps a mite—called *coya*, in Popayan, is very poisonous; the juices of its body when crushed, coming into contact with the punctured skin, causes tumours, or even, it is said, death. This is no doubt an exaggeration, but it is probable that the juices are acrid and irritating, and it is therefore better not to crush these animals when detected on the person, but to brush or blow them away.

In India, a streak of almost erysipelatous redness of the skin coming on rapidly is often attributed to a spider. No one has defined the species; it is possible that it may be analogous to that just referred to.

TREATMENT.—The treatment of spider-bites is similar to that of centipedes and scorpions.

8. Acarina.—DESCRIPTION AND EFFECTS.—Some mites have the power of causing considerable irritation by a secretion ejected on the surface, or injected into the wounds they make in their burrowing operations with claws and mouth.

The *Tetranychus autumnalis*, *Leptus autumnalis*, or Harvest Bug, is brick-red in colour, and very minute. It is bred on plants, but leaves them to fasten on to animals, especially man, when it adheres firmly, and causes swelling, great irritation, and severe itching, if in numbers. The intense irritation causes fever. The symptoms are not unlike the sting of a nettle, erythema or even blistering being caused. The *leptus* is covered with hairs, and effects entrance into the skin with its claws, and thus gives rise to the great irritation, which is probably aggravated by some acrid excretion. These animals are found in Britain, France, and other parts of Europe; varieties of them in the tropics, for example, in Brazil, Honduras, on the Mosquito Coast, and in the West Indies. The *T. irritans* of the Mississippi valley causes great irritation in the same way.

TREATMENT.—The treatment is to extract the bug with a needle or the point of a knife, and then apply some soothing lotion.

Argas persicus, a gamosid, known also as the *Teigne de Miana* (venomous bug of Miana), is common in Persia. It is found in houses, and it is said that its puncture produces serious symptoms, such as convulsions, delirium, and gangrene, or even death. This is an exaggeration, though probably it is true that local irritation, and perhaps some constitutional disturbance, may be caused. It is blood-red in colour, spotted with white on the back, the feet yellow. *Argas moubata*, a native of Angola, is said to have much the same properties.

The *Argas talaje* of Guatemala produces great irritation. It bites like an ordinary bug, and the punctures are followed by great irritation, swelling, and pain. It lives in holes in the bamboo walls, or similar crevices, and issues at night to attack the sleepers.

9. Hemiptera.—Some of the *Geocorysæ* and *Hydrocorysæ*, or land- and water-bugs, have irritating properties, and also an offensive odour; they have a suctorial mouth, armed with a grooved instrument or rostrum for piercing the skin.

Cimex lectularius, the bed-bug, causes much irritation, and in some persons inflammatory action in the bitten part. The effects are transient.

Notonecta and *Nepa*, common in pools of water in our islands, are also capable of inflicting a painful puncture. *Cimex nemorum* causes nearly as much pain by its puncture as the sting of a wasp. The wheel-bug, *Reduvius serratus*, of the West Indies, gives an electric shock to the person it touches. St. Pierre mentions a species of bug in the Mauritius whose bite is as venomous as the sting of a scorpion. The *Benchucha*, or great black bug, of the pampas of South America, is more obnoxious, it is said, than the common bed-bug.

10. Aphaniptera.—*Pulicidæ* or Fleas comprise several families. *Pulex irritans*, the common flea, is universal. It varies much in size and colour; some are almost black and very large, and are found on the sandy shores of the Mediterranean. There are many species, such as *P. canis*, *P. musculus*, *P. vespertinus*, and *P. penetrans* of the West Indies and South America, known also as the jigger or chigoe (see CHIGOE). Though the irritation of the flea-bites is chiefly due to the wound, there is reason to believe that this is aggravated by the presence of some irritating secretion. No special treatment, beyond the application of ammonia, which may be useful, need be described.

11. Diptera.—DESCRIPTION AND EFFECTS.—To this order belong the gnats, mosquitoes, pipsas, sand-flies, and gad-flies, all more or less dreaded for their bites. They have a proboscis composed of a grooved and flexible sheath, through which long, slender, sharp darts are protruded, that pierce the skin and inoculate some venomous secretion, though its nature is not known. They draw blood, and raise white lumps or swellings; some, such as the pipsa of the Cossiah Hills, India, leave a livid spot of effused blood, which gives to the sufferer the appearance of a purpuric rash. They swarm in many countries, generally near water. The principal forms are the *Culex pipiens*, *C. reptans*, *C. mosquito*, *C. laniger*, and the whame-fly, *C. tabanus*. Some of these are formidable insects, and are insatiable blood-suckers. The *tsetse* or *timb* (*Glossina morsitans*) of Africa is one of the most remarkable. The bite of this poisonous insect is almost certain death to the horse, ox, or dog;

though it appears not to trouble man more than by causing slight irritation.

The female *Simulium*, or sand-fly, is irritating to man, the bite often giving rise to painful swellings. The pipsa is probably a *simulium*. It appears from the great irritation and the swelling that follows the puncture of most of these insects that some acrid secretion is injected into the wound. In young, full-blooded persons, especially recent arrivals in India or the tropics, the irritation caused by mosquito-bites is often so severe as to give rise to violent inflammatory symptoms, resulting in suppuration or ulceration, and even gangrene.

TREATMENT.—The application of common salt, solution of ammonia, soda, potash, lead, oil, ipecacuanha, or alum combined with opium, allays irritation in the first stage. The more violent inflammatory symptoms are amenable to ordinary surgical treatment. Camphor, pulegium, and lime-juice, applied to the skin, are all regarded as preventives.

12. Hymenoptera. — **DESCRIPTION AND EFFECTS.**—A number of species that secrete poison are found among the different families of hymenoptera, including bees, wasps, and ants. See **STING**.

They are distinguished by the presence of an ovipositor in the female, which is used not only for depositing the eggs, but as a weapon for injecting venom. It consists of two valves as a sheath, and three bristles which form a grooved sting. Through this groove the poison is injected into the wound, the ovipositor being connected with a poison-gland at its base.

Formicide.—Ants include *Formica smaragdina* and many others. The sting of the ant causes considerable irritation, especially if there are many. It has been suggested that formic acid is the irritating principle. There are several venomous species of ants, black and red, of various sizes. Some of the larger forms in the tropics are capable of inflicting a very painful injury. Some ants have no sting, but eject a fluid which irritates the skin.

Vespidæ.—The females and workers of the wasps and hornets are provided with a poison-sac and sting. *Vespa vulgaris* is a type of the tribe *Crabro*. It lives in communities. Its sting produces much irritation, pain, and swelling, especially when inflicted on the face, or where the cellular tissue is loose.

Apidæ.—True bees, and the *Bombidæ* or humble bees, have similar properties, their sting producing very much the same effect as that of the wasp.

Some of the parasitic *Hymenoptera* inject a poison into the wound made by their ovipositor. The best-known instance is that of the genus *Ophion*. The genus *Paripala* also injects a poison in the same way, and probably others of the *Ichneumonidæ*.

TREATMENT.—Many remedies of a simple nature have been recommended to allay the pain and irritation caused by the sting of the wasp and bee, such as vinegar, eau de Luce, ammonia, tobacco-juice, solution of soda or potash, oil, indigo, eau de Cologne, alum, and all those recommended in scorpion-stings (see **STING**). In cases of venomous stings, where constitutional disturbance is induced, stimulants or sedatives may be necessary; and as the sting is liable to be left in the wound, it ought to be picked out. In cases of wasp- or bee-stings in the mouth or throat, which may happen when children bite a peach or other fruit that conceals

a wasp, severe consequences may arise from the œdema that supervenes, and extends to the glottis. An emetic is then useful, along with the ordinary treatment of œdema; laryngotomy may become necessary. In other cases, should violent symptoms intervene, surgical aid may be required to relieve tension, or give exit to matter. Such untoward results, however, are happily rare.

Mutilla coccinea, a native of the warmer parts of North America, is said to produce loss of consciousness within five minutes of the infliction of its sting, life being in danger for some days afterwards.

13. Lepidoptera.—A stinging lepidopterous insect has been found. The species is not mentioned (F. Smith). The bee-moth of the Cape of Good Hope is said to defend itself with a sting. Though the majority of the perfect insects of this tribe are harmless, some of the caterpillars appear to be possessed of irritating properties, residing in the fine hairs with which they are cased, and which, being sharp and brittle, break off and remain in the skin, causing irritation mechanically; but also probably from the presence of some acrid substance concealed within the hairs. In Ceylon, a greenish hairy caterpillar, longitudinally striped, probably of the genus *Bombyx*, which frequents the leaves of *Hibiscus populneus*, alighting on the skin, causes as much irritation as the sting of a nettle. The larva of *Neara lepida* has similar properties. It is short and broad, of a pale green, with fleshy spines on the upper surface, each of which is charged with venom that occasions acute suffering. The larvæ of *Adolia* are also armed with venomous hairs. Another, not uncommon in certain trees in the terai of the Himalaya, is a dark-coloured hairy caterpillar, which is apt to fall on people and cause intense irritation. It is known as the *Komlah*, but the moth that produces it is not known. In schoolboys or others who handle the common 'woolly bear' caterpillar an erythematous rash may be produced.

14. Coleoptera.—Several beetles have acrid secretions capable of exciting great irritation and inflammation, raising blisters, and if absorbed causing painful strangury and great urinary irritation. Such are *Mylabris Cichorii* of India, *Cantharis* or *Lytta*, or *Meloe vesicatoria*, *Lytta gigas* of Senegal, *Lytta vittata* of America, and *Lytta ruficeps* of Chili.

15. Echinodermata.—The long sharp-pointed spines of some of the echinids are capable of inflicting painful punctured wounds, but convey no true venom. Whether, as in the case of some spiny fishes, there may be an irritating mucous secretion inoculated is uncertain.

16. Cœlenterata.—Some of the *Medusæ* or jelly-fish have the power of stinging. The poison-apparatus is placed in certain tubercles on the surface. These contain a collection of granules, among which are small vesicles. Within these corpuscles or nematocysts a spiral thread is found, which bursts out on pressure. These corpuscles are found in the mucus exuded by the creature, and to them is attributed the urticating power it possesses. There are several stinging species, some found on our own coasts, others in other seas. It is the larger forms generally that are venomous, the small ones having no effect on man. *Cyanea capillata* of our seas is a rather formidable creature, and the terror of bathers. It has a broad tawny disk, and a long train of ribbon-like streamers floating after

it; it makes its way through the waters; and whoever comes in contact with these trailing trains soon writhes in torture, the effect produced being not unlike that of the nettle.

Physalea pelagica, the 'Portuguese man-of-war,' has similar properties. It causes severe and stinging pain, extending up the limb, with feverishness, which has been known to continue for some hours, white wheals forming on the skin, as in urticaria. Several other medusæ possess these properties, and hence they have received the name of *Acalephæ*, or sea-nettles. The application of vinegar or olive oil is said to remove the unpleasant symptoms.

The *Actinia*, or sea-anemones, and the hydroid polyps, appear to possess a similar power, and are provided also with thread-cells. They cause urtication of the human skin when brought in contact with their tentacles. The *Sagartiade* furnish examples of sea-anemones with this property. The effects, however, of any of them are transient. In some parts of Europe the *Acalephæ* have been used therapeutically as counter-irritants, by being brought in contact with the patient immersed in a salt-water bath.

JOSEPH FAYRER.

VENOUS HUM.—A peculiar murmur heard on auscultation of the larger veins, especially those of the neck and chest, in anæmia, and in cases of interference with the flow of the blood through these vessels. See PHYSICAL EXAMINATION.

VENTNOR, in the Isle of Wight.—A mild, dry, tonic climate. Mean winter temperature for forty years, 42–43° F. Sheltered from N., N.E., and E.; exposed to S.S.E. and S.W. winds. See CLIMATE, Treatment of Disease by.

VENTRICLES OF THE BRAIN, Diseases of.—SYNON.: *Maladies des Ventricules du Cerveau*; Ger. *Krankheiten der Gehirnhöhlen*.—The chief morbid states of the ventricles of the brain are (1) New-growths, Degenerations, and Inflammatory changes in the *lining membrane* (ependyma) and *velum interpositum*; and (2) Accumulations of blood, pus, and serum in the *ventricular cavity*. The more important of these changes are fully described in special articles.

1. **Diseases of the Lining Membrane and Velum.**—In old age, and in some degenerative brain-diseases, such as general paralysis, the ependyma of the ventricles becomes *thickened*. The surface is smooth, or, in some cases, covered by minute warty granulations. Some of the latter may attain the size of a pea, and constitute small fibrous tumours. Similar changes are sometimes found when the brain has been subjected for a long time to passive congestion. In rare cases the thickened membrane has been found *calcified* in places.

A few *morbid growths* have been met with in the ependyma, the most common being the granulations of tuberculosis, which have been found both on the lining membrane and the choroid plexus. The latter and the velum interpositum frequently present thickening, and undue adhesion to the ependyma. In rare cases *fatty growth* has been met with in this situation. The choroid plexus may present partial *fatty degeneration*, and frequently contains *corpora amylacea*. Aggregations of *brain-sand* (see CONCRETIONS) are common in the choroid

plexus, and occasionally occur in the lining membrane.

Cystic degeneration is the most common morbid appearance in the choroid plexus, especially in that part which is within the descending cornu. The cysts are clear, delicate, colourless, transparent, from the size of a pea downwards. They consist of delicate cells pressed together; these are simply normal cellular elements of the part which have undergone a peculiar degeneration. In some of the larger cysts, these cells have been destroyed in the centre, so that a true fluid-containing cyst remains.

Adhesions sometimes take place between contiguous surfaces of the lining membrane; these may cut off one posterior cornu from the rest of the ventricle, and it may thus be obliterated by the union of its walls.

The ventricles may undergo passive *congestion* in common with other intracranial structures, or from pressure upon the veins of Galen, which carry the blood from the velum interpositum. The latter may cause effusion of fluid into the ventricles, but its influence was formerly over-estimated. The cause which obstructs the veins is generally a growth which also hinders or prevents the escape of fluid from the third into the fourth ventricle.

Inflammation involves both the ependyma and the velum interpositum. It is rarely confined to the ventricles, still more rarely to one. Commonly it is part of a general meningitis. The ependyma and the velum are thickened and pulpy, being infiltrated with cells of new-formation. The velum is always injected; the ependyma may be injected or pale. Occasionally a 'false membrane' is found upon its surface. The tissue of the brain beneath the ependyma is softened, and may be injected. The fluid in the ventricles is increased in quantity, and is turbid from pus and exudation-cells, and even (it is said) from the *débris* of nerve-fibres. The inflammation, of which this is part, is usually tubercular and fatal; but, when simple, it may pass away, the ependyma and velum remaining thickened and adherent. See MENINGES, CEREBRAL, Inflammation of, Tubercular, p. 979.

2. **Intraventricular Accumulations.**—*Hæmorrhage* rarely occurs directly into the ventricles; it has resulted from the rupture of a vein by injury; but blood often enters them from an effusion into the cerebral substance, an ordinary hæmorrhage bursting into the cavity. In meningeal hæmorrhage blood may even pass up into the ventricles from the subarachnoid space, by the passages through which it escapes. True *pus* may be found in the cavities, from the bursting into them of a cerebral abscess; and a purulent fluid may result from inflammation of the lining membrane. A slight amount of *serum* results from inflammation, but is rarely considerable, unless the escape of that secreted by the choroid plexus is prevented by the closure of the passage to the fourth ventricle or by the obliteration of the foramina in the membrane closing in the fourth ventricle, by which its cavity communicates with the subarachnoid space (Hilton) (see HYDROCEPHALUS). In atrophy of the brain, the fluid within the ventricles (as beneath the arachnoid) undergoes a considerable compensatory increase, which has been without reason regarded as a cause of symptoms.

Lastly, by violent commotions of the brain the septum lucidum may be *ruptured* (Wilks and Moxon).

Ventricular hæmorrhage and *Hydrocephalus* are described in special articles. See BRAIN, Hæmorrhage into; and HYDROCEPHALUS.

The other conditions mentioned are marked by no distinctive symptoms, and call for no special treatment. W. R. GOWERS.

VERBIGERATION.—See p. 767.

VERDIGRIS, Poisoning by.—See COPPER, Poisoning by.

VERMES (Lat. worms).—See ENTOZOA.

VERMICIDES (*vermis*, a worm; and *cædo*, I kill).—A group of anthelmintics which kill worms. See ANTHELMINTICS.

VERMIFUGES (*vermis*, a worm; and *fugo*, I expel).—A group of anthelmintics which expel worms, but do not necessarily kill them. See ANTHELMINTICS.

VERRUCA (Lat. a wart).—See WART.

VERRUCA PERUANA.—See CARRION'S DISEASE.

VERTIGO (*verto*, I turn).—SYNON.: Giddiness; Dizziness; Swimming of the head; Fr. *Vertige*; Ger. *Schwindel*.

DEFINITION.—The consciousness of disordered equilibration.

PHYSIOLOGICAL RELATIONS.—To understand vertigo normal equilibration must be briefly considered. The equipoise is maintained by a sensorimotor mechanism. The co-ordinating centre is the cerebellum; the afferent or sensory apparatus consists of visual, tactile, muscular, and labyrinthine impressions; the efferent or motor mechanisms are the muscles, chiefly those of the head, neck, spine, and lower extremities. Derangement of any part of this apparatus may lead to vertigo, by the interruption of its power of adjustment being appreciated by cortical centres. Vertigo is often associated with reeling or staggering, and is incorrectly said to cause it. Actually vertigo is the consciousness of disturbed locomotor co-ordination—a rudimentary disorder of co-ordination of locomotive movements (Hughlings Jackson)—while reeling is an adaptive effort to preserve the equilibrium. It is quite possible that cortical centres in an unstable condition may give rise to vertigo, without there being any disease or disturbance of subordinate centres, or of peripheral impressions. It is probable that migrainous vertigo is due to discharging lesions of the cortical centres concerned in the consciousness of equilibratory perceptions. Experimental researches and observations in disease have established the conclusion that the semicircular canals take an important share in normal equilibration; injury and disease of these parts occasioning locomotive inco-ordination, temporary when one side only is deranged, permanent when both sides are involved. It has been demonstrated by Flourens that injury of each canal is followed by definite locomotive disturbance, causing the body to tend to fall, or actually to fall, in a definite and precise direction, forwards, backwards, or to one or other side, according to which of them is injured. The sensory impressions originating in the semicircular canals are caused by varying tension of the endolymph, communicated to the

vestibular division of the auditory nerve spread out on the ampullæ of the membranous canal. Variations in labyrinthine tension may be produced by alterations in the position of the head, by differences in the vascular tension of the labyrinthine blood-vessels, and by the varying pressure in the middle chamber of the ear, induced by obstruction of the Eustachian tube, spasm of the tensor tympani muscle, and other causes; and it may also be due to disease of the labyrinth itself, or communicated to the labyrinth. Moreover, it is asserted that 'if the horizontal canal is laid bare, and the membranous canal opened so as to expose the endolymph, blowing gently over the opened canal with a fine glass cannula will produce a definite movement of the head, which is turned to the one side or to the other, according as the current of air drives the endolymph towards or away from the ampulla. From this it is inferred that a movement of the endolymph over, or an increased pressure of the endolymph on, the surroundings in the ampulla gives rise to afferent impulses which in some way determine the issue of efferent impulses leading to the movements of the head' (Michael Foster). In some cases of aural vertigo, the giddiness is much influenced by the position of the head, and it is only in certain positions that this symptom is produced. This is readily accounted for on the supposition that the disease causing it is in the semicircular canals, which are so arranged as to lie in the three directions of space; and change in the position must affect the pressure of the endolymph on the various ampullæ, resulting in adjustment of position when the co-ordinating centres are in proper working order, but when these are deranged leading to the consciousness of disordered equilibration or vertigo. Further, the evidence supplied in a *post-mortem* examination of a case of Ménière's disease, where hæmorrhagic inflammatory material was found in the semicircular canals, and no disease of the brain, proves that disease of the semicircular canals *per se* may give rise to vertigo. Visual and tactile impressions are liable to be deranged in many ways, for instance, by unexpected or unusual movements, as in swinging, being at sea, &c.; by local disease of the visual and tactile apparatus; and by disease in the nerve-trunks and spinal cord, interrupting conduction from the periphery to the centre. By disturbances in visual, tactile, or labyrinthine impressions the equilibrating centre is uninformed or misinformed, and inco-ordination results, outwardly shown by reeling or falling, and inwardly by the sensation we call vertigo. Loss or perversion of visual or tactile sensations may be compensated for if the two remaining sensory processes continue intact, but nothing compensates for entire loss of labyrinthine impressions (Ferrier).

PATHOLOGY.—Vertigo may be excited by variations in the local or general blood-pressure, which cause variations in the labyrinthine tension, as in anæmia, gout, and other affections. It may be excited reflexly by disease of the nose (*vertigo a naso læso*, Joul), or by disease of the larynx. The symptom is also produced by certain drugs, such as quinine, salicin, and the salicylates, which may act on the labyrinth through the vascular system, as is rendered probable by the deafness and tinnitus accompanying it, but which may be due to its action on the auditory nucleus, or the cortical centres concerned in consciousness of auditory perceptions. Vertigo may be excited by sending a galvanic

current through the head from one mastoid process to the other, but the exact mode of its action is not known.

VARIETIES.—The important forms of vertigo which occur in practice will be further considered under the following heads: (1) Ocular; (2) Auditory; (3) Gastric; (4) Nervous; (5) Epileptic; (6) Migrainous; (7) With organic brain-disease; and (8) Cardio-vascular.

1. Ocular Vertigo.—Vertigo is frequently caused by ocular disorders, and is often mistaken for serious cerebral disease. The simplest form is in paralysis of a single muscle, as the external rectus. The vertigo is not occasioned by the diplopia, but by the incorrect notion formed of external objects by the paralysed eye, due to what is known as 'erroneous projection.' The confusion thereby produced gives rise to vertigo, and often to reeling. One of the most important varieties of ocular vertigo is that occasioned by insufficiency of the internal recti muscles—*muscular asthenopia*. This is most commonly met with in myopia. During reading, these muscles, which have long been overtaxed by exertions to maintain the convergence of the eyes rendered necessary when looking at near objects, suddenly give way under the strain; they relax, the eyeballs turn out, and the letters on the page become indistinct, run into each other or overlap, and a sense of confusion and giddiness occurs. It is usually accompanied by aching at the back of the eyes, headache, and sometimes by nausea. Muscular asthenopia may occur also with hypermetropia, and as a sequel to exhausting diseases, such as fevers and diphtheria. Many instances are recorded where, owing to these causes of vertigo not being recognised, serious errors of diagnosis and treatment have resulted. For the diagnosis of the particular optical defect and treatment, the reader is referred to the article VISION, Disorders of.

2. Aural or Auditory Vertigo.—**SYNON. :** *Vertigo ab Aure Læsa*; Labyrinthine Vertigo; Apoplectiform Vertigo; Menière's Disease.

Under the term 'Menière's disease' is grouped a class of cases in which vertigo is caused by perversion or abeyance of the labyrinthine function. The labyrinthine disturbance may be caused either (1) *directly* by an affection of the labyrinth, such as (a) hæmorrhage, (b) congestion and inflammation; or (2) *indirectly*, by (a) disease of the middle ear (otitis media), (b) obstruction of the Eustachian tube, (c) spasm of the tensor tympani, or paralysis of the stapedius, or (d) irritation or obstruction of the external auditory meatus, and pressure on the membrana tympani, as by cerumen, foreign bodies, or by syringing the ears, especially when the membrana tympani is perforated. In Menière's disease, strictly speaking, there is always coincident disturbance in the functions of the semicircular canals and cochlea, as indicated by the three most important associated symptoms—vertigo, tinnitus, and deafness. Accompanying these cardinal symptoms there are accessory phenomena, due to secondary visceral disturbance, namely, pallor, faintness, and nausea or vomiting—a condition of syncope. Aural vertigo is rare in young persons, and is chiefly met with in the later half of life. It is more frequent in men than in women.

The disease makes its appearance, in a person apparently quite well, or the subject only of some chronic aural disease, with a loud noise in the ear,

compared by different persons to the whistle of a steam-engine, the firing of a gun, or the roar of the ocean. When a person, as not infrequently happens after the first attack, has an habitual noise in the ear, this at the time of the attack is sometimes, but not always, greatly exaggerated. The noise, which is wholly or principally in one ear, is soon followed by the feeling of giddiness. This is generally of a high degree, causing a sensation of movement of surrounding objects in some one direction, a feeling of translation of the patient's body in the same direction, or actual movements of the body. The movement, whether apparent or real, is usually *from* the side on which the ear is affected. In recurring attacks the movements, whether of objects or of the individual, are nearly always in the same direction. Usually the sensation of movement is from behind forward, or to one or the other side, or the patient has a feeling of rotation round a vertical axis. When in bed, the room, bed, and occupant are felt as if turning round and round, or rising or sinking. Accompanying the vertigo there is reeling, and the patient clings to surrounding objects for support. In some cases the movement is too rapid for the patient to obtain security in this way, and he is thrown to the ground, sometimes with such violence as to occasion serious injuries. One patient described the sensation as 'if his heels went up into the air.' When falling takes place, it is usually forwards or to one side. It is, however, to be especially remembered that, except in rare cases, there is no loss of consciousness; the patient being able immediately after the attack to describe the sensations he experienced, or even to answer questions in the attack itself. In some cases deafness, more or less complete, but sometimes transitory, follows the vertigo at an appreciable interval, and in some cases it is altogether wanting. Following the tinnitus and vertigo, in more or less rapid succession, there occur nausea and in most cases vomiting, accompanied by pallor of the face; the skin becomes cold and covered with a clammy sweat. In some cases oscillatory movements of the eyes are observed. It is generally asserted that objects appear to move in a direction opposite to that of the ocular movements. This is not universally true; and probably, contrary to the statements of most writers, the apparent movement of objects is in the same direction as the observed movements of the eyes. Gradually the attack passes off; the noises in the ear lessen, but deafness is left behind. The body recovers its warmth, and the pallor subsides, but vertigo and vomiting may persist for some hours or even days, both being aggravated or induced by rising from a horizontal position. Slight attacks may only last a few minutes. In cases where there is a direct lesion of the labyrinth, a certain degree of deafness—a limitation of the field of audition, that is, the loss of certain sounds in the musical scale—and tinnitus remain. The patient is in all other respects well, except for the dread of a recurrence of the attack. Occasionally, however, some amount of vertigo and reeling persist, liable to be aggravated by gastric derangement. The writer has known a patient who had extremely severe and typical attacks, who both previously and subsequently suffered from functional dysphagia between the attacks—a full-sized bougie could be easily passed. It was evidently due to disturbance in the vagus-nucleus. A patient rarely escapes with one attack. Subsequent attacks are separated by dis-

tinct intervals, but in severe cases these may become less and less, until a permanent vertiginous state, of a most distressing character, may be reached, liable to paroxysmal exacerbations. In such very grave cases spontaneous cure may occur on the establishment of complete and permanent deafness, or relief may be obtained by therapeutical measures. When the labyrinthine disturbance is secondary to disease of some other part of the auditory apparatus, removal of the primary disease, as cerumen or tympanic catarrh, will, when practicable, promptly remove the symptoms, and the attacks may not recur.

DIAGNOSIS.—Ménière's disease has to be distinguished from epilepsy, apoplexy, gastric derangement, and other forms of vertigo. From all these it is distinguished by the almost invariable co-existence of tinnitus, deafness, and vertigo; with, in addition, a tendency to syncope and nausea, or vomiting. The concurrence of the first three symptoms renders it probable that the labyrinth is involved, a point which will be further established by testing audition with a tuning-fork and watch. The vertigo is generally a sensation of movement in a certain definite and uniform direction. There is never numbness, tingling, or any sensations analogous to an aura. As to the diagnosis of the nature of the labyrinthine affection, whether primary or secondary, some rules have been laid down by authorities. If a person who has formerly heard well becomes suddenly deaf or hard of hearing, with the symptoms of an apoplectic attack, and if there is at the same time an uncertain and staggering gait, but no symptoms of paralysis in the nerve-tracts, and if the examination shows a normal membrana tympani, and perfectly permeable Eustachian tube, we may believe with great probability that there is an affection of the labyrinth (Trötsch). Deafness and tinnitus occurring without vertigo indicate an affection of the middle ear. Vertigo and tinnitus without deafness may be due to a similar affection. Vertigo, tinnitus, and deafness are certainly due to an affection of the labyrinth. When the vertigo is markedly influenced by changes in the position of the head, it is, in the writer's opinion, strong evidence that the disease is in the labyrinth. Careful otoscopic examination should be made, the permeability of the Eustachian tubes tested, and the tuning-fork and watch employed to ascertain the condition of the conducting apparatus, before an exact opinion can be formed as to the seat and nature of the disease. Vomiting, following the ingestion of some rich or indigestible food, may be so severe and lasting as to monopolise attention, and the vertigo and tinnitus may not be complained of. In such a case, a mistake may readily occur in a first attack.

PROGNOSIS.—When the labyrinthine affection is due to some remediable defect, the disease will subside on removal of the cause, such as cerumen or tympanic catarrh; hence the great importance of an exact diagnosis as to the nature of the case. When the lesion is primarily of the labyrinth, a certain degree of deafness and tinnitus is nearly always left, and recurrence of the attack is to be anticipated, though some cases recover completely under treatment. In some instances the tinnitus and vertigo may cease on the patient becoming completely deaf.

TREATMENT.—In the attack, and for a short time following it, the recumbent position should be strictly maintained. Bromide of potassium or ammo-

nium, in ten- to twenty-grain doses, should be administered, and small pieces of ice swallowed. Belladonna is also recommended, especially in combination with bromide. Next, any gastric derangement should be corrected, for in some cases such derangement excites a paroxysm in a person predisposed to it by some aural affection, insufficient alone to induce an attack. Alkalis and vegetable bitters, with or without bismuth, will generally be useful for this purpose. Any abnormal local condition must be treated. Subsequent to the attack quinine in full doses, 3 to 5 or 10 grains three times a day, perseveringly used, is sometimes attended by the best results (Charcot). The writer has seen many cases which corroborate this statement. Gelsemium and salicylate of sodium have been found useful (Gowers). Counter-irritants, including the actual cautery, applied to the mastoid region, have proved serviceable in some cases, and may be used in addition to other measures. Threatened attacks of aural vertigo may be often avoided, especially in cases in which arterial tension is high, by a dose of calomel, and it is a good plan to give a patient liable to attacks calomel-powders (gr. iij or v) to be always carried in the pocket-book, and order one to be placed on the tongue when any threatenings occur.

3. Gastric Vertigo.—**SYNON.** : *Vertigo a Stomacho Læso*.

Vertigo, occasionally of a high degree, sometimes accompanies chronic gastric derangement. It is more common with slight than with grave affections of the stomach, but has been met with in well-marked organic disease of this organ. It sometimes occurs soon after a meal, but more often when the stomach is empty (Trousseau). At the same time it is now generally agreed that cases of gastric vertigo are much less common than Trousseau's description would lead one to believe. In the majority of such cases some ear-disease is revealed by careful examination. Associated with the vertigo are usually pain and a feeling of fulness in the stomach, increased by food; heartburn; eructations; vomiting; flatulence; and pain in the left hypochondrium and chest. The bowels may be torpid, or diarrhoea may be present. The patient often suddenly experiences a swimming in the head, objects may appear to revolve, the patient's gait becomes tottering, and he may even fall. Often there is constrictive headache, faintness, and pallor with nausea, and sometimes troublesome vomiting, but there is no loss of consciousness. Visual hallucinations may be present, and buzzing in the ears experienced, but there is no deafness. The vertiginous symptoms may so predominate that the gastric symptoms may not be complained of; but treatment directed against dyspepsia cures the vertigo. When predisposing gastric disturbance is present, trivial causes, such as looking at objects which lead to confused visual impressions, may excite an attack, but this may also arise spontaneously. In many cases relief is obtained by the recumbent position, but attacks may occur when the patient is lying down.

DIAGNOSIS.—This form of vertigo is diagnosed from epilepsy by absence of loss of consciousness; and from labyrinthine vertigo by the absence of deafness, and the physical signs of aural disease. It cannot be concluded that the vertigo is essentially gastric without thorough examination of the ears, for, as already stated, vertigo may be excited by gastric disturbance when there is labyrinthine affection insufficient alone to determine an attack.

It must also be remembered that signs of gastric and intestinal derangement are induced in Menière's disease, and may be so prominent as to cause the aural affection to be overlooked.

4. **Nervous Vertigo.**—**SYNON.** : Fr. *Vertige Nerveuse*.

Not uncommonly, vertigo is one of the most troublesome symptoms of nervous exhaustion and depression. This occurs in persons unduly taxing their nervous powers by severe intellectual strain, especially when combined with anxiety, or by sexual excesses. It occurs also from the depressing effects of the immoderate use of tobacco, alcohol, and tea. The vertigo rarely reaches a high degree, manifesting itself by a sensation of confusion, or of objects revolving, only occasionally by the feeling of a tendency to fall. It may be associated with a slight reel, but more often the patient feels as if he were walking unsteadily, when there is no perceptible peculiarity of gait. As a rule giddiness is only experienced in the upright position, but in some cases it occurs when the subject is recumbent, and the patient often complains of sudden and violent startings when just in the act of falling asleep. It is often intensified by an elevated position, and in large buildings and assemblies. Hence it is often experienced in church. It is peculiarly distressing, owing to the sufferer's emotional equilibrium being easily disturbed, and is frequently associated with a dread of impending cerebral disease—epilepsy, apoplexy, insanity, &c. There often co-exist gastric derangement and flatulence, with irritability of the heart, palpitation, and sleeplessness. There may be slight and temporary buzzing in the ears, but deafness is absent, and loss of consciousness does not occur. In these respects it is readily distinguished from Menière's disease and *petit mal*.

TREATMENT.—This variety is to be treated by removal of the cause—over-work, excessive sexual indulgence, or the abuse of alcohol, tobacco, or tea; by correction of any dyspeptic symptoms; and by the administration of nervine tonics, such as iron, quinine, or strychnine. Bromides should be avoided if possible.

5. **Epileptic Vertigo.**—Vertigo may occur in a slight fit of epilepsy, or at the commencement of a severe attack. The symptom may replace an epileptic fit, or may co-exist with epilepsy. It is more common in epileptic vertigo for the patient to imagine that he himself is moving or turning round, than for external objects to appear in motion (Russell Reynolds). If the vertigo is related to change of position of the head, it is probably labyrinthine. The latter is not usually accompanied by loss of consciousness, and is more apt to be followed by vomiting (Gowers).

6. **Migrainous Vertigo.**—Vertigo commonly constitutes one of the phenomena of megrim, occurring as a rule after the disorders of sight, touch, and speech, when these form part of the seizure, and either attends or follows the development of the headache (Liveing). Vertigo sometimes replaces the attacks of megrim. It is apt to occur on change of posture, or on suddenly turning the head. As a rule, migrainous vertigo is slight in degree, but it may be quite severe, and accompanied by nausea and vomiting. It is unassociated with noises in the ear, or with deafness. See MEGRIM.

7. **Vertigo in Connection with Organic Disease of the Nervous System.**—Vertigo sometimes accompanies disease of the cerebrum, both acute, as apoplexy, and chronic, as a tumour. There are reasons for believing that vertigo may be excited by cortical lesions, thus explaining epileptic and migrainous vertigo. Diseases of the cerebellum and of its middle crura are often attended by reeling gait, and sometimes by vertigo. This symptom sometimes accompanies the ataxy of tabes dorsalis, and is a symptom of many cases of insular sclerosis.

8. **Cardio-vascular.**—Disease of the heart accounts for some cases of vertigo, while in others the symptom is due to arterio-sclerosis; but apart from cardiac or vascular disease the symptom may arise from sudden alteration of the cerebral circulation, anæmia or hyperæmia of the brain; and women at the climacteric period often suffer from giddiness.

A peculiar form of disease has been described by Gerlier, which he has called 'paralysing vertigo,' and which subsequent writers have named 'Gerlier's disease.' It consists of three groups of symptoms: (1) muscular weakness in the muscles of the neck or trunk and legs, and occasionally in the hands; (2) pain in the neck and occiput; (3) ocular symptoms, of which ptosis is the most common. Occasionally diplopia and amblyopia are present. Dizziness or mistiness before the eyes is often present, more rarely rotatory vertigo. The attacks usually occur about once or twice a day, and between the attacks the patient is well. The disease has only been observed in some Swiss villages on the French frontier, where the malady has received the name of *le tourniquet*. It appears to have had a kind of epidemic prevalence. Its nature is very doubtful, but it appears to be a functional disturbance or psychosis. No evidence of organic disease has been present in the cases recorded.

An affection described by Miura, in Japan, and known as *kubisagara*, is probably the same as 'Gerlier's disease.' See p. 1740.

STEPHEN MACKENZIE.

VESICANTS (*vesica*, I blister).—A class of counter-irritants which produce blisters. See COUNTER-IRRITANTS.

VESICLE (*vesicula*, diminutive of *vesica*, a bladder).—**SYNON.** : Fr. *Vésicule*; Ger. *Bläschen*. A vesicle is a lesion of the skin produced by a small localised collection of fluid in the epidermis. The usual contents are blood-serum with fibrin, leucocytes in varying numbers, degenerated epithelial cells, and in many cases micro-organisms. If the leucocytes are in large numbers, the contents of the vesicle are purulent, and the name 'pustule' is applied; when the vesicles become confluent, or are of large size, the name 'bulla' is made use of. Vesicles may arise in any of the layers of the epidermis. Frequently they arise immediately under the stratum corneum or in the upper layers of the stratum granulosum. Such vesicles are found in the early lesions of eczema, or in some of the varieties of pyoderma. As a rule they contain micro-organisms in considerable numbers. They may also arise in the stratum granulosum or at the junction of this layer and the stratum mucosum. In such cases the vesicle may be surrounded by the stratum granulosum or may be covered by both the stratum granulosum

and the stratum corneum. The vesicles of dysidrosis frequently arise in this situation. They may also form at various depths in the stratum mucosum. With an uninjured horny layer the contents of the vesicles may be free of organisms.

Vesicles may be divided into compartments by strands of epithelial tissue, or umbilicated when rising round one of the ducts of the skin-glands or a hair-follicle. They may be developed in rings, as in erythema multiforme; in groups, as in herpes zoster; and may be acuminate, rounded, or flattened.

Not infrequently the red blood-cells, as well as the serum, may be contained in the vesicles.

In certain diseases of the sweat-apparatus, vesicles may arise containing sweat only.

The vesicle may heal by absorption of the contents, or after their escape on account of rupture of the epidermis, followed by subsequent desquamation of the overlying epidermis. As the epidermis is reproduced no scar results from an uncomplicated lesion.

JAMES GALLOWAY.

VESICULAR EMPHYSEMA.—A form of emphysema of the lungs, in which the alveoli are distended with air. See LUNGS, Emphysema of.

VIABLE (Fr. *vie*, life).—SYNON.: Fr. *Viable*; Ger. *Lebendig*.—An epithet applied to a newly born child, to indicate its capacity for maintaining an independent existence. Viability has chiefly to be determined by the age of the fœtus, and by its condition as regards formation, health, and strength (see MONSTROSITIES; and FŒTUS, Diseases of the). It has also been supposed to depend in some measure upon the season of the year in which a child is born. The question of viability has important medico-legal bearings, for which reference should be made to works upon forensic medicine.

VIBICES (*vibex*, a wale).—SYNON.: Fr. *Vergesures*; Ger. *Striemen*.—A term applied to patches of discolouration on the surface of the body, somewhat resembling the marks of stripes or wales, and due to the presence of altered blood in the part. Vibices may arise either during life, as the result of a variety of causes (see EXTRAVASATION); or after death, as one form of cadaveric lividity or hypostasis. See DEATH, Signs of.

VIBRIO (*vibro*, I shake).—SYNON.: Fr. *Vibrion*; Ger. *Zitterthierchen*. See BACTERIA.

VICARIOUS (*vicarius*, in place of another).—This word signifies substitution, and in physiology and pathology implies that some part or organ performs certain functions, or is morbidly affected, instead of some other part or organ, thus becoming a substitute for it. The notion of vicariousness is chiefly associated with a discharge of blood, whether physiological or morbid. Thus it is very common to speak about *vicarious menstruation*, which is understood to mean that the discharge of blood that takes place normally from the uterus at the menstrual period either does not occur at all or only imperfectly, and that its place is taken by hæmorrhage from some other part, evidenced by epistaxis, hæmoptysis, hæmatemesis, or other forms of bleeding. The same idea is extended to morbid hæmorrhages, such as bleeding from piles, when this becomes habitual in an individual at frequent or regular intervals. It is supposed that bleeding may sometimes

take place from other parts as a vicarious hæmorrhage, instead of from the hæmorrhoids.

Again, discharges, whether normal or morbid, as of secretions, mucus, pus, or other materials, are believed by many to exhibit a vicarious relation to each other in some instances, coming from one part while ceasing or diminishing at another, and so on. This may be illustrated by expectoration and diarrhoea in phthisis, which appear to modify each other as to their amount in some cases of this disease. Further, secretions and excretions are regarded as acting vicariously with reference to each other. Thus some of the secretions of the alimentary canal are undoubtedly capable of acting mutually as substitutes, and this may be looked upon as an instance of vicarious action; while such a connection existing between the perspiration and urine is generally recognised.

Certain morbid conditions are also considered as having a vicarious relation. For example, congestion of, or hæmorrhage from, one part may take the place of congestion at another; or inflammation in one region may be the substitute for inflammation in another region.

Enlargement of one lung or one kidney after complete or partial destruction of the other—examples of a condition generally known as ‘compensatory hypertrophy’—may also be quoted as instances of vicarious action.

There is probably more or less truth in these notions of vicariousness, as applied in relation to physiology and pathology. In actual practice, however, no case ought to be regarded as belonging to this category, without careful and thorough investigation. It has happened that hæmorrhages supposed to be vicarious of menstruation have been important signs of grave diseases, such as gastric ulcer, or pulmonary phthisis. The principle may be of value in certain conditions as an indication for treatment.

FREDERICK T. ROBERTS.

VICHY, in Allier, France.—Thermal alkaline waters. See MINERAL WATERS.

VIDAGO, in Portugal.—Bicarbonated alkaline waters, with lithium and arsenic. See MINERAL WATERS.

VILLOUS GROWTH (*villus*, hair).—A growth composed of hypertrophied villi. See TUMOURS.

VIRGINIA SPRINGS, in Virginia, United States.—Sulphur-waters. See MINERAL WATERS.

VIRULENT (*virus*, a poison).—This word is generally employed to indicate great intensity or malignancy of a disease; for example, *virulent inflammation* and *virulent small-pox*. See also p. 721.

VIRUS (Lat.).—Literally this word signifies a poison, but in medical language it is used to designate any kind of specific organic poison. See INFECTION.

VISION, Defects of.—SYNON.: Fr. *Troubles de la Vision*; Ger. *Sehenstörungen*.

Sight may be defective as to perception of form, of colour, or of light; and the whole or only a part of the visual field may be affected. Sight is also disordered whenever *binocular single vision* becomes difficult or impossible (see STRABISMUS);

and when *visual endurance* is impaired. The terms 'vision' and 'sight,' as commonly used, indicate acuteness of vision, and refer to the perception of form at the yellow spot. In this article disorders (A) of *perception of light*, (B) of *perception of colour*, and (C) of the *visual field*, will be shortly alluded to; but attention will be chiefly given to (D) disorders of *acuteness of vision* caused by optical defects in the eyes.

A. Disorders of Perception of Light.—Perception of light is equally good in all parts of the retinal area, except the most peripheral zone, which appears to be blind. Impaired perception of light causes disproportionate defect of vision by dull light—'night-blindness.' It may affect the whole field, or only its periphery. It occurs chiefly in diseases of the outer layers of the retina, especially syphilitic retinitis and retinitis pigmentosa, and sometimes in chronic glaucoma. Lowered light-sense over the whole field occasions the symptoms in the peculiar disease known as functional or endemic nyctalopia (*torpor retina*). The opposite condition, day-blindness with true retinal photophobia, is much rarer and more obscure. It is usually congenital, and accompanied by nystagmus, amblyopia, and colour-blindness. See NYCTALOPIA; and HEMERALOPIA.

B. Colour-Blindness.—SYNON.: *Dyschromatopsia*; *Achromatopsia*; Daltonism.—This, when *congenital*, is usually not related to any other defects of vision. Congenital colour-blindness occurs with greater intensity and far greater frequency in males than in females (M. about 3·5 per cent.; F. ·2 per cent. or less). It is shown by inability to distinguish between certain colours owing to absence of one or other of the chief colour-sensations. The spectrum seen by a red-blind person may appear shorter at its red end than it does to one with normal colour-vision, and he sees in it only two chief colours. The red, orange, yellow, and green are all 'green,' the blue and violet are 'blue,' and the two are separated by a neutral or 'white' band at the part that to the normal eye is bluish-green. In green-blindness the spectrum is not shortened, but the red, orange, yellow, and green are 'yellow' of various shades, or sometimes 'red'; the neutral band is in the pure green. It is often impossible to distinguish red-blindness from green-blindness with certainty except by using the spectrum; and in ordinary examination the two forms are best grouped together as 'red-green-blindness.' In incomplete red-green-blindness, green, bluish-green, and often rose are confused with grey of corresponding shade, and red is confused with shades of brown, greenish-brown, and yellowish-brown. In a complete case full green and scarlet look identical, and dark yellows are more or less confused with them. The best test (of many) for ordinary use is Holmgren's, in which a skein of Berlin wool, of a particular colour and shade (green, rose, or red), is given to the patient, and he is required to match it with all the others which seem to him of the same or a similar colour, among a large bundle of skeins of many colours. He is not usually allowed to name the colours, because even the colour-blind often guess the colours of common objects correctly. A very pale, pure green is the first test used; and the colour-blind, even of slight degrees, will match with it not only other green skeins, but also shades of pale grey, buff, pink, or blue. Slight cases may easily be overlooked, unless

the wools are carefully selected, and the examiner practised. In deciding as to the fitness of a candidate for signal work it is often desirable to test with a lantern and coloured glasses in addition to the wools. Red and green are not well seen even by the normal eye, except at the central part of the visual field (i.e. the field for these colours is smaller than for white); but even at the periphery these colours are recognised if very brightly lighted and of large size.

Acquired colour-blindness often comes on in degenerative or inflammatory diseases which begin in the optic nerve. It is rare in diseases of the retina, and in glaucoma. Like the congenital form, it usually concerns only, or chiefly, red and green. It may affect the whole visual field of these colours, or only certain parts, a gap, or 'scotoma,' being present, on the area of which the red and green are not perceived in their true colours. When acquired colour-blindness is well marked in the whole extent of the field, in cases of disease of the optic nerve, the prognosis for sight is generally very bad; but if it be localised on a central scotoma, even though it may there reach a high degree, the prognosis is usually good. Progressive atrophy of the optic nerve, however, occasionally reaches a very high degree without any colour-defect.

C. Disorders of the Visual Field.—The visual field is the whole surface visible to one eye singly while at rest. It forms a concave surface, all the points of which are equidistant from, and perpendicular to, their corresponding points on the retina. In the outward and downward part it reaches to 95° from the centre; inwards, upwards, and downwards to about 60°. Projected on a flat surface it forms an oval. The centre ('fixation-point') corresponds to the yellow spot, and the 'blind spot' corresponding to the optic disc is about 15° outwards from this point. In order to measure the field roughly, the patient, placed with his back to the light, and covering one eye, looks steadily from a distance of eighteen inches at the nose or eye of the observer, who then moves his hand, or a small object, such as a square inch of paper, about in the different parts of the field, and notes any places where the object is invisible or badly seen. This test, carefully applied, will detect any considerable loss of the field. Or the patient may gaze at a spot on a black board about one foot off, and a piece of white chalk be moved from various places at the periphery until it comes into view; a line joining these points will form the boundary of the field. For accurate measurements a special instrument, the Perimeter, is necessary.

D. Disorders of Perception of Form.—SYNON.: Acuteness of Vision; *Visus*; *V.*; Fr. *Acuité Visuelle*; Ger. *Sehschärfe*; S.—Perception of form is normal only when the image of the object looked at falls on the retinal layer of rods and cones, at the centre of the yellow spot, is clearly defined, sufficiently bright, and of a certain minimum size.

PRINCIPLES.—The size of the image depends (1) upon the size of the 'visual angle' enclosed by the two lines drawn from the extremities of the object to the 'nodal point' just behind the crystalline lens; and (2) on the distance of the nodal point from the retina, which in the normal eye is 15 mm. The form of any letter or character is distinguished by a properly formed and healthy

eye, in moderate light, if it subtend a visual angle of five minutes, each of its separately distinguishable parts subtending an angle of one minute. If the nodal point be more than 15 mm. from the retina, the image will be larger, and the acuteness of vision therefore increased; this occurs in myopia, and also when a convex glass is held in front of the eye. The reverse is true if the distance be less than 15 mm., as in hypermetropia and when a concave glass is held before the eye. Hence convex lenses always increase, and concave lenses always diminish, the size of the retinal images. Vision or 'fixation' is called *direct* or *central* when the image of the object looked at falls on the yellow spot; *indirect* or *excentric* when, in consequence of impairment of function at the yellow spot, an image falling on some other part is better seen. The sharpness of the image depends (opacities of the media apart) upon the retina being exactly at the focus of the refracting (dioptric) media of the eye; it is also influenced somewhat by the size of the pupil, being, *ceteris paribus*, better when the pupil is small.

Normal acuteness of vision is expressed as unity (V . or S . = 1); subnormal vision being expressed as a fraction. Various *test-types* are in use, composed of letters, figures or words, of such a size that each subtends the minimum angle of five minutes at a certain distance. The test-types of Dr. Snellen are in most general use, and include letters visible under the standard angle at from 60 metres to $\frac{1}{5}$ metre. If No. 60 be read at 60 m., then $V. = \frac{60}{60}$ or 1; if No. 60 can only be seen at 6 m., $V. = \frac{6}{60}$; &c. V ., therefore, is expressed by a fraction whose numerator is the greatest distance at which a given type can be read, and the denominator the distance at which it ought to be seen; or the fraction may be reduced ($\frac{6}{60} = \frac{1}{10}$, &c.). The acuteness probably becomes somewhat lowered in some old persons without demonstrable disease.

The principal disorders of perception of form calling for description here are as follows: (1) Functional Affections of the Optic Nervous Apparatus; (2) Abnormalities of Refraction, including Hypermetropia, Myopia, and Astigmatism; (3) Anisometropia; (4) Disorders of Accommodation; and (5) Asthenopia.

I. Functional Affections of the Optic Nervous Apparatus.—Amblyopia without ophthalmoscopic changes may be permanent or temporary, and exhibit many differences in the character of the failure of sight. Many persons see much better with one eye than the other, though the defective organ shows no sign of past or present disease. Hypermetropia, or some other form of ametropia, is often present, and is usually of higher degree in the amblyopic eye. When, as is common, squint occurs in such a person, the squinting eye is almost always the defective one; and it has been assumed that the defect is a result of the squint, and due to a purposive suppression of sight in order to avoid double vision. This kind of amblyopia is, however, seen without either squint or ametropia—a fact which, with others, renders it almost certain that the defect is usually, or chiefly, congenital. Whether the seat of deficiency is in the eye or the brain remains to be proved; but it is well to realise that this form of amblyopia can seldom be improved even by long practice. In cerebral hemianæsthesia there may be blindness, or amblyopia with contraction of the field and colour-

blindness, in the eye opposite to the lesion, with a lower degree of the same condition in the other eye. Some rare cases of defective sight in one eye without changes, in which there is a history of previous paralytic symptoms, probably belong to this group. In *hemioptia* (properly *hemianopsia*) there is usually loss of the corresponding (R. or L.) halves of the visual fields, vision being lost on the side opposite to the lesion. The lesion may be in the tract, but is much more often higher up (optic thalamus or occipital lobe). Sometimes there is contraction of the remaining half field. Loss of both temporal halves indicates disease at the chiasma; neither this, nor loss of both nasal halves, is frequent. In hemioptia, even of long standing, from disease above the chiasma, the optic discs are seldom altered. In some cases of 'hemioptia' only a quarter of each field is lost. Hemioptia, usually temporary, for colours only, without loss of light- or form-sense also occurs.

Disease of the optic nerve between the eye and the chiasma causes blindness or defective sight, often at first with little or no ophthalmoscopic change; but if the loss of sight remain, ophthalmoscopic signs either of inflammation or atrophy appear in a few weeks. These changes may, however, be very slight; as in the common cases of central amblyopia caused by tobacco-smoking, in which disease of the optic nerves has been demonstrated, and in some cases of amblyopia due to disseminated sclerosis.

Temporary fogginess of sight, usually with the appearance of coloured rings around a candle, occurs in the premonitory stage of glaucoma; these last from half an hour to a day or more; they do not usually occur in both eyes at once (*see EYE, AND ITS APPENDAGES, Diseases of*). Attacks of megrim are often ushered in by a peculiar transient subjective defect of sight; a small cloud, appearing near the middle of the field, quickly spreads with a quivering movement and zigzag outline over about half the field; its borders are often brilliantly coloured; it affects *both* eyes; is equally visible whether the eyes are open or shut; lasts about a quarter of an hour; and is generally followed by the other megrim-symptoms to which the patient is subject. But some persons merely complain of a 'cloudiness' or of 'spots' before their headaches (*see MEGRIM*). Brief attacks of defect or blindness of *one* eye, coming on suddenly, and recurring in the same eye, occasionally take place; and in some of these the eye eventually remains blind with the changes characteristic of obstruction of the retinal artery.

Persons who suffer from severe neuralgic pain in the fifth nerve sometimes describe dimness of the same eye during an attack, but the opportunity of verifying the statement seldom occurs. In hysterical persons sight is sometimes much lowered, and may seem altogether lost in one or both eyes. There may be photophobia, and symptoms of accommodation-spasm, and the field is, or seems to be, highly contracted. Though it may be exceedingly difficult to say that there is conscious dissimulation, the groundless nature of the ocular symptoms is sometimes proved by the fact that acuteness of vision, even in the 'blind' eye, is at once and perfectly restored by the weakest possible lens, or by a piece of flat glass mounted to resemble a trial-lens. Intentionally feigned blindness of one eye can nearly always be detected by one device or another;

but pretended defect of both eyes is more difficult to expose.

2. Abnormalities of Refraction.—SYNON.: *Ametropia*.—These conditions are of importance by preventing the formation of clear retinal images; in addition they often make the sustained use of the eyes difficult or impossible (*asthenopia*). They include (a) *hypermetropia*, (b) *myopia*, and (c) *astigmatism*. The varieties of asthenopia will receive a short separate account at the end of this article. As ametropic conditions are remedied by optical aids, it will be convenient first to refer to the subject of spectacles.

Spectacles and Eye-glasses.—Refracting spectacles are made either of crown-glass or of rock-crystal. The latter is more expensive, but harder, less breakable, and rather lighter. Ordinary spectacles are biconvex or biconcave spherical lenses. Meniscus lenses are sometimes used, and are called 'periscopic,' because they give a larger field. In 'Franklin' or bifocal spectacles the upper part is of a different focal length from the lower; they are used by persons who need distance- and reading-glasses of different strengths in the same frame. The various non-refracting protective glasses (goggles, domed glasses, horseshoe or D protectors, &c.) are generally included under the term 'spectacles.' The most important points in the mounting of spectacles are that the hinges should be strong, the sides long enough to hold securely without uncomfortable pressure, and that the bridge should fit the nose well. The optical centres of the lenses should, unless otherwise ordered, be opposite the centres of the pupils when the glasses are in use. All concave glasses and convex distance-glasses should sit as close to the eyes as possible; convex reading-glasses may be further from the eyes, and so shaped that the eyes look over them when raised to gaze at a distant object.

For 'simple' astigmatism the correcting lens is a segment of a cylinder; for 'compound' and 'mixed' cases the effect of a cylindrical and spherical lens is required, and may be obtained either by combining two suitable cylindrical curvatures at right angles to each other, or by grinding the cylinder on the flat side of a plano-convex or concave lens; they require, of course, to be mounted with the curvature of the cylinder exactly in the right direction. When prisms are ordered they are mounted like ordinary spectacles, and a lens may be ground upon each surface of the prism if necessary; it is not practicable to wear prisms of more than about 8°. Spherical lenses can be made to act to a varying degree as prisms, by putting them with their centres nearer to or farther from each other than the pupils.

Numbering.—Spectacle-lenses are at present numbered on two different systems, namely—(1) the *inch* scale; and (2) the *metrical* scale. (1) In the old system the refractive unit is a lens of 1-inch focal length, and the inch may be English, Parisian, or other. The lenses in use being all weaker than the unit are expressed by fractions; thus the strongest in use in the trial-case being a 2-inch lens is expressed as $\frac{1}{2}$ (+ or −, according as it is convex or concave); a lens of 10 inches focus is $\frac{1}{10}$; and so on. It is desirable that the series of lenses should rise by equal refraction-intervals, and here the inch-scale is inconvenient because it introduces difficult fractions. (2) The inch-scale has largely given place to the metrical dioptric scale, in which the measure

is international, the refractive unit is a weak instead of a strong lens, and the refractive intervals are equal. The unit is a lens of 1 metre (100 cm.) focal length, and is called one *dioptre* (1 D.). Stronger lenses are written as whole numbers; thus a lens four times as strong as the unit is 4 D.; a lens equal to half the unit is .5 D. The disadvantage of the system is that the numbers do not, as on the inch-system, express the focal length of the glasses; but the latter is easily arrived at by dividing 100 by the number of the lens in dioptries; thus the focal length of 5 D. = $\frac{100}{5}$ = 20 cm.

To convert a lens made by the Paris inch into its equivalent in dioptries, multiply its inch-value by 36 (1 m. = 36 Paris inches nearly); thus, $\frac{1}{36} \times 36$ = 1 D. To convert a metrical lens into its equivalent in Paris inches, divide its value in D. by 36; thus 4 D. = $\frac{4}{36}$ = $\frac{1}{9}$.

The following are the most important equivalent numbers:—

Focal length in		Focal length in	
Dioptries (D.)	Paris inches	Dioptries (D.)	Paris inches
.5	72	4	9
(written $\frac{1}{72}$, &c.)		4.5	8
.75	50	5	7
1	36	6	6
1.25	30	7	$5\frac{1}{2}$
1.5	26	9	4
2	18	11	$3\frac{1}{2}$
2.5	14	13	3
3	12	15	$2\frac{1}{2}$
3.5	10	18	2
	(nearly)		

Several intermediate numbers found in the trial-cases have been omitted.

The several abnormalities of refraction may now be discussed in due order.

(a) **Hypermetropia.**—In hypermetropia the retina lies within, instead of at, the principal focus of the dioptric media. Parallel rays, such as come from very distant objects, therefore meet the retina before being focussed; and divergent rays, from near objects, meet it still more in advance of their focus. Hence the hypermetropic eye, in repose, sees nothing clearly. Distant objects can be seen clearly if, by exerting accommodation, the crystalline lens be made more convex; or if the rays, before they enter the eye, be made sufficiently convergent by passing through a suitable convex lens.

Hypermetropia, due to flatness of the posterior segment of the eyeball, *axial hypermetropia*, is always congenital; and extended observations by different authorities have shown that nearly all children are hypermetropic at birth. In sections the circular fibres of the ciliary muscle are, or appear to be, more abundant than in the normal eye. The cornea is not flatter, but the anterior chamber is rather shallower, and the pupil rather smaller than normal. In high degrees the eyeball is too small in all directions.

The hypermetropic eye cannot see clearly even at a long distance without using accommodation; and a proportionate increase of accommodation is required by the hypermetropic eye for near vision. The absolute quantity, amplitude, or range of accommodation appears as a rule not to be greater in hypermetropic than in normal eyes; hence in hypermetropia it becomes sooner insufficient for the needs; and the higher the degree of hypermetropia the earlier does this occur.

SYMPTOMS.—The symptoms depend on the patient's age, occupation, and health, and on the degree of hypermetropia. The lower degrees only exceptionally cause symptoms in childhood. The higher degrees in children, and the lower degrees in young adults, cause difficulty in reading, writing, or sewing, especially by artificial light, and towards the end of the day's or week's work—'accommodative asthenopia.' The difficulty is expressed in the forms of mistiness of sight, weariness or aching of the eyes, headache, sleepiness, watering, chronic congestion, and irritation of the palpebral conjunctiva. In the highest degrees the attempt to see clearly is often given up; such persons often partly compensate for the bad definition of the images by holding the book very close, and so increasing the size of the images; thus they may seem myopic. All the symptoms are worse when the health is low. As accommodation fails with age, a time arrives for every hypermetrope when, unless aided by glasses, no clear vision is possible at any distance; but spectacles are generally adopted before this occurs.

Concomitant convergent squint often arises in hypermetropia (*see* STRABISMUS). It is at first, and may remain, periodic, present only during strong accommodation; but often it becomes constant. In either case it may alternate, or may always affect the same eye. When constant and fixed, the sight of the squinting eye is usually found to be more or less defective, as already described. This defect is greatest in the nasal part of the visual field, which is shared with the good eye. It may be so great that only the largest objects are visible, yet the direct reflex activity of the pupil is never impaired.

When the crystalline lens is absent (*aphakia*) the eye is very hypermetropic. Distant vision is restored by means of a convex lens of 10 or 11 D. ($3\frac{3}{4}$ or $3\frac{1}{2}$ inches) held about half an inch in front of the cornea; objects at, say, 25 cm. (10 inches) are clearly seen through a lens of about 15 D. ($2\frac{1}{2}$ inches). Accommodation is abolished in the aphakic eye; but if the pupil be round and movable, its contraction aids a little in near vision, by cutting off the peripheral rays of light.

From the age of fifty-five and onwards the normal eye acquires a low degree of hypermetropia, owing to a change in the refraction of the crystalline lens.

Glaucoma is commoner in hypermetropic than in normal or myopic eyes. The habitual use of glasses by hypermetropic persons from early life may aid indirectly in preventing this disease.

DIAGNOSIS.—The diagnosis is made subjectively by testing with glasses, or objectively by the ophthalmoscope. The former is the more generally useful. Even distant objects are seen indistinctly by the hypermetropic eye with relaxed accommodation; but they are made clear if a suitable convex lens be held in front of the cornea. (1) This test is easy to apply when the ciliary muscle is temporarily paralysed by atropine, or abolished by natural senile changes. (2) But when it is active the matter is less simple; since the old-standing habit of exerting accommodation whenever clear vision, even at a distance, is needed, in many cases inseparably connects the effort to see with the action of the ciliary muscle. Such persons cannot relax their accommodation when looking through a convex lens at a distant object. The effect of the lens is therefore added to, instead of substituted for, that of the accommodation, and distant vision made worse;

no hypermetropia can be found by trial with glasses: it is entirely 'latent' (*H.L.*). (3) Between these extremes we find a large number who can partially relax their accommodation for distance in favour of a convex lens, but still use a part. They see well, or perfectly, in the distance without aid; they see equally well or better with convex lenses up to a certain strength. If now the accommodation be suspended by means of atropine we shall often find still more hypermetropia. The part that can be detected when accommodation is active is the 'manifest' (*H.m.*); the sum of the 'manifest' and the 'latent' is the 'total' (*H.*).

In testing hypermetropia, the patient being not less than three metres from the test-types, we begin with a very weak convex lens, and if vision is *not made worse*, try successively higher lenses until we reach the highest which allows the best attainable vision. This lens represents the manifest hypermetropia if accommodation be present, the total if it be absent. A stronger lens causes indistinctness by bringing the focus in front of the retina. In general the younger the patient the less is the manifest in proportion to the latent hypermetropia, even though troublesome asthenopia be present.

Hypermetropia is diagnosed by the ophthalmoscope if an erect image of the fundus is easily seen when the observer is at a distance of eighteen inches or more from the patient. The image is seen equally well when the observer comes as close as possible to the patient; and if he possess a 'refraction' ophthalmoscope, he can *in this position* measure the degree of hypermetropia by finding the strongest convex lens through which the details of the fundus still look perfectly clear. In this test the accommodation of both persons must be fully relaxed; the observer has to learn to do this, but the patient generally relaxes his ciliary muscle at once in the dark room, even though he could not do so when tried with glasses for the distant types.

Another method, the *shadow-test*, is based on the fact that when light is thrown by the ophthalmoscope into the eye from a distance of three or four feet, slight rotation of the mirror causes a shadow to move across the illuminated field; in hypermetropia the shadow moves in the same direction as the rotation of the *plane* mirror. This method is now largely relied upon, especially for young patients; and in skilled hands it is expeditious and very accurate.

The optic disc in hypermetropia, especially in children, often seems, and sometimes is, hazy, and is sometimes too red; and the retinal arteries are often too tortuous.

TREATMENT.—Treatment is necessary for hypermetropia whenever there is asthenopia, and when strabismus has arisen. Convex spectacles are ordered which, according to circumstances, neutralise a part or all of the hypermetropia; and are worn constantly, or only for near work. Periodic squint may always be cured by the constant use of fully correcting glasses; but in most cases where it has become constant, an operation is necessary (*see* STRABISMUS). In children with asthenopia it is usually best to order glasses for constant use, which correct almost the whole hypermetropia; but if the symptoms are in connection with weak health and the hypermetropia be slight, the temporary use of glasses for near work alone is enough. Young adults using glasses for the first time are often satisfied with those which neutralise only the

manifest hypermetropia, using them for all near work ; but after some weeks or months asthenopic symptoms often recur, we find that there is more manifest hypermetropia than before, and we are obliged to order stronger glasses. But either ophthalmoscopic estimation, or the shadow-test, will generally reveal almost the total even at the first examination ; and when these methods make it clear that the total is much greater than the manifest hypermetropia, glasses of nearly the full strength should be ordered at once. On theoretical grounds it is undoubtedly best for glasses to be worn constantly by hypermetropes, so that the accommodation may never be strained. But a good deal of latitude must be allowed to grown-up, and especially elderly, patients in regard to wearing glasses for distance, unless there be constant asthenopia.

Acuteness of sight is usually normal in corrected hypermetropia. In many cases of high degree, where vision is, both with and without glasses, subnormal, some astigmatism is also present ; but cases occur where the defect cannot be thus accounted for, and it is then assumed to be due to defective development of eye or visual centre. But probably want of early education of the retina in the perception of clear images in a great degree accounts for the phenomenon.

(b) *Myopia*.—In myopia the retina lies beyond the principal focus of the dioptric media, generally on account of lengthening of the posterior part of the eye—*axial myopia*. It is consequently at the conjugate focus of a point at some definite distance in front of the eye, which indeed is the 'far-point,' or greatest distance of distinct vision of the eye in question. The greater the elongation of the eye, the nearer is the 'far-point,' the 'shorter' the sight, or the higher the degree of myopia. By using accommodation objects can be seen at a still shorter distance.

Ætiology.—Myopia is comparatively seldom present at birth. The elongation usually comes on between about seven and fifteen years of age, progresses for a time, and stops between puberty and adult age ; but in some cases the stretching (and its attendant structural change) persistently increases through life, and leads to serious and even disastrous consequences. Myopia is often hereditary, and inheritance doubtless accounts entirely for some very severe cases where no other causes exist. But habitual use of the eyes upon close work, especially in a stooping posture and with bad light, aids strongly in its production. Any severe or lasting ill-health may determine the onset or increase of myopia in a predisposed person.

Myopia may also be caused by increased curvature of the cornea after keratitis, and is an invariable result of 'conical cornea.' Certain changes in the lens in the stages of senile cataract often produce myopia, even of considerable degree ; but this form of myopia does not, as axial myopia may, indicate degeneracy of the deeper tissues, and hence does not influence the question of operation.

ANATOMICAL CHARACTERS.—The elongation occurs chiefly in the posterior part of the eye, and especially at the yellow-spot region. The sclerotic and choroid are thinned in proportion to the distension, and the choroid often locally atrophied ; the term 'posterior staphyloma' is given to the bulging region. In high degrees the eye is enlarged, and its coats are thinned, in all directions. The term 'sclerotico-choroiditis posterior' is also used to

indicate the supposed nature of the change. In high degrees, particularly late in life, the vitreous often becomes fluid and contains opacities ; and hæmorrhagic and other effusions may occur in the choroid ; and there is a strong liability to detachment of the retina and incomplete cataract. In the ciliary muscle of myopic eyes the circular fibres are deficient or wanting. The anterior chamber is often deeper, and the pupil larger than usual. Owing to its large size the highly myopic eye is often prominent and its mobility somewhat curtailed ; and the latter condition is apt to cause fatigue of the eye-muscles.

SYMPTOMS.—A low degree of stationary myopia usually causes no inconvenience. In the higher degrees advice is sought, either because distant sight is bad or near work has to be held inconveniently close ; or on account of eye-ache, headache, watering, photophobia, or dimness ; or for inefficiency of the internal recti (muscular asthenopia), or actual divergent squint. In the highest degrees divergent squint is nearly always present at the natural distance of distinct vision, and sometimes even for distance ; and in much lower degrees there is often difficulty in keeping up convergence, and consequent pain and weariness. Aching frequently shows that the myopia is increasing ; it is made worse by use of the eyes, but is often present even when at rest in bed ; it may accompany the development of a squint, or of detachment of the retina. Myopic eyes, even of low degree, are often intolerant of bright light. Acuteness of vision is often sub-normal in the high degrees of myopia, especially in old people ; such defect, when not accounted for by visible structural changes, is assigned to congestion of the choroid.

DIAGNOSIS.—A myopic person with healthy eyes can read the smallest print fluently at his own 'far-point,' but not farther. He gains perfect distant vision by looking through a concave lens, which gives to rays of light from distant objects a divergent direction, as if they came from his natural 'far-point.' Placing him not less than three metres from the test-types we find experimentally the *weakest* concave lens that gives the best attainable vision. A stronger lens over-corrects the myopia, producing hypermetropia, which, in its turn, is corrected by the exercise of accommodation.

Myopia is diagnosed objectively as follows : (1) By the shadow-test with the *plane* mirror, the shadow moves in the opposite direction to the rotation of the mirror. (2) By direct examination close to the patient, a clear image (erect) can be obtained only by placing a concave lens behind the mirror ; the *weakest* lens which gives a clear image being the measure of the myopia. (3) By direct ophthalmoscopic examination at a long distance, an image of the fundus is seen, which, on the observer moving his head from side to side, seems to move in the opposite direction. This image disappears when the observer comes near to the eye examined. (4) By indirect examination the size of the ophthalmoscopic image increases on withdrawing the objective lens from the patient's eye.

The ophthalmoscopic changes depend chiefly on the atrophy of the choroid, which often occurs on some part of the staphylomatous area ; and the commonest form is the 'myopic crescent,' a patch of yellowish-white exposed sclerotic, due to atrophy of the choroid at the outer border of the optic disc.

But a similar 'crescent' is sometimes seen in eyes not myopic. When more advanced it extends all round the disc (annular staphyloma). There may also be myopia with signs of past or present inflammation and hæmorrhage, at the yellow spot. In high myopia with abrupt bulging of the tunics, the disc is often tilted and then looks oval, and its outer side often becomes pale.

COURSE AND PROGNOSIS.—Axial myopia cannot diminish. Though its increase as a rule ceases about the same time as the cessation of the bodily growth, it may continue, or may take a fresh start later in life, especially if the health be bad or the eyes be excessively used for fine work. But often its course seems to depend upon causes which are not under direct control; for we see myopia of high degree, leading to disastrous results or blindness, in persons who have never learnt their alphabet or strained their eyes in any way; and, on the other hand, it is common to meet with very myopic people, of studious habits and advanced age, in whom the eyes have not changed since youth. In general the prognosis is worse the higher the degree, the older the patient, and the feebler the health.

TREATMENT.—Much may doubtless be gradually done to prevent the acquisition and transmission of myopia, by improvements in the lighting of school-rooms, and construction of seats and desks, and by the choice of well-printed books. During the progress of myopia the time given to school work should, whenever possible, be shortened; and if the disorder be quickly increasing, or if there be much aching or irritation, rest of the eye should be insisted upon for several months, or longer. Myopic children should use their eyes only as much as is comfortable, and should be forbidden to read fine print, to read by bad light, or to stoop. If there be severe aching and intolerance of light, or rapid increase of the myopia, especially with diminished acuteness of sight, prolonged rest, plane smoked glasses, and the use of blisters or leeches, at intervals of a few days, with derivative treatment, are of service.

The corrective treatment consists in the use of concave glasses. Myopic children should as a rule wear glasses for distance on educational grounds. Adults may use their own judgment as to wearing distance-glasses; these glasses should be .5 D. less than the full correction in each case. If the eyes be strong the same glasses can often be used for near work, too; but if the internal recti or accommodation be weak, the full correction often cannot be continuously worn. Except in low degrees of myopia it is therefore best not to begin with fully correcting glasses for near work, for they require full action of the hitherto little exercised accommodation, and also derange the relation between accommodation and convergence, and are thus likely to tire the eyes; they also cause difficulty by diminishing the retinal images; if their use be persisted in for reading or other purposes, when they cause discomfort, they may help indirectly to increase the myopia. When the natural far-point in myopia is not nearer than 13 inches (33 cm.) (= 3 D.) reading-glasses are seldom required; but for higher degrees it is often necessary to order spectacles for reading which partly correct the myopia, that is, make the eyes less myopic, and thus remove the far-point farther off, and allow the patient to read, or use them in other ways, without

stooping. As a general rule, subject to the peculiarities and needs of each case, about half the full correction may for this purpose be safely and comfortably used. For music or painting a strength intermediate between those for distance and reading may be needed. When there is muscular asthenopia, shown by the fact that in near vision one eye, if covered, deviates outwards, relief may sometimes be given by combining with the reading glasses prisms with their bases inwards; the prisms, by allowing the convergence to be lessened, relieve the internal recti.

The curative treatment of high myopia consists in the removal of the lens by discission or absorption; the operated eye becoming emmetropic, or slightly myopic or hypermetropic, according to the degree of the original myopia. This operation gives very good results, and is much appreciated by the patients because they are able to dispense with the strong concave glasses they had been using. The durability of such eyes has, however, not yet been sufficiently tested to justify a final opinion on its place in ophthalmic surgery.

(c) **Astigmatism.**—Astigmatism may be either *regular* or *irregular*. *Regular* astigmatism depends upon the refracting surfaces of the eye, chiefly of the cornea, not being spherical, but having different curvatures, that is, focal lengths, in different meridians, the meridians of greatest and least curvatures ('chief' or 'principal' meridians) being always at right angles to each other, and the others have regularly intermediate curvatures. The meridian of greatest curvature of the cornea is generally vertical or nearly so. The astigmatism of the lens, though less regular than that of the cornea, tends to correct the latter. In 'simple' astigmatism one chief meridian is normal, the other either myopic or hypermetropic; when 'compound' both chief meridians are myopic, or both hypermetropic, but in different degrees; when 'mixed,' the eye is hypermetropic in one chief meridian, and myopic in the other. When the focal difference between the chief meridians, i.e. the degree of astigmatism, is not greater than is represented by a lens of 72 inches focus (.5 D.) it may generally be neglected; even much higher degrees often cause no trouble.

Astigmatism is to be suspected in all cases of ametropia where spherical lenses do not raise vision to the normal, no other cause of the defect being found. It is detected subjectively by numerous tests, most of which consist essentially of straight lines running in various directions, some of the lines being seen by the astigmatic eye better than others. It can also be measured by the shadow-test, the ophthalmometer, and direct ophthalmoscopic examination.

TREATMENT.—Astigmatism is corrected by cylindrical lenses, which neutralise the difference of refraction of the two chief meridians; but in the higher degrees acuteness of vision often remains even then subnormal. *Irregular* astigmatism can seldom be remedied.

3. **Anisometropia.**—This signifies different refraction in the two eyes, and is a very common condition, the difference sometimes being extreme. When one eye is normal and the other myopic, each may be, and often is, used for vision at different distances, and each remains perfect; but if one be astigmatic, or very hypermetropic, it is generally defective.

When slight, this condition may be neutralised by corresponding spectacles, but when the inequality is great, fully correcting glasses cause so much difference in the size of the images in the two eyes that equalisation is seldom possible. But it should be attempted when there is any tendency to squint, in order to encourage binocular vision.

Effect of blindness of one eye.—Acuteness of sight is always rather better with both eyes than with either alone; further, both eyes are necessary for the appreciation of solidity and distance. Patients often think that blindness or disuse of one eye throws 'double work' upon the other and 'weakens it.' Nearly always, however, in such a case some other cause can be found for the asthenopia of the sound eye.

4. Disorders of Accommodation.—(a) **Presbyopia.**—The 'amplitude' or 'range' of accommodation is expressed by the difference between the greatest distance, 'far-point,' (r), and the least distance, 'near-point,' (p), of distinct vision. Age for age, it is nearly equal in all eyes, whatever their refraction. Its natural failure with age causes presbyopia, the onset of which has been arbitrarily fixed to begin, in the emmetropic eye, at the age of about 40 to 45, when the near-point is at nine inches (22 cm.); and the failure generally progresses at a constant rate. Presbyopia is corrected by the convex lens, which enables the patient to read at nine inches; the strength of this lens varies inversely as the amplitude of accommodation; and at the age of 65, the near-point being removed to infinity, the correcting lens is one of nine inches focus.

SYMPTOMS.—Presbyopia is first shown by difficulty in reading or sewing by artificial light, or in the train or carriage; defective accommodation prevents the work being held close enough to compensate for the defective light or for the shaking, and to remedy the former the candle is often placed between the eyes and the book. When more advanced, the patient becomes 'long-sighted,' and has to put his book at arm's length unless he wear glasses. If the refraction is normal, distant sight is perfect. In hypermetropia, presbyopia begins at an earlier age, less accommodation being available for near vision; and in myopia it sets in later because less accommodation is needed for seeing at a given distance. Hence a low degree of myopia is an advantage. When the far-point in myopia is at or within nine inches (22 cm.) presbyopia does not occur.

DIAGNOSIS.—Presbyopia is to be distinguished from loss of accommodation due to paralysis of the ciliary nerves, and from failure due to feeble health or other causes, both of which may occur at any age. True presbyopia, however, sometimes occurs earlier and progresses more quickly than usual, especially in eyes which are threatened with glaucoma.

TREATMENT.—The treatment of presbyopia consists in ordering convex glasses which enable the patient to read at nine inches or a greater distance. Most people prefer glasses which enable them to read easily at twelve or fifteen inches, and with which reading at the standard nine inches is possible only for a very short time, if at all. The smaller the quantity of accommodation remaining, the less is the range of clear vision; and if accommodation is abolished, clear sight is possible only when the object is at the focus of the glasses.

Hence the increase of strength of the glasses which becomes necessary as age advances should be made gradually, that the patient may grow accustomed to the loss of range, and to the necessity for keeping his book more and more at an unvarying distance. As the book has to be placed nearer by artificial light than by daylight, it is generally best to have a rather stronger pair of glasses for evening use than for the daytime. The following table, giving the strength of the glass necessary to bring the near-point to nine inches (22 cm.), at various ages, serves as a useful basis for the selection of spectacles for presbyopia in emmetropic persons:—

Glass required to bring ' p ' to 9 in. (22 cm.)			
Age			
40	0	=	
45	$+\frac{1}{3\frac{1}{2}}$ inch	=	+1 dioptr.
50	$\frac{1}{4}$ "	=	2 "
55	$\frac{1}{3}$ "	=	3 "
60	$\frac{1}{2}$ "	=	4 "
65	$\frac{2}{3}$ "	=	4.5 "
70	1-6 $\frac{1}{2}$ "	=	5.5 "

(b) **Paralysis of accommodation.**—**SYNON.**:

Cycloplegia.—Paralysis of the ciliary muscle occurs in paralysis of the whole third nerve. But it may occur without affection of the extrinsic muscles of the eyeball. In these cases it is generally combined with paralysis, more or less complete, of the iris (*ophthalmoplegia interna*); but it may be present as an isolated symptom, the pupils being normal, and of this the commonest example is post-diphtheritic cycloplegia. The failure of accommodation in glaucoma may be accounted for in acute cases by compression of the ciliary nerves, but in old cases is doubtless due to the atrophy of the ciliary muscle which always exists. Cycloplegia, usually with some affection of the iris, is a common result of blows on the eye; sometimes recoverable, it is, however, often permanent. Lowered endurance of sight, pain, and sudden temporary failures of accommodation, are among the most important phenomena of sympathetic irritation.

(c) **Spasm of accommodation.**—Temporary spasmodic action of the ciliary muscle, often exceeding the necessary amount, frequently occurs in hypermetropia, with each effort to see clearly; it usually ceases at once on going into a dark room. In low myopia with irritative symptoms, the ciliary muscle often acts unnecessarily; and such spasm, when persistent, is probably one cause of further elongation of the eye. Spasm of accommodation also occurs in some functional and hysterical affections of the eyes, with other symptoms of ocular irritation. The function of accommodation is closely associated with that of convergence, although the two can be exerted separately to a limited extent. The accommodation of one eye cannot be exercised without, and scarcely in any different degree from, that of the other; and it is doubtful whether, as has been supposed, different parts of the ciliary muscle can act in different degrees and thus correct astigmatism.

(d) **Micropsia.**—**DEFINITION.**—Any condition of sight in which objects seem lessened in size, without diminution in the size of the retinal images. This indicates either an extreme effort of accommodation, and may be thus complained of when this function is weakened; or disease of the deep layers of the retina.

5. Asthenopia.—Asthenopia is any condition in which the eyes cannot be used for long without fatigue, pain, or other symptoms.

Muscular asthenopia is caused by difficulty in maintaining the convergence of the visual lines, and is commonest in myopia, though it is often seen with normal refraction, especially in youths and young adults. It causes, besides aching of the eyes, 'confusion' of the print, and sometimes double vision. In slight cases, accompanying myopia, partially neutralising concave glasses, which enable the book to be held at a greater distance, will often give relief. In a few cases, with or without myopia, spectacles, consisting of prisms with their bases inwards, are of service, by lessening the convergence necessary for vision at a given distance. In high degrees, tenotomy of the external rectus is called for (see STRABISMUS). Asthenopia may also be caused by slight vertical deviations (upward or downward) of one eye.

Asthenopia from deficient accommodation is also shown by inability to read for long, but there is no 'moving' or 'dancing' of the letters, nor any diplopia. The object simply becomes 'misty' or 'the sight goes' for a time, returning when the eyes are rested for a few minutes; or the eyes feel tired and hot, and ache. Headache and other discomforts may follow neglect of such symptoms. It is commonest in hypermetropia (asthenopia from excessive demand on accommodation); but is also seen in emmetropic, and even in slightly myopic eyes, if the tone of the ciliary muscle is low (asthenopia from weakness of accommodation). Asthenopic symptoms are not common in presbyopia.

Neurasthenic Asthenopia.—All causes of asthenopia are more effective in neurasthenic persons, and some of the worst cases are in those who have good range of accommodation, and no ametropia. Sensitiveness of lids, eyeball, and perhaps retina, may have been left by previous stytes, phlyctenulæ, or follicular granulations, and the onset of symptoms often dates from some piece of eye-work requiring strenuous effort; but serious breakdown of the eyes seldom occurs unless the general conditions of neurasthenia—excitability without staying power—are present.

Retinal Asthenopia.—Functional exhaustion of the retina or optic nerve is sometimes seen in optic neuritis, and other diseases of the optic nerve; sight being good, but becoming duller after a short period of use. It is not, on the whole, an important diagnostic symptom. E. NETTLESHIP.

VIS MEDICATRIX NATURÆ (Lat.), the healing power of Nature.—An expression formerly much used to indicate the tendency of wounds and diseases toward spontaneous recovery.

VITAL STATISTICS.—For the purposes of public health, vital statistics are concerned mainly with the incidence of disease and death upon communities and upon different fractions of communities, and with the renewing of population by births. Such statistics may be regarded from several points of view. It may be desired to investigate the average incidence of a certain disease, or a group of diseases, upon different populations or different sections of a population; sections marked out by race, locality, occupation, class, age, sex, or other selected characteristic. Or, again, one disease may be compared with another as to incidence upon the same population. From yet another point of view inquiry may be made into the changing incidence of a given disease upon a given population in the

course of time, the change being perhaps progressive, perhaps fluctuating at long or short intervals, regular or irregular. Thus comparison may be made between the various seasons of the year, between one year and another, or among the averages of terms of years; and the change may prove to be one of quantity, or quality, or both. By patient record and analysis of the available data, it becomes possible to learn *how*, *when*, *where*, and *whom* a given disease attacks, and hence to obtain a clue to the further problem *why* it attacks, and even to the most important matter of all, the means of prevention.

The materials necessary for such research include, on the one hand, records of births, deaths, and sickness; and, on the other hand, accurate information as to the population among which the events so recorded have happened.

Population.—A census in this country is taken at the end of the first quarter of the first year in each decade. Between these widely distant known points, estimates can be made on the assumption that the rate of increase is uniform. Thus, if P and P' be the numbers enumerated in 1881 and 1891 respectively, the rate of increase in ten years is $\frac{P'}{P}$, in one year therefore $\sqrt[10]{\frac{P'}{P}}$, in a quarter of a year $\sqrt[40]{\frac{P'}{P}}$. For the sake of brevity we may denote

the rate of annual increase, that is $\sqrt[10]{\frac{P'}{P}}$, by r , and the quarterly rate by $\sqrt[4]{r}$. Then the estimate at the end of the first quarter of 1882, one year after the census, will be $P \times r$, in two years $P \times r \times r (= Pr^2)$, in three years Pr^3 , and so on, year by year, till we come to $P \times r^{10}$, which is of course equal to P' . But the mid-year population, which is always adopted as the basis of birth-rates and death-rates, will be in advance of these estimates by one quarter's growth: $P \times \sqrt[4]{r}$ in 1881, $P \times r \times \sqrt[4]{r}$ in 1882, $Pr^2 \times \sqrt[4]{r}$ in 1883.

Further than this, it is assumed that the population P' of 1891 goes on increasing at exactly the same rate as the population P of 1881 was found to have done; the estimates for the years after 1891 are made upon the old data, until the next census again gives certainty. The estimate for the mid-year 1891 is $P' \times \sqrt[4]{r}$, for 1892 $P' \times r \times \sqrt[4]{r}$, for 1893 $P'r^2 \times \sqrt[4]{r}$, for 1900 $P'r^8 \times \sqrt[4]{r}$.

In practice, the values of P and P' are known from the published census returns, and the use of logarithms makes the calculations perfectly simple. A rougher method, sufficiently accurate for small populations, is to assume that the increment in every year is one-tenth of that recorded in the ten years, and to add $\frac{P' - P}{10}$ for each year. It is obvious that

if the rate of increase as explained above remains constant the result will only be accurate about the middle of the decade, the increment being overstated during the first half, and understated during the second; for, as the population is increasing, $P' - P$ bears a higher ratio to P than it does to P' , so that the increment in 1881 is made to be *relatively* larger than that in 1891.

Sometimes the estimate is based upon other data altogether, by adding to the last census-population the so-called 'natural increase,' that is, the excess of births over deaths, it being assumed that there is no gain or loss from other sources, or that these

balance each other. Experience has shown that while mathematical estimates are tolerably correct for very large mixed populations, such as a whole nation, they are liable to error in proportion to the smallness of the numbers concerned. In towns the growth is chiefly marginal, the central portion being capable of little increase; and the growth, even if continued uniformly, may be outside the more or less arbitrary boundaries of the area under consideration. Fluctuations of trade are of great moment as affecting local immigration and emigration. In many instances the 1891 estimates, based upon the 1871 and 1881 census, were proved by the census of 1891 to be far wide of the mark. Liverpool, instead of increasing as had been supposed, was found to have actually decreased, and the population was over-estimated by 20 per cent. Salford was over-estimated by 27 per cent., and Newcastle under-estimated by 11 per cent. For at least five years out of every decade local birth-rates and death-rates are liable to serious error, although their untrustworthiness will usually be made known either by persistent abnormality of the rates themselves, or by the discrepant results of local observations, such as influx or efflux of artisan population, records of school attendance, inhabited houses, &c.

For many statistical purposes, much further detail is required. It is necessary to know how many there are of each sex, of each group of ages, or of each occupation, for the tendency to sickness and death varies greatly, and rates may need to be calculated separately for each class. The data are supplied by the census, and the relative proportions may be assumed to remain unaltered during the intercensal decade. For the infant population, however, the recorded number of births affords a closer estimate.

Births and Deaths.—Births must be registered within six weeks, and deaths within five days, of their occurrence. These form the basis of the national statistics of births and deaths. As regards the latter, the record includes not only the time and place of death, but also the age, sex, and place of residence of the deceased, the causes (primary and secondary) of death, and their duration. The age to be given is that attained at the last birthday; if less than one year it should be stated in months, weeks, days, or hours. In compiling statistics of deaths from different causes only one cause can be accepted for each death, and when two or more are recorded it is usual to give precedence to 'zymotic' diseases over all others, to 'specific' over non-specific, and to 'primary' over 'secondary' causes. Where these criteria are indecisive, priority may be given to the cause mentioned first in the certificate. 'Uncertified' deaths, in which no certificate is given either by a registered medical practitioner or by a coroner, were in 1898 1.9 per cent. of the total number. A large proportion of deaths (in towns not often less than 10 per cent., and in London as many as 25 per cent.) take place in public institutions, such as hospitals, asylums, and workhouses. These ought to be credited to the locality of former residence, which may or may not be the same as that in which the institution is situated, and in which, therefore, the deaths are registered.

Still-births are not registered in this country; they are estimated to be equal to about 4 per cent. of the live births. Of the latter rather more than

4 per cent. are illegitimate, the proportion being greater in rural than in urban communities, and declining in England generally. Over 103 males are born for every 100 females, but owing to the higher death-rate among male infants the female population exceeds the male in the second year of life and at all later ages.

Rates.—Statistics of births and deaths have to be considered with reference, first, to the magnitude of the population concerned, and, secondly, to the length of time covered by the record. It is convenient to adopt fixed standards of population and time, and birth-rates and death-rates are usually stated 'per thousand per annum,' that is, as the number of such events among each thousand of the population in the course of a year. The true (astronomical) year has 365.24 days, while the statistics of births and deaths will usually be those of 364 days (52 weeks) or 365 days. Hence an adjustment becomes necessary if great accuracy be desired. Thus, if the record of a 'year' of 52 weeks give a death-rate of 20.0 per 1,000 per annum, the true death-rate will be $20.0 \times \frac{365.24}{364}$, or

20.07. Similarly, birth-rates and death-rates for fractions of a year are stated as *annual* rates; they are the annual rates which would be attained if the conditions observed during the period in question were continued unchanged for a whole year. In general terms, if n be the number of days during which events are recorded, the rate per 1,000 per annum will be

$$\frac{\text{No. of events recorded during } n}{\text{Population at middle of year}} \times \frac{365.24}{n} \times 1,000.$$

Thus, if there be 40 deaths in a given week in a population of 100,000, the death-rate for that week is $\frac{40}{100,000} \times \frac{365.24}{7} \times 1,000$, that is, 20.9 per thousand per annum.

The population must of course be that in which the events happen, neither more nor less. To find the death-rate at ages between 10 and 15 years, for instance, we must take as our basis, not the whole population, but merely the number of persons living at those ages; the deaths at ages 10 to 15 years must be compared with the population at ages 10 to 15 years.

Birth-rate.—The English birth-rate has declined steadily from 36.3 in 1876 to 29.4 in 1898. It is highest in districts containing the largest proportion of young married people, and high, therefore, in towns which are rapidly growing by influx of young adult persons. In prosperous mining districts, local birth-rates of 40 or 50 are not uncommon. Although birth-rates are always calculated on the whole population regardless of age or sex, it ought to be remembered that the population more immediately concerned is that of married women under 45 years of age, and that a community containing an unusually large or unusually small proportion of such persons may be expected to have a correspondingly abnormal birth-rate.

Death-rate.—Death-rates may be calculated for a community as a whole, or for a particular class or section of a community; and with regard to deaths from all causes, or deaths from one cause or group of causes only.

The English death-rate has materially declined

during the last twenty years, and, on the whole, more rapidly among females than among males.

Mean Annual Death-rates in

Years	Both Sexes	Males	Females
1841-50	22.4	23.1	21.6
1851-60	22.2	23.1	21.4
1861-70	22.4	23.6	21.3
1871-80	21.3	22.6	20.0
1881-90	19.1	20.2	18.0
1891-95	18.7	19.8	17.7
1896	17.1	18.1	16.1
1897	17.4	18.6	16.3
1898	17.6	18.7	16.6

The decline has not been free from interruptions, and, indeed, after reaching a minimum in 1894 there has since been an increase as the table shows.

In infancy and in old age the tendency to death is high, the minimum being at ages between 10 and 15 years. The following table gives the mean annual rates in England and Wales for the decades 1871-80 and 1881-90 :

Ages	Both Sexes		Males		Females	
	1871-80	1881-90	1871-80	1881-90	1871-80	1881-90
0-5	63.1	56.8	68.1	61.7	58.1	52.0
5-10	6.4	5.3	6.7	5.3	6.2	5.3
10-15	3.7	3.0	3.7	2.9	3.7	3.1
15-20	5.3	4.4	5.2	4.3	5.4	4.4
20-25	7.0	5.6	7.3	5.7	6.8	5.5
25-35	8.9	7.5	9.3	7.7	8.6	7.3
35-45	12.6	11.4	13.7	12.3	11.6	10.5
45-55	17.7	17.1	20.0	19.3	15.6	15.0
55-65	31.5	31.3	34.8	34.7	28.5	28.4
65-75	64.9	64.7	69.6	70.2	60.8	60.1
Over 75	161.6	153.7	169.1	162.2	155.8	147.3
All ages	21.4	19.1	22.7	20.2	20.1	18.0

The comparison of these two decades shows that in both the death-rate was lower among females than among males, not only at all ages taken together, but also at each group of ages separately, except in the second decade of life. It shows, too, that the general death-rate had declined in both sexes, and that the decline was shared by almost all of the age-groups, although much more marked at the earlier ages.

It is usual to state the 'infant mortality' in a different way, taking advantage of the accurate statistics of births as a basis of population, and thus avoiding the uncertainty of estimates. The infant mortality is therefore

$$\frac{\text{No. of deaths under one year}}{\text{No. of deaths during year}} \times 1,000.$$

It is not comparable with death-rates at other ages, for it is not calculated upon a mean population. It is higher in towns than in the country, and among males than among females. For the

decade 1871-80 the mean infant mortality was 149—that of males being 163 and females 134. It declined to 142 in the decade 1881-90, but has on the average exceeded 150 in the decade 1891-1900, the exact figures for which cannot yet be stated.

Notwithstanding the high mortality among infants, a high birth-rate does not usually carry with it a high general death-rate, but rather the reverse. It implies a large proportion of young adults in the population as parents, and also a large proportion of children who have passed the period of early infancy. Among these groups the death-rate is low, as is evident from the foregoing table, and as a net result the excess of infant population is more than balanced by the excess at ages of low mortality.

The age-constitution of the population ought always to be borne in mind as a possible source of fallacy in comparing crude death-rates. Extreme instances are met with in dealing with selected populations—for example, the public services. The death-rate among soldiers stationed in the United Kingdom was 6.9 during the decade 1881-90, and 4.9 in the quinquennium 1891-95. In order to form an opinion whether these rates are high or low, comparison must be made with the standard death-rate among males of military ages, and not with that of a community containing women, children, and old people. Reference has already been made to the differences in age-constitution between urban and rural communities, and between one town and another. From census-data it is possible to calculate a 'factor,' or number, by which the crude death-rate may be multiplied if it be desired to nullify the effect of a local age- and sex-distribution, differing from that of the country at large. The 'corrected death-rate' so obtained represents that which would prevail under local conditions if the local population had the same composition, as regards age and sex, as that of the kingdom as a whole. For the decade 1881-90 the crude death-rate for Lancashire was 22.4, and for Huntingdonshire 16.4; the corrected death-rates for these counties were 13.9 and 24.2, the respective 'factors' being 0.84948 and 1.07589. Rural districts usually contain an unduly large proportion of young and old persons, with comparatively few young adults, and the factor for correction is less than unity; but most towns contain an excess at those ages at which mortality ought to be low, and the factor in all such cases is greater than unity. Corrected death-rates enable us to compare the mortality of different towns upon equal terms, and the comparison is further facilitated by calling the death-rate of the whole country 1,000, and stating the 'comparative mortality figure' of each town in terms of this. The calculation is simple.

$$\text{C.M.F.} = \frac{\text{Death-rate of whole country}}{\text{Corrected local death-rate}} \times 1,000.$$

Life-Tables.—The death-toll at each age being known, it is possible to construct a life-table—that is, to estimate the gradually diminishing number who would survive at the end of each successive age-period, out of, say, a million born.

The following data are taken from life-tables constructed by Dr. Ogle (1871-80) and Dr. Tatham (1881-90). The chance of survival at each age and in both tables is greater among females than among males. The later table shows a greater number of survivors than the other at every age up to 83 in males, and 85 in females.

MALES					FEMALES				
Survivors out of a million born			Expectation of life		Survivors out of a million born		Expectation of life		
Age	1871-80	1881-90	1871-80	1881-90	1871-80	1881-90	1871-80	1881-90	
0	1,000,000	1,000,000	41'4	43'7	1,000,000	1,000,000	44'6	47'2	
10	708,990	733,477	47'6	49'0	738,382	766,151	49'8	51'1	
20	680,033	712,555	39'4	40'3	707,949	744,321	41'7	42'4	
30	630,038	669,279	32'1	32'5	658,418	700,049	34'4	34'8	
40	563,077	604,923	25'3	25'4	596,113	638,912	27'5	27'6	
50	476,980	517,639	18'9	18'8	520,901	564,299	20'7	20'6	
60	365,011	398,400	13'1	12'9	422,835	457,682	14'2	14'1	
70	222,056	238,632	8'3	8'0	277,225	299,220	9'0	8'8	
80	77,354	80,023	4'8	4'5	108,935	114,536	5'2	5'0	
90	8,015	6,786	2'7	2'4	14,225	13,418	2'9	2'8	
100	82	30	1'6	1'2	225	157	1'6	1'5	

The calculation may be carried a step farther, and an estimate made of the 'expectation of life' at each age—that is, of the average number of years which persons who have reached that age will live. It has already been stated that while the death-rate as a whole is decreasing, the decrease is mainly in the earlier age-groups. Accordingly, we find on comparing the two life-tables, that while the expectation of life is greater under the new table than under the old at all early ages, it is actually less at

general death-rate. Thus whooping-cough and measles kill few except in early childhood, while cancer kills few except in later adult life, and phthisis is most destructive in early adult life.

As regards sex, similar disproportion may be met with. The majority of diseases cause a higher mortality among males, the principal exceptions being diphtheria, whooping-cough, cancer, and, of course, the diseases connected with parturition. Cancer is nearly twice as common among females as

Mean Annual Death-Rates, 1881-90.—England and Wales.

Ages	Small-pox	Measles	Scarlet Fever	Enteric Fever	Whooping-cough	Diphtheria	Diarrhoea	Cancer	Phthisis	Heart-Disease &c.	Respiratory Diseases	Urinary Diseases
0-5	'08	3'13	1'67	'13	3'37	'69	4'35	'02	'54	'13	12'97	'19

Over 75	'02	'00	'00	'06	'00	'01	2'58	4'30	0'52	18'86	29'09	4'17

ages over forty-five years, in each sex. The expectation at birth is also termed the 'mean duration of life,' and at later ages the 'mean after-life-time.' Owing to the high death-rate among young children, the expectation is greater at three years of age than it is at birth; thenceforward it declines uninterruptedly. The detailed 1881-90 life-table shows that out of a given number of males born, exactly half survive between 51 and 52 years of age; and this has been termed the 'probable duration of life.' For females it is between 56 and 57 years.

Causes of Death.—So far only total death-rates have been considered, without distinction of cause. If the incidence of the general death-rate upon different ages and sexes is unequal, that of single diseases or natural groups of diseases is still more so. Each disease has its characteristic curve of age-mortality; and for obvious reasons this curve is almost always more intense than that of the

among males, while in deaths from violence there is a still greater inequality in the opposite direction. These are extreme instances; but in comparing different local or specialised death-rates with each other or with a standard, it is necessary to bear in mind that the comparison is only legitimate on the assumption that there is no *material* difference with regard to age- and sex-constitution.

The following table shows the progressive changes during the last thirty years in the mortality attributed to certain causes.

The possibility of altered nomenclature of disease, as well as altered environment, must be taken into account in interpreting these changes; and as regards some of the zymotic diseases, the occurrence of epidemic variations in quantity and quality, at long or short intervals, makes it difficult to measure their average incidence against that of the more equable causes of death, or to compare the course

of the death-rate of one zymotic disease with that of another upon anything like equal terms (see PERIODICITY IN DISEASE). It is a disputed point whether the ominous increase in the mortality

Mean Annual Death-Rates.—England and Wales.

Cause of Death	1861-70	1871-80	1881-90	1891-95
Small-pox . . .	0'16	0'25	0'05	0'02
Measles . . .	0'44	0'38	0'44	0'41
Scarlet Fever . .	0'97	0'72	0'34	0'18
Typhus . . .	?	0'06	0'02	0'00
Enteric Fever . .	?	0'33	0'20	0'17
Whooping-cough .	0'53	0'51	0'45	0'40
Diphtheria . . .	0'18	0'12	0'16	0'25
Diarrhoea . . .	0'97	0'92	0'66	0'63
Cancer . . .	0'39	0'47	0'59	0'71
Phthisis . . .	2'49	2'13	1'74	1'46
Heart-Diseases, &c.	1'05	1'34	1'58	1'68
Respiratory Diseases .	3'36	3'74	3'59	3'68

Violence . . .	0'77	0'74	0'65	0'56
ALL CAUSES . . .	22'5	21'4	19'1	18'74

attributed to cancer is real, or only due to the better diagnosis of cases which in former years would have been assigned to other causes.

Density of Population.—Even apart from any correction for age- and sex-distribution, the death-rate is generally higher in urban than in rural districts. In both it is declining, but as the fall is more rapid in the former the difference is growing less.

England and Wales.—Urban and Rural Death-Rates, 1861-90.

Years	Persons per Square Mile	Death-rate per 1,000 living		
		England and Wales	Town Districts	Country Districts
1861-70	365	22'5	24'8	19'7
1871-80	416	21'4	23'1	19'0
1881-90	470	19'1	20'3	17'3

The average density in 1891 was 500 persons per mile, or 0'8 per acre. If below this average, the density seems to have little influence upon the death-rate; but if above it, the increasing density is in general associated with increasing death-rate. But the density per acre or per square mile is a very crude measure of the overcrowding which is hygienically most important. In a sparsely populated district there may still be overcrowding of villages, of alleys, of houses, or of single rooms. Sheffield is said to have rather less than 17 persons per acre, but this bare average goes for little, since in one registration sub-district the density is 249 per acre, and in another 0'5 only. In London the death-rate among the better class of many-storeyed 'model dwellings' was found to be lower than the average, notwithstanding a more than tenfold greater density per acre. Farr held that, *other things being equal*, the death-rate varies as the twelfth root of the density of the population; the very necessary proviso makes the formula difficult of practical application in a given case.

Each of the principal zymotic diseases causes, on the whole, higher mortality in urban than in rural districts. Observations of a narrower kind, having regard to crowding of tenements, indicate that phthisis, respiratory diseases, and infant mortality are also conspicuously increased.

Mortality as affected by Occupation.—Here we have to do with a selected population—selected sometimes (e.g. miners) on account of robust health, sometimes by unfitness for other pursuits. In all cases the age- and sex-distribution differ widely from that of a general population, and comparison has to be made after correction for this. Such a comparison upon equal terms has been made by Tatham (*Suppl. to the 55th Ann. Rep. of the Reg.-Gen.*) with regard to a large number of trades. The following may serve as examples:—

Comparative Mortality according to Occupation.

Industry	Phthisis	Respiratory Diseases	Nervous Diseases	Urinary Diseases	Liver Diseases	Heart, &c. Diseases	Comparative Mortality Figure
ALL MALES	102	224	102	44	29	112	1,000
Agriculture . . .	106	115	51	24	17	83	602
Coal-Mining . . .	97	269	67	30	17	120	925
Wool . . .	191	256	100	45	21	131	991
Plumbers . . .	217	224	131	84	22	142	1,120
Cotton . . .	202	338	114	42	25	152	1,141
Innkeepers . . .	259	287	160	90	201	193	1,642
Earthenware . . .	333	668	123	63	32	227	1,706
File-makers . . .	402	423	212	124	36	304	1,810
Dock Labourers .	325	564	114	68	26	236	1,829

The comparative mortality figure is lowest (533) among the clergy, and much higher (966) among medical men.

Sickness.—Statistics of sickness are very incomplete. Those arising out of the compulsory notification of certain infectious diseases are published annually by the Local Government Board, and in local reports. Their chief statistical value at present is the measure which they afford of the local and periodic fluctuations in diffusion and case-mortality of each disease separately. Statistics of hospitals, asylums, and poor-law practice are useful, though fragmentary; and the records of the public services and of 'Friendly Societies' have yielded valuable results. All these have reference to 'selected populations,' and are not strictly relevant to average communities. For example, it is unsafe to draw conclusions as to the comparative age-incidence of enteric fever from hospital data, for there is no assurance that the cases in hospital are a fair sample of those outside in severity or in age-distribution.

It has been estimated that in a given community there will be about two weeks of sickness per head per annum, or about two to three years of continuous illness for each death. The incidence of sickness, unlike that of births or deaths, has to be considered with regard to *degree* and *duration*, so that the data, such as they are, scarcely lend themselves to statement in the ordinary form of rates.

Statistical Tests of Sanitary Condition. It has become customary to regard certain statistical data as proof of the healthiness or unhealthiness of a locality, in the sense of prevalent impurity of air,

water, soil, or dwellings. Chief among these in popular appreciation are the general death-rate, and the zymotic death-rate. The former is, upon the whole, a fairly trustworthy index of sanitary condition, but is liable to fallacy if the figures be small, or if the population be not accurately known, or if the age- and sex-distribution be abnormal, or, lastly, if care be not taken to exclude deaths of strangers and to include deaths of residents dying outside the district. Further, purely local death-rates for limited periods of time are liable to disturbance by epidemics of a kind not dependent upon insanitary conditions.

The zymotic death-rate is of little constant significance in this respect. It is made up of the combined death-rates of the 'seven principal zymotic diseases,' of which four (small-pox, measles, whooping-cough, and scarlet fever) have little claim to rank as filth-diseases, although the others (enteric fever, typhus, diphtheria, and diarrhoea) have a much more direct significance.

An excessive infant mortality may be due to diarrhoea and other diseases attributable to filth-conditions, but may also be accounted for by maternal neglect, or by epidemics of measles or whooping-cough. With equal reason the death-rates from phthisis and from respiratory diseases deserve to be taken into account.

The *mean age at death*, obtained by adding together the ages of those who die, and dividing by the number of deaths, is often cited as evidence of longevity, but has very little significance. It depends largely upon the age-distribution of the population; if there are many young children it will be low. By far the best criterion of longevity is, of course, the expectation of life, which can only be accurately ascertained from a life-table. Approximately it may be found by Farr's formula $x = \frac{2,000}{3D} + \frac{1,000}{3B}$, x being the expectation of life, B the birth-rate, and D the death-rate.

B. A. WHITELEGGE.

VITILIGO.—See LEUCODERMIA, p. 1256.

VITILIGOIDEA (*vitulus*, a spotted calf).—A term once applied to the disease now known as *xanthoma* and *xanthelasma*. See XANTHOMA.

VITTEL, in the Vosges, France.—Earthy mineral waters. See MINERAL WATERS.

VOCAL FREMITUS.—The sensation of vibration conveyed to the hand when applied over any part of the respiratory organs during vocalisation. It is felt in health, but presents various modifications in disease. See PHYSICAL EXAMINATION.

VOCAL RESONANCE.—The sound heard on auscultation over certain parts of the respiratory organs, during vocalisation, both in health and in certain forms of disease. See PHYSICAL EXAMINATION.

VOICE, Disorders of.—SYNON.: Fr. *Troubles de la Voix*; Ger. *Störungen der Stimme*.

INTRODUCTION.—Voice is the sound produced in the larynx by air driven from the lungs through the rima glottidis, modified in accordance with acoustic laws in the upper air-passages. Vocalisation is a function needing for its perfect production a healthy condition of the respiratory muscles, of

the lungs, trachea, and larynx, of the pharyngeal, oral, and nasal cavities, and of the nerves and nervous centres on which these parts depend for their isolated or co-ordinated muscular movements and their normal sensitiveness. For the production of the simplest vocal tone the cords must be free to approximate within a line of one another, while the co-ordinated action of a large number of muscles is required, to regulate their tension and that of the walls of the air-passages, to modify the form of the latter, and to produce the current of air.

Acoustically the organ of the voice must be regarded as a combined reed and pipe; and for the production of a perfect note it is necessary that the pipe should be in perfect unison with the reed. This unison depends not only on the shape of the various cavities, but on the relative rigidity or flexibility, and the tension of their walls; every variation in the number, size, or form of vibrations of the vocal cords, effected by the intrinsic laryngeal muscles, calling for similar modifications of the shape, size, and tension of the consonating cavities.

The word 'voice,' when used alone, always implies the presence of a musical tone (periodic vibrations), but sound sufficient for every purpose of speech and articulation may be produced without a musical tone. This is the *whispering voice*, caused by the rustling of air through the half-open rima and relaxed air-passages. To this condition—absence of musical tone in the voice—the term *aphonia* is applied, and it must be distinguished from the actual inability to produce sound, which we see after tracheotomy, where, in the effort to speak, the organs of articulation and sound are seen to move, but neither noise nor musical sound is heard.

PATHOLOGICAL RELATIONS.—The morbid modifications of vocalisation are necessarily numerous, in proportion to its complexity and the number of parts concerned in its production; but it may be generally stated that, in consequence of disease or perverted action in any of these parts, the voice may be altered either (1) in *loudness or force* (size of sound-waves); (2) in *pitch*, or relative height of its note (rate of sound-waves); or (3) in *quality* (shape of sound-waves). And even before there is obvious change in any of these respects, the power of passing rapidly and easily from one pitch to another, constituting melody, may be seriously impaired. The morbid alterations of the voice in these several directions will now be discussed; and brief reference will also be made to (4) *stammering of the vocal cords*; (5) *aphonia*; and (6) *the vocal signs in the chest*.

1. Changes in Force.—The voice is weakened in every disease which lowers the general muscular tone, or depresses the nervous system. The gradual change is well seen in phthisis without laryngeal affection, where at last even the effort to approximate the vocal cords is too much for the patient, and he speaks in only a whispering voice. In the same way painful affections of any of the parts enumerated above, interfering with muscular effort, weaken the voice. Speaking generally, mere diminished loudness of the voice depends usually on general rather than on laryngeal disease.

2. Alterations in Pitch.—The note of ordinary speech may be habitually raised or lowered, and the range of the singing voice may be seriously limited. The note of the voice depends primarily on the rate of vibration of the vocal cords; and this is the mean result of the tension, the length, the

density, and the thickness of the cords at the time the tone is produced, and the force of the current of air sent through the rima. Structural changes, therefore, in any one of these respects, will alter the pitch of the voice; and change in the ordinary vocal note is usually to be referred either to an affection of the tensor muscles of the larynx, or to structural change in the mucous membrane covering the cords or in the cords themselves. Lowering of the pitch of the speaking and of the range of the singing voice occurs with any condition which relaxes the mucous membrane, weakens the nervous and muscular systems, or makes the tense condition of the vocal cords and the consonating cavities painful. Paralysis of the intrinsic muscles, which admits of the approach of the vocal cords but interferes with their tension and density, affects the pitch as well as the quality, the voice being rough and deep in the paresis of the external tensors (superior laryngeal nerve).

The imperceptible transition from the 'chest' to the 'falsetto' voice, in which, while the condition of the vocal cords is suddenly altered, the form of the larynx, trachea, and other consonating cavities is simultaneously changed, requires a perfect control of the vocal organs, attained only by accomplished vocalists. On this change of register occurring involuntarily, the cracked voice in speaking is the result; and being referable to imperfect co-ordination, it is common in males about puberty, when the form of the larynx is changing, or may even persist occasionally throughout life. A curious affection of the pitch of the voice, in speaking, when two tones of different pitch are simultaneously produced (diphonia), appears to depend on the division of the rima into an anterior and posterior opening, either by small morbid growths, strings of mucus, or irregular action of the muscles.

3. Change of Quality.—The quality of the voice is affected by every alteration, either in the cords or in the consonating cavities, the purity and character of the tone being liable to numerous modifications, until, the musical note disappearing entirely, mere noise (aphonia or whispering) remains.

Hoarseness.—Hoarseness and huskiness, a combination of whispering and a badly sustained musical note, imply imperfect and irregular approximation of the vocal cords. Over-exertion of the voice, catarrh, &c., produce it temporarily, giving rise to irregular tension of the cords, to shreds of mucus, and to swellings of the mucous lining, which interfere with their regular approximation; while all changes short of those which absolutely prevent the closure of the cords may cause it as a persistent phenomenon. To the larynx itself we look, therefore, for the source of persistent hoarseness. Among the pathological conditions of which hoarseness is a symptom are chronic swelling of the mucous membrane, general or local, interfering with the closure of the rima; exudation or ulceration, and therefore inflammation, simple, specific, or diphtheritic; neoplasms; old cicatricial contractions; paralysis of the adductors of one cord, which necessitates the crossing of the normal cord beyond the median line to meet its fellow, as well as other forms of paralysis; and fixing of one vocal cord by ankylosis of the crico-arytænoid joint. The paralysis may, of course, depend on disease of the nervous centres, on the nerves themselves, or on pressure by intrathoracic or other tumours on the nerve-trunks. Hoarse-

ness, short of aphonia, is also a symptom of general exhaustion, as seen in phthisis and cholera.

The character of the speaking voice is also altered by any change in the resonating cavities. Thus the voice is said to have a *nasal twang* when the upper pharyngeal and nasal cavities are not completely shut off in vocalisation; while, on the other hand, obstruction in the nares, preventing the passage of the air through them and the formation of the nasal consonant sounds, is popularly, though wrongly, called 'speaking through the nose.' If the obstruction be situated in front of the nares, the sounds can be produced, but not continued; if the obstruction be in the upper pharynx, or at the back of the nares, they cannot be produced at all. When with obstruction in the nares there is swelling of the pharynx and the soft palate, the voice assumes the character so familiar in cases of quinsy.

Changes in the walls of the chest and the pectoral cavities also alter the character of the voice, the hollow voice of the emaciated phthisical patient illustrating this. The phonation, on inspiration, of spasmodic croup and of child-crowing or laryngismus stridulus must be referred to as the result of spasm of the vocal cords, though this involuntary function hardly comes within the definition of 'voice,' which term should be limited to sound produced in the vocal organs to establish communication between living beings.

4. Stammering of the Vocal Cords.—Spasm and defective co-ordination are the source of this peculiar affection of the voice, in which there are sudden interruptions of the voice without affection of the articulation (Prosser James).

5. Aphonia.—The various modifications of voice hitherto considered only occur where the vocal cords are free to meet more or less perfectly. Aphonia, or complete loss of the musical tone, occurs where the cords cannot meet. Among the conditions which will prevent the approximation of the cords and cause aphonia are paralysis or paresis of the adductor muscles, on whatever cause it may depend; fixation of the cords by cicatricial contractions, or by ankylosis of the crico-arytænoid joints; their destruction by ulceration; any painful affection which makes the patient unconsciously rest them; or coating with false membrane. But by far the most frequent cause of this aphonia is the abrogation or perversion of the will, occurring in the morbid mental condition of hysteria or other nervous disease; perfect power of phonation existing, but the patient, for months or years, declining to exercise the power, or to make the necessary effort. The intimate relations of the voice to the higher functions of the brain would lead us to expect that it would be influenced by the emotions. Thus we have a person hoarse with rage, speechless with terror, &c.; and the origin of these cases of nervous aphonia is frequently some sudden emotion, causing loss of control over the voice. Ziemssen believes that, even where the vocal cords cannot meet, by a great effort the patient may produce a hoarse, monotonous tone by vicarious vibrations of the ventricular bands.

TREATMENT.—The local treatment of the various diseases of the respiratory organs which give rise to disorders of the voice is fully discussed in the several articles on these subjects (*see* LARYNX, Diseases of; STAMMERING; PHARYNX, Diseases of; TRACHEA, Diseases of). The *general* treatment

will depend upon the constitutional state. See HYSTERIA; and PHTHISIS.

6. Vocal Signs in Chest.—Some consideration must be given to the changes in the voice which are audible when the stethoscope is applied to the chest. Normally the vibrations of the vocal cords are conveyed to the ear applied to the chest by propagation along the contained air, the rigid portions of the air-chambers, and the thoracic walls, the voice being heard as a feeble, buzzing, musical tone. This sound is weakened when the original tone is weakened by laryngeal disease; when fluid is interposed between the lung and the chest-wall; and when the bronchial tubes are obstructed by secretions or other cause, preventing the conveyance of the vibrations. The sound may, on the contrary, be exaggerated, giving rise to the phenomena of *bronchophony*, *amphoric voice*, and *egophony*. Bronchophony is simple increase in the vocal resonance, and is heard under the same conditions which give rise to bronchial breathing, that is, over lung consolidated by exudation or condensed by compression, and over cavities with solid walls. The term *pectoriloquy* is commonly applied to excessive bronchophony, but Bristowe limited it to those instances in which not only the laryngeal tone, but the articulate sounds produced in the mouth, are conveyed back to the chest, and thence through the chest-wall to the ear. Amphoric voice (*amphorophony*) is the term applied where the vocal resonance is not only increased, but acquires a metallic ring, from the addition of a consonant tone acquired in large cavities of the lungs. This is sometimes heard in a marked degree in pneumothorax, though in other cases of the same disease the vocal resonance may be absent or greatly diminished.

Egophony is heard where there is a thin layer of fluid between the ear and the lung, as in small effusions or at the margin of larger effusions. It is a bleating, tremulous tone, supposed by Stone to result from the interposed fluid preventing the fundamental note-vibrations from reaching the ear, while it permits the finer and closer vibrations of harmonics to penetrate. The same sound may be heard in some cases of consolidation of the lung. See PHYSICAL EXAMINATION. THOMAS J. WALKER.

PERCY KIDD.

VOLVULUS (*volvo*, I roll).—A form of intestinal obstruction in which the bowel is bent or twisted on itself. See INTestinal OBSTRUCTION.

VOMICA (*vomo*, I vomit, I cast up).—SYNON.: *Fr. Vomique*; *Ger. Lungengeschwür*.

DEFINITION.—A term applicable to all ulcerative spaces in the lung in open communication with bronchi. See CAVITY.

VOMIT : Examination of Vomited Matters.—Vomited matters may consist either of substances present in the stomach when vomiting begins, or of substances entering it during the process. Those present in the stomach when vomiting begins include articles of food and drink, drugs, poisons, or other ingesta, more or less altered by digestion or fermentation; saliva, epithelium, mucus, pus, or blood from the nasal passages, mouth, pharynx, or œsophagus; fluid or mucus secreted by the stomach itself, epithelium-cells, casts of tubules, or even shreds of gastric mucous membrane, blood more or less altered proceeding from the walls of the stomach, cells or small pieces

from morbid growths; fungi, as *torulæ* and *sarcinæ*; parasitic worms; bile; pancreatic juice; pus from abscess of the stomach or liver; or feculent matter from the intestine. During vomiting much saliva may be swallowed; and bile, pancreatic juice, pus or feces, not originally present in the stomach, may be pressed into it by the straining. Effusion of blood into its cavity may also be caused by the efforts of retching.

Method of Examination.—In examining the vomited matters it is advisable, first, to separate the larger pieces of undigested food by filtering the vomit through canvas or muslin.

The solid residue may be investigated by washing the larger pieces and tearing them up, or making sections of them, so that their nature may be ascertained. Partially digested curd is sometimes not very easy to recognise. If a large quantity of milk have been drunk at one time, the curd which it forms in the stomach may, when vomited, have the appearance of a piece of thick, dense, grey felt.

The filtrate should be put into a conical glass and allowed to settle. The reaction of the fluid is to be ascertained by litmus paper. For the methods of identifying the various acids—hydrochloric, lactic, acetic, butyric, &c.—and other volatile substances, see STOMACH, Examination of, p. 1591.

To ascertain the presence of pepsin in the vomit we add to it its own bulk of dilute hydrochloric acid (ten minims of diluted hydrochloric acid, B.P., to an ounce of water) and a flock of fibrin or a piece of hard-boiled white of egg; let it stand for several hours in a warm place; and then see whether or not the fibrin or albumen is dissolved.

To test for trypsin, we proceed in the same manner, but use the vomit without the addition of acid; and if it be already acid, neutralise it with bicarbonate of sodium.

To test for rennet, we add some neutralised filtrate to some neutral milk, and let the mixture stand at 98° for half an hour. If rennet is present coagulation will occur.

To test the vomit for peptone, we must put some of it into a small dialyser, and let it stand for some hours. We then add to the water in which the dialyser has stood solution of corrosive sublimate, which gives a precipitate with peptones; or some liquor potassæ and a drop of very dilute solution of sulphate of copper, which gives a precipitate dissolving on shaking, and forming a rose-red solution, changing to purple when more copper is added.

Bile is tested for in the filtered liquid by Gmelin's and Pettenkofer's tests.

For blood in the vomit, see HÆMATEMESIS, p. 620.

If the vomited matter be too thick to allow the sediment to subside, a little of it should be mixed with some distilled water and allowed to settle. A drop of the sediment is then to be examined microscopically; and the examination is facilitated by adding to one specimen a drop of iodine-solution, and to another a drop of aniline red or blue solution. The substances most likely to occur are partially digested fibres of voluntary or involuntary muscle, elastic fibres, connective-tissue bundles from meat in the food, spiral fibres and green chlorophyll-granules from vegetables, starch-granules (stained blue by iodine), *torulæ* or *sarcinae*, blood-corpuscles, leucocytes, scaly epithelium from the mouth, cylindrical epithelium from the stomach, and casts of the gastric follicles—sometimes fibrinous, sometimes composed of cells and granules

which take up the aniline colour and are thus rendered more easily visible.

Poisons in vomited matters must be searched for by special chemical methods.

Clinical and Pathological Indications.—

If the vomited food be unchanged, or but little changed, it indicates either that the vomiting has occurred soon after a meal, or that the secretion of gastric juice is deficient either in quantity or in quality. The food is usually comparatively little changed in nervous vomiting, or in cancer of the cardiac extremity of the stomach. In vomiting from cancer of the pylorus, or duodenal ulceration, the food is much more digested, as it remains much longer in the stomach. If undigested food be vomited some hours after a meal, the vomit should be examined in order to ascertain whether pepsin or acid be deficient. Complete absence of hydrochloric acid has been observed in cases of cancer and amyloid degeneration of the stomach, and a deficiency of this acid has been found experimentally in acute anæmic and febrile conditions. Abnormal acidity from fermentation of saccharine or farinaceous articles of food, and the consequent production of acetic, lactic, and butyric acids, occurs in chronic catarrhal conditions. In some cases of gastric catarrh starch appears to undergo a mucous fermentation, and large quantities of glairy material are formed. When fermentation has gone on to a great extent, the vomit may have a yeasty look, and should then be examined for sarcinæ and torulæ. See SARCINA; TORULA; and STOMACH, Dilatation of, p. 1595.

Sometimes large quantities of a watery fluid are vomited. This is occasionally alkaline or neutral, contains potassium sulpho-cyanide, and digests starch. It consists of saliva, which has been secreted abundantly on account of reflex irritation arising from the stomach, and swallowed. At other times it is strongly acid, and appears to be secreted by the stomach. Sometimes the vomit appears to be a mixture of both of these fluids. Such vomiting may occur from nervous disturbance of the stomach, but may be symptomatic also of catarrh, ulcer, or cancer. Mucus in the vomit indicates catarrh of the gastric mucous membrane; and the more acute the inflammation, the more leucocytes occur in the mucus. Bile may be vomited pure, in the form of a tasteless golden-yellow substance like yolk of egg, from the action of poisons, but this rarely happens. Vomiting of bile, more or less green and diluted, or mixed with digestive secretions or food, occurs as a symptom in congestion of the liver; but it may take place in all kinds of vomiting, whatever its cause. Large quantities of bile, mixed with the secretions from the mouth and stomach, and forming a grass-green liquid (*vomitus æruginosus*), may be vomited in peritonitis and cerebral affections. The writer has also observed this character of vomit in opium-eaters. Constant absence of bile, when vomiting is persistent, points to pyloric stenosis. Pus may get into vomit from the bursting of an abscess in the mouth or tonsils; it sometimes, though rarely, may arise from an abscess in the walls of the stomach; but it is more likely to come from abscess of the liver. Blood vomited in large quantity, and of a bright red colour, usually indicates ulceration of the stomach or cirrhosis of the liver. More or less altered, and in smaller quantity, it occurs in the diseases just mentioned, and also in cancer and

yellow fever (see HÆMATEMESIS, p. 620; and YELLOW FEVER). It may also be present in hysterical persons who have swallowed blood, obtained from external sources, or by sucking hollow teeth. Cancer-cells in the vomited matters are diagnostic of the presence of malignant disease.

T. LAUDER BRUNTON.

VOMITING (Lat. *vomo*). — SYNON.: Fr. *Vomissement*; Ger. *Erbrechen*.

DEFINITION.—Forcible expulsion of the contents of the stomach through the œsophagus.

ÆTIOLOGY AND PATHOLOGY.—Two things are necessary in vomiting, namely, squeezing of the stomach, and relaxation of its cardiac orifice. Although the muscular fibres of the stomach itself may contract under the action of emetics, they seem to be unable to expel its contents unless aided by external pressure, for when the muscles of the abdomen are cut across vomiting does not occur. When the diaphragm and abdominal muscles are paralysed, vomiting is impossible, though the stomach may be in active movement. The stomach is not necessary to vomiting, which will occur when that organ is excised, and a simple bladder tied in its place; but when the stomach is present, mere pressure upon it by the diaphragm and abdominal muscles, as in coughing, does not expel its contents. In vomiting, the contents of the stomach are squeezed out of it by the mechanical pressure of the diaphragm and abdominal parietes contracting simultaneously. When these muscles contract, if the cardiac orifice of the stomach remains closed, an ineffectual effort at vomiting, or retching, occurs; but if the cardiac orifice dilate, the gastric contents are expelled. The cardiac orifice is relaxed by means of the longitudinal fibres, which run along the under end of the œsophagus below the diaphragm, and then radiate completely over the stomach. When they contract they dilate the cardiac orifice, and at the same time aid the evacuation of the stomach by drawing the whole viscus towards the diaphragm. In the act of vomiting, then, the simultaneous contraction of three sets of muscles is required: (1) of the diaphragm, (2) of the abdominal wall, and (3) of the muscular fibres just mentioned in the stomach itself. The movements of these muscles are co-ordinated by a nervous centre, situated in the floor of the fourth ventricle in the medulla oblongata. This centre is closely associated with, though of course not identical with, the respiratory centre. The motor impulses from this centre are sent to the abdominal muscles, diaphragm, stomach, and œsophagus, by the intercostal, phrenic, and pneumogastric nerves respectively. The reasons for supposing that the nervous centre for vomiting is closely associated with the respiratory centre, are that the movements of vomiting are modified respiratory movements, that emetics excite the respiratory centre, and that their action is usually preceded by increased respiratory movement, while depression of the activity of the respiratory centre stops vomiting. When the blood is rendered very arterial by excessive respiration, a condition of apnoea, in which no need of respiration is felt, and no respiratory movements are made, is produced; but if emetics are then injected into the veins, respiration not only becomes more frequent, but apnoea can no longer be induced, unless the activity of the respiratory centre be lowered by narcotics.

The vomiting centre is usually excited to action by irritation of certain *afferent nerves*. These may act either directly upon it, or through the medium of the brain. The nerves of special sense act through the brain. The sight of a disgusting object, a disagreeable stench, or an unpleasant taste, may excite vomiting, and it may also be produced by the simple thought of such subjects. A blow on the head, or inflammation of the brain or its membranes, also excites vomiting. According to Budge, the cerebral centres for the movements of the stomach are in the right corpus striatum, and especially in the right optic thalamus. When these parts are irritated the stomach moves. Irritation of the corresponding parts on the left side of the brain does not affect the stomach. Vomiting occurs in certain cerebral conditions, either affecting the brain itself or its membranes, such as cancer or tubercle of the brain, apoplexy, cerebellar hæmorrhage, softening of the cerebral substance, sometimes encephalitis, poisoning by narcotics, melan- cholia, profuse hæmorrhage, or tubercular meningitis. It is also one of the symptoms of Menière's disease of the semicircular canals. It also occurs in various diseases, in which, however, it is difficult to say whether the vomiting be due to direct affection of the brain itself, or to reflex action upon it from other organs. Such diseases are typhus, plague, yellow fever, cholera, and the cold stage of ague. Very painful impressions on sensory nerves throughout the body may excite vomiting. This is seen in cases of loose cartilages in the knee, in dislocation of a joint, or in a painful wound or operation. Here, also, it is uncertain whether the vomiting be produced through a direct connection of sensory nerves with the vomiting centre, or whether the irritation acts indirectly through the cerebrum.

Certain afferent nerves appear to have a more direct connection with the vomiting centre than others, and these require special consideration :—

1. *Branches of the glosso-pharyngeal nerve to the soft palate, the root of the tongue, and the pharynx.*—These parts have a very close connection with the vomiting centre, and tickling them with the finger or with a feather is one of the readiest means of inducing vomiting.

We find vomiting occurring in inflammation of the soft palate or tonsils, and also of the pharynx, especially in children.

2. *The nerves of the stomach.*—The sensory nerves of the stomach are chiefly branches of the vagi, but they belong partly also to the sympathetic system. When the vagi are cut, vomiting becomes difficult, but efforts at retching occur, and the writer has seen vomiting take place from the action of emetics after section of the vagi. It is therefore evident that irritation of the stomach produces vomiting reflexly through other nerves than the vagi. Vomiting may occur from irritant substances in the stomach, whether introduced into the stomach, or formed within it; from irritation within the stomach, due to an inflamed or irritated condition of its walls; or from mechanical pressure, from without or from within. Thus it may occur from the presence of undigested food, from irritating substances produced by imperfect digestion, or from irritant poisons within the stomach. It may be due to catarrh or congestion of the mucous membrane itself, to softening of the mucous membrane, or to ulcer or cancer in the gastric wall. It may be produced by extreme distension of the stomach by

gas, liquids, or solids; by compression of a part of it within the body, as in hernia of the stomach; or by the pressure of a tumour upon it. It may be caused by violent compression externally with the hands; by the pressure of a too tightly laced corset; by the pressure against the abdominal walls of hard tools or benches in certain trades. It frequently occurs in cough, especially the cough of phthisis; but here it is probable that the vomiting is due partly to the violent compression between the diaphragm and abdominal walls, and partly to the congestion of the vessels which the continued interruption of the circulation during the fit of coughing brings on.

3. *The nerves of the liver and gall-duets.*—These consist chiefly of branches of the vagus and sympathetic. From irritation of them vomiting occurs in hepatitis, or during the passage of a biliary calculus. It is from irritation of these branches, also, that vomiting may occur in pleurisy of the right side, the congestion of the pleura on the upper surface of the diaphragm having led to congestive changes in the liver.

4. *Intestinal nerves.*—Ligature of the intestine in animals produces vomiting, which is arrested by dividing the nerves passing from the ligatured parts. In man it is the almost invariable accompaniment of strangulated hernia or intussusception, and it may even occur in obstruction of the bowel by fecal matters in cases of obstinate constipation. It also takes place in peritonitis from irritation of these nerves.

5. *The renal nerves.*—Vomiting occurs from irritation of these nerves, as by calculi in the pelvis of the kidney or passing down the ureter, and also in nephritis.

6. *Vesical nerves.*—In cystitis vomiting occurs. It may possibly be due, however, not to irritation of the vesical nerves, but to extension of inflammation to neighbouring parts.

7. *Uterine nerves.*—Irritation of these nerves is one of the commonest causes of reflex vomiting. It may be produced in animals on irritation of the uterine plexus, and occurs in the human subject during pregnancy or in metritis.

8. *Ovarian nerves.*—Vomiting is a symptom of inflammation of the ovaries.

9. *The nerves of the testicle.*—A blow on this organ tends very readily to produce nausea and vomiting.

The cause of vomiting in *sea-sickness* is uncertain; but it appears to the writer to be partly due to the condition of the nerve-centres, and partly to that of the viscera. See SEA-SICKNESS.

TREATMENT.—The treatment of vomiting is to be directed to two ends—(1) to *remove the cause* if possible; and (2) to *lessen the irritability of the vomiting centre*. The chief drugs which lessen the irritability of the vomiting centre are opium, morphia, bromide of potassium, chloral hydrate, and probably, also, hydrocyanic acid and belladonna. Strychnine and small doses of ipecacuanha are also useful in vomiting, and they probably owe their power to their action on the vomiting centre. Most of these drugs have a local sedative action on the stomach, and therefore it is advantageous to give them by the mouth when possible. Even when the stomach is very irritable, they may be retained by giving them in a concentrated form. When the stomach will not retain them, they must be given by the rectum or by subcutaneous injec-

tion. In sea-sickness the effect of the position of the head is sometimes very marked, and the vomiting may occasionally be arrested completely by removing all pillows and putting the head on a level with, or rather lower than, the body.

In cases of disease of the brain or its membranes, where it is difficult or impossible to remove the cause, we must try to lessen the congestion by means of leeches and cold applications to the head; and also to soothe the vomiting centre by diluted hydrocyanic acid, or by bromide of potassium. At the same time, however, considerable benefit is obtained from the use of remedies which act locally on the stomach, these seeming to have some reflex effect upon the vomiting centre. One of the most useful is ice, which may be constantly sucked, and also swallowed in small lumps. Where the vomiting is dependent on the action of the poisons circulating in the blood, as in the later stages of contracting kidney, we must endeavour to eliminate these by increasing the action of the kidneys and of the skin. In vomiting dependent on inflammation of the mouth and fauces, we lessen the irritability by soothing or astringent gargles, confections, or glycerine. A confection or glycerine is often better than a gargle, inasmuch as it remains longer attached to the parts, and thus exercises a more prolonged effect upon them. When vomiting is due to irritant substances in the cavity of the stomach, such as indigestible food, and acrid fluids or poisons, it is best treated by evacuating them. A large draught of lukewarm water, alone or mixed with a teaspoonful of mustard, is one of the best means. Large draughts of warm water alone, even if they are not ejected, may give relief by diluting the acrid substances in the stomach so much as to prevent their irritating the mucous membrane. In this way they sometimes relieve sick-headaches. It is of great importance sometimes, not only to prevent the formation of acrid substances by slow and imperfect digestion, but to prevent the mechanical irritation of the mucous membrane by undigested food. For example, we not infrequently notice that sickness and vomiting will occur in susceptible individuals after meals containing such substances as are not only slowly digested, but are swallowed in lumps. Examples of these are uncooked apples and cheese, or even potatoes, especially when imperfectly boiled or new. These articles, instead of being crushed to a powder by the teeth, are swallowed in lumps of considerable size, and apparently, instead of passing the pylorus, are retained in the stomach, and, partly by the mechanical irritation, and partly by their giving rise to acrid products, cause sickness. Milk, when swallowed in large draughts, or when there is too much acidity in the stomach, instead of falling in fine flakes will coagulate in large lumps, which have an effect similar to that of cheese. To prevent this it is advisable to mix the milk with soda-water or lime-water, or to take it, as in the whey-cure, by sipping.

When vomiting is due to slow or imperfect digestion, which allows decomposition or fermentation of food to take place in the stomach, it may be arrested by improving the digestion. Thus five grains of calomel, by acting on the stomach through the liver, may arrest vomiting; and tincture of walnut (the active principle of which, juglandin, is an hepatic stimulant) has also been recommended. Pepsin also, by facilitating digestion, may prevent

vomiting; and bitters, such as calumba, may do so by preventing putrefaction or fermentation.

When decomposition or fermentation of food, with formation of acrid or irritating products, has once set in, it may continue a long time, as the organisms which cause it remain constantly in the stomach, and renew the process in every fresh supply of food. It may be stopped by antiseptics. Where the vomited matters are frothy and yeasty-looking, the sulphurous acid of the Pharmacopoeia, in doses of one fluid drachm, diluted with half a wine-glassful of water, often arrests such vomiting like a charm. Creosote has a similar action, but possibly has some additional action on the nervous system, as it is useful even in cases where the vomiting does not appear to be due to decomposition of food. In dilatation of the stomach these antiseptics may fail, and the best results are obtained by washing out the stomach by a syphon-apparatus. *See LAVAGE.*

For the treatment of irritant poisoning, *see POISONS.*

When the mucous membrane of the stomach itself is inflamed or irritated, we must try to lessen the irritation. The best drugs for this purpose are ice, diluted hydrocyanic acid, opium, and bismuth. The insoluble salts of bismuth, and especially the subnitrate, are to be preferred to the solutions; and it is advisable to combine them with magnesia, potash, soda, or carbonate of lime, according to the condition of the intestines, preferring the magnesia when the bowels are confined, and carbonate of lime when they are too loose. Sometimes the tendency to vomit is increased by lying on the right side. This is probably partly due to the dragging of the stomach itself upon the cardiac extremity, and partly to the difficulty with which gaseous eructations escape from the stomach in this position. When there is a tendency to vomit, therefore, the patient should lie down on the left side after a meal. In the vomiting of hepatitis, in addition to opium and diluted hydrocyanic acid, we may use ice-water, or ice swallowed, and leeches over the liver. In biliary calculus, we may give, along with opium, a full dose of ether internally, and in addition may employ ether or chloroform by inhalation; similar treatment may be adopted in cases of renal calculus.

In intussusception or hernia we must remove the cause, if possible. In peritonitis full doses of opium are best. For the vomiting in cystitis and ovarian diseases we must lessen the sensibility of the vomiting centres by the drugs already mentioned, and treat the local conditions.

In the vomiting of pregnancy we trust partly to the drugs already mentioned to act on the vomiting centre, and partly to local applications. It is sometimes arrested by the application of a 10-per-cent. solution of nitrate of silver to the os uteri, or by slight detachment of the membranes around the margin of the internal os. Where all other methods fail, the induction of premature labour must be resorted to. *See PREGNANCY, Diseases and Disorders of, p. 1307.*

VON GRAEFE'S SIGN.—*See EXOPHTHALMIC GOITRE.*

VON RECKLINGHAUSEN'S DISEASE.—*SYNON.: Multiple Neuro-fibromata. — See TUMOURS.*

VOYAGES.—See SEA-VOYAGES.

VULVA, Diseases of.—**SYNON.** : Fr. *Maladies de la Vulve*; Ger. *Krankheiten der Schamritze*.—The vulva or external genitals of the female comprise all the structures external to the hymen, having the navicular fossa and perinæum behind, the urethral orifice, vestibule, clitoris, and mons Veneris in front, and at the two sides the nymphæ and labia majora. These organs may be the seat of many diseases, which will be described in the following order :—

1. **Atresia Vulvæ.**—Closure of the genital fissure is sometimes found as a *congenital* malformation. This is usually of itself of no great importance, as it is almost always associated with other defects in development, as with atresia ani, hermaphroditism, and extroversion of the bladder. *Acquired* atresia results from mismanagement of infantile vulvitis, from injuries of the pudenda in childhood, or from cicatrization following upon some ulcerative process. It may give rise to trouble in micturition if the urethral orifice be involved. In rare cases it is only after puberty that trouble arises, from retention of the menses, or after marriage, from dyspareunia; or even during labour, from narrowness of the orifice delaying the escape of the infant. In the slighter and more recent cases, where the labia have only been agglutinated, they may be torn apart by pressure with the thumbs; or by passing a probe or sound behind the line of adhesion, and tearing it up with the handle of a scalpel, or with the nail. Where the union has become organised, the edge of the knife must be employed. In any case the patient should be anæsthetised; and care must be taken to prevent the reproduction of the adhesions.

2. **Inflammation.**—**SYNON.** : Vulvitis.—Inflammation of the vulva may be (a) *general*; or (b) *localised*.

(a) *General vulvitis.*—This variety is found affecting the apposed aspects of the labia, and the whole of the mucous surface they enclose, up to the borders of the hymen. It may be due to gonorrhœal infection, in which case the catarrhal process is apt to extend to the urethra and the vagina. In infants and young children of strumous constitution, it sometimes arises from exposure to cold, want of cleanliness, or irritation from ascarides that have passed out of the anus. In the adult it may result from injury, or rude coition; or from the escape of acrid uterine or vaginal discharges. It shows itself with heat, and tenderness, or sometimes itching in the part; a discharge of viscid glairy mucus bathes the surfaces, which sometimes becomes purulent, and glues together the labia. When the labia are separated the seat of the mischief is exposed, and is seen to be red, and sometimes painful to touch. Apart from the constitutional remedies that may be indicated in individual cases, the treatment consists in keeping the parts at rest, and carefully clean; and in bathing or douching the surface with hot water, followed by an astringent lotion or dusting powder.

(b) *Localised vulvitis.*—The vulvitis may be localised—(a) in the *vestibule*; (β) in the *navicular fossa*; or (γ) in the *muciparous follicles and glands*, and especially in the *Bartholinian glands*. (a) and (β) occur under the same conditions as the more diffused inflammation, and may be a source of considerable distress in walking or when the part is

touched, without being attended by any leucorrhœal discharge. Such cases require the same treatment as cases of general vulvitis; only it is important to make the applications directly to the affected spot, and hence it is usually best to apply sulphate of copper in the form of a solid crystal. (γ) Inflammation in the Bartholinian glands is the commonest cause of *labial abscess*. It may attack females at any age, but is most frequently seen in women from twenty to thirty, whether married or unmarried. It may arise during pregnancy, and some women are liable to repeated attacks, the glands becoming swollen and cystic whenever the patient gets a chill. In some cases there is profuse secretion, which escapes freely. Far more frequently the swelling in the lining of the duct leads to occlusion. This occlusion is in some instances transitory, and when the swelling in the duct and around its orifice subsides, the secretion that had accumulated escapes. In other instances the duct becomes permanently closed. These are the cases where the patient acquires a swelling in the labium majus of the affected side, varying in size from a pigeon's to a hen's egg. The accumulated fluid may be clear and limpid; but often it is turbid and distinctly purulent. In all the suppurative cases, if the cyst be evacuated through a small opening, the fluid is apt to reaccumulate, and the cyst-walls are now more likely to be the seat of a mischievous inflammation. Hence the *treatment* consists, first, in trying to reduce the inflammation with hot fomentations or poultices, perhaps aided by sedative lotions containing belladonna or laudanum, with the view of getting the orifice relaxed; and where the contents do not escape through the duct, the cyst should be freely opened, and the cavity cauterised. Huguier's suggestion, to extirpate the gland, is not ordinarily required, especially if the evacuation be effected with a Paquelin's thermo-cautery, which first makes a large and safe cut into the cyst, and can then be applied to the interior, so as to destroy the secreting surface.

Specific inflammations.—The specific inflammations, *gonorrhœal* and *syphilitic*, are treated of in their respective articles. But it is to be noted that the vulva may be the seat of *erysipelas*; and female children have sometimes suffered from a gangrenous vulvitis or *noma*, of the same nature as the *noma* of the mouth and cheeks, which may come on after some of the eruptive fevers, such as scarlatina, and requires the same kind of treatment, with chlorate of potassium and tincture of the perchloride of iron and stimulants, from an early stage of the mischief. The labia and perinæum are also occasionally the seat of *lupus*, which may be mistaken for cancer, but is not attended by enlargement of the inguinal glands, and should be treated by curetting and the application of escharotics.

3. **Eruptions.**—Various forms of eruption may be met with in the vulva, sometimes on the nymphæ or internal aspect of the labia majora, sometimes on the external aspect, and extending to the mons Veneris, or inside of the thighs. The commonest are *eczema*, *erythema*, *herpes*, *prurigo*, and *acne*. They are diagnosed and treated in the same way as the same affections in other situations. It is to be remembered, however, that the tendency to chronicity, which is a marked feature of inflammatory processes in the sexual apparatus generally, is apt to show itself in these vulvar eruptions, and that patients, from motives of

delicacy, are apt to allow them to remain untreated for too great a length of time. Further, many of them give rise to itching, which tempts the patient to rub and scratch herself to obtain relief, and may thus perpetuate the pruritus.

4. **Pruritus.**—**ÆTIOLOGY.**—Itching of the vulva is a not infrequent symptom of some of the eruptive and inflammatory affections of the part, when these are either healing or have got into a chronic stage; and it may remain as a permanent trouble after healing has taken place, if the patient have acquired the habit of relieving herself by friction. Sometimes it is reflex, from oxyuric irritation in the rectum, or when the worms have travelled from the anus to the vulva. Or it may be associated with disease of the vagina or uterus, as in cases of chronic colpitis or carcinoma of the cervix, in which the itching may either be due to irritation from the nature of the discharge, or be a reflex phenomenon. In some instances it can be traced to circulatory disturbance in the labia, as when the veins are enlarged, and in the congestion of early pregnancy. In others the renal secretion is at fault; and it is such a common phenomenon in women who are the subjects of diabetes mellitus, that in every patient who suffers from pruritus vulvæ, the urine should be tested for sugar. Lastly, there are some cases that can only be described as idiopathic.

SYMPTOMS.—The itching may be localised on the internal aspects of the nymphæ, or of the labia majora, or around the clitoris or the perineum. In most cases of long standing it becomes diffused all around to the anus and inside of the thighs. Sometimes it is temporary, as in the pruritus of pregnancy, which passes off under careful management in a few weeks, or in rarer cases during the puerperium; in other patients it becomes chronic, and constitutes one of the most distressing troubles to which a woman is liable. The itching may come on only occasionally. For the most part it is likeliest to prove distressing when the patient is warm, as at bedtime or after exercise; but with some the feeling is never quite in abeyance, and the patient has the almost constant desire to relieve herself, as for a time she can do, by scratching or, rather, rubbing the parts with her dress or a towel, until the pain overcomes the feeling of itch, or sometimes until the collapse consequent on the onanistic orgasm which she has involuntarily produced, renders her for a time less sensitive to her trouble. The result of such friction, however, is to keep up the local irritation; so that even in cases where there may not originally have been any local pathological change, but where the itching and friction have persisted for months or years, the skin and mucous membrane become thickened and indurated, and a condition resembling that of a chronic eczema becomes induced. In several cases the writer has seen epitheliomatous nodules develop at the sides of the clitoris and in the vestibule.

TREATMENT.—When diabetes mellitus is present it must be combated; and if the patient is gouty, or have her urine too acid or alkaline, these conditions must be rectified. Morbid processes that may be present in the vulva or other neighbouring structures must be treated according to the requirements of the case. A carefully regulated non-stimulating diet should be enjoined, and a due amount of exercise. The internal remedies that have been found most helpful are bromide of potassium

and arsenic. Then, for the relief of the itching, the patient must be warned against the danger of rubbing the parts, and be taught to soothe it by bathing with very warm or sometimes with cold water, and drying the parts with a soft towel or napkin. It can be still better allayed by mopping with a lotion containing infusion of tobacco or belladonna or opium; or by applying afterwards a piece of lint soaked in black lotion, or a lotion of acetate of lead. The most effectual sedatives are ointments containing sulphur, camphor, tar, carbolic acid, thymol, iodide of lead, perchloride of mercury, bismuth, prussic acid, iodoform (deodorised with Tonquin bean), or cocaine. The free application of lunar caustic followed by cocaine has been strongly commended by Olshausen. In several otherwise intractable cases, patients in private practice and in the Buchanan ward of the Royal Infirmary of Edinburgh have been cured by ablation of the clitoris and surrounding mucous membrane, as far back as the vaginal orifice, and bringing the raw surfaces together by means of catgut sutures. See p. 1309.

5. **Tumours.**—The following enlargements may be found in the vulva:—

(a) *Hypertrophy.*—The clitoris has sometimes been found of a size sufficient to cause discomfort, and warrant its removal. Far more frequently the nymphæ are of unusual dimensions, their margins projecting beyond the labia, and then they are liable to become the seat of ulcerative processes, and require to be trimmed, which may be done with the knife or scissors, but better with the thermocautery. Enlargements of the labia majora, in the form of elephantiasis, are met with among Hindu women. The mass is sometimes of enormous size, and in consequence of the calibre of the nutrient vessels, ablation is apt to be attended by dangerous hæmorrhage, so that the application of an elastic ligature is in most cases the best means of effecting its removal.

(b) *Hernia.*—Hernial protrusions may occur into the labia, and be found among the swellings of this part. The detection and treatment are to be effected and conducted as in the case of other hernie.

(c) *Cysts.*—Cystic swellings are found in the upper part of the labia, when the canal of Nuck becomes the seat of an accumulation of fluid, which corresponds to hydrocele of the cord in the male; or lower down, when the duct of a Bartholinian gland has become occluded, and the secretion of the acini accumulates so as to distend the gland without its becoming inflamed. If a complete aspiration in either case is not followed by perfect cure, and the fluid reaccumulates, as it is apt to do, the second tapping should be accompanied by an injection of iodine; and in the case of the Bartholinian cyst, the wall of which is formed of a mucous rather than of a serous membrane, the evacuation may require to be effected through a larger opening, and followed by the application of a more powerful escharotic.

(d) *New-growths.*—Various neoplasms may have their seat in the vulva. At the orifice of the urethra not infrequently small red fleshy growths, the so-called *urethral caruncles*, make their appearance. They are sometimes unattended by any symptom; more frequently they cause intense suffering during micturition, during coitus, or when the patient takes exercise. The pain is usually referred to the urethral orifice, but it is sometimes reflected to

distant parts, as to the heel. Relief from suffering may be temporarily obtained by application of sulphate of copper or nitrate of silver; but cure is only effected by removal of the growth. It is imperatively necessary to remove not only the small red body, but the portion of the urethra from which it springs, and the raw surface should be freely cauterised if the ablation have not been effected with a thermo-cautery. *Specific* swellings, warty or gummatous, are, of course, frequently to be met with on the vulva. *Lipomata* sometimes grow under the skin of the labia pudendi. More frequently *fibromata* occur, which may attain considerable size, and demand removal. Lastly, the law that *carcinomata* have a predilection for surfaces where a transition takes place from one variety of epithelium to another is illustrated by the frequency with which different forms of cancer affect the vulva. Their development, symptoms, and treatment pre-

sent no special features. Only it is well to remember that when the mischief is met with in a stage where there is still hope of eradication, it is best to effect the removal of the neoplasm by some of the bloodless methods with which modern surgery has become familiar. The tissues in which the growth develops are very vascular; and while in some situations—as at and around the clitoris—it is comparatively easy to control hæmorrhage by pressure against the pubic bones, in the parts immediately to the side and back of the vaginal aperture the bleeding from a cut surface is apt to be uncontrollable and dangerous. Hence commencing *carcinomata* ought to be extirpated with the *écraseur*, or, better still, with Paquelin's thermo-cautery, which is the most serviceable of all instruments for the removal of the different varieties of neoplasm that infest the vulva.

ALEXANDER RUSSELL SIMPSON.

W

WANDERING OEDEMA.—See ANGIO-NEUROTIC OEDEMA, p. 70.

WARTS.—SYNON.: Lat. *Verruca* (an excrescence); Fr. *Verrue*; Ger. *Warze*.

DEFINITION.—The ordinary wart is a benign circumscribed cutaneous papilloma.

ÆTIOLOGY.—A wart is an aberration of growth of certain of the constituents of the skin; it is mostly found in children and elderly persons, and less frequently in the adult. As children become developed by growth and their tissues acquire strength, these partial exuberant growths disappear. In young persons of feeble organisation they are sometimes thrown out like an exanthem, and yield to a constitutional treatment directed towards the improved innervation and nutrition of the tissues. Their direct relation with the nervous system is often evinced by their sudden disappearance under the influence of mental emotion, a circumstance which has led to the popular use of charms for their cure. In elderly persons they are often met with on the face, where their presence must be ascribed to debility of integument; and they are frequently associated with dirt and neglect. Briefly, warts may be said to be due to aberration of nutritive function of the skin, consequent on defective organisation and vitality. Warts may be associated with Adenoma Sebaceum (p. 26).

DESCRIPTION.—Pathologically a wart is an hypertrophy or excessive growth of a small group of papillæ of the skin, forming a hard prominence of the integument. Warts vary in size, are never congenital, and are modified according to situation. They may be simple or branched, flat or acuminate, simple or multiple, or pigmented. One kind, the senile wart (*Verruca senilis*) is remarkable for the minimum of prominence, resembling a flat, dirty-looking blotch on the skin; while another, as on the hands, may have a prominence of a quarter of an inch, or on the scalp of half an inch.

Warts on the hands—the fingers, dorsum, wrist, not the palm—afford the commonest illustration of

verruca, as in this situation, from the greater nutritive energy of the skin and the abundance of epidermis, they are most frequent and most highly developed. When of recent growth they are convex and smooth on the surface, but when of longer standing the apex is flat, from the wearing away of the superficial cuticle, and the anatomy of the wart becomes disclosed. Then it is apparent that the wart is composed of a bundle of fibres, held together in a cylindrical form by a boundary of thickened cuticle. Each of these fibres is a vascular papilla of the skin, enclosed in a sheath of cuticle, and the collective mass forms the body of the growth. An old wart will frequently split up into several segments (*V. lobosa* or lobulated wart), and then its construction of fibres (*V. fibrosa*) is strikingly conspicuous. If a wart be cut through horizontally, the vascular papillæ will be cut across, and then the structure consisting of papillæ and horny sheaths is still more evident. On the fingers and especially the knuckles of children, the verruca is isolated and large; but it is not infrequently confluent, while on the back of the hands and wrists, as also on the forehead, it is often developed in crops, like an eruption; the latter, however, never attain the dimensions of the isolated warts of the fingers.

Thread-like, often pedunculated, warts (*V. filiformis*) are met with on the neck, chest, ears, and eyelids; warts may also occur on mucous surfaces, e.g. vesical (p. 145), and laryngeal (p. 853) papillomata.

Verruæ are generally sessile (*V. sessilis*); but on the scalp they are frequently pedunculate (chiefly in women), and, from a peculiarity of structure, have been denominated digitate (*V. digitata*). The digitate character of the warts of the scalp is due to the smaller quantity of epidermis occurring in that region; consequently the hypertrophied papillæ are not held together by a ring of thickened cuticle as elsewhere, but, being left to themselves, shoot out from the centre like fingers; the papillæ likewise grow to a greater length, and

their cylinder is swollen so that the bulk of the mass greatly exceeds that of the base from which they spring. Nevertheless, the digitate verruca must be distinguished from *V. acrochordon* and the cauliflower-shaped venereal warts (see ACROCHORDON). Both of these are growths of the integument, and are not restricted to the papillæ cutis alone; and thereby fall into the category of molluscum, with which, especially acrochordon, they are closely allied in pathological structure.

Telangiectatic wart-like patches are met with in angio-keratoma. See ANGIO-KERATOMA.

The normal colour of warts on the hands is a pale lemon-yellow, but from their roughness they are apt to retain dirt in their crevices, which gives them a brownish appearance. The flat warts of the trunk of the body and face are accompanied by the production of pigment, and their dirty colour is consequently more striking. See MOLLUSCUM CONTAGIOSUM; XANTHOMA; LICHEN PLANUS; MOLES; LUPUS; KERATOSIS.

Warts, especially senile flat warts, frequently give rise to pruritus, and may be the starting-point of transformation to malignancy. Black papillary formations accompany the very rare affection, Acanthosis Nigricans (see p. 12); and warty growths are not infrequently present in cases of myxœdema (p. 996).

DIAGNOSIS.—True idiopathic warts must be distinguished from other diseases which sometimes put on a warty appearance, especially carcinoma and syphilis. Epithelioma of the skin is occasionally seen as a circumscribed warty growth, but generally with adherent scabs covering superficial ulceration. These signs, together with infiltration of adjacent tissues, implication of neighbouring glands, and pain, would arouse suspicion. It must be remembered, however, that epithelioma frequently attacks a simple wart which has remained quite passive during a lifetime; rapid increase of growth with the above-mentioned symptoms would suggest the supervention of epithelioma.

Any chronic inflammatory process of the skin, especially syphilis, is liable to take on a papillary character. Without referring to the papillary growths of early syphilis (condylomata), which could scarcely be confounded with simple warts, on account of their position and moisture, mention may be made of the dry warty character assumed by old syphilitic lesions, especially such as have been preceded by ulceration. The history of the disease (previous ulceration, &c.), together with other concomitant symptoms of syphilis, would assist the diagnosis.

As of venereal origin, though never syphilitic, ordinary venereal warts must also be noted. Other names by which they have been described suggest their characters, such as 'pointed condyloma,' and 'cauliflower excrescence.' They are generally soft, bright red in colour; and the individual papillæ are pointed. The rapidity of their growth, and the situation where they usually occur (the genitals), serve to distinguish them from ordinary verruæ. Moreover, they most often accompany gonorrhœa, eczorrhœa, or other irritating discharge. Balanoposthitis may cause warts (p. 135, and p. 582). In the male they are on or under the prepuce, in the female on the inner side of the labia (see p. 1120).

Cadaveric warts, or dissecting-porter's wart or anatomical tubercle (*V. necrogenica*) is one of the rare effects of the application of tuberculous matter

to the skin. The back of the hand over the knuckles or the joints of the fingers is its usual site. The skin is warty and thickened, and may resemble epithelioma (p. 244). See SKIN, Tuberculosis of.

Peculiar wartlike granulomata characterise the remarkably infective endemic disease, Verruca Peruviana (p. 250). Melanotic warts are examples of pigmentary changes resulting from cell-action on the blood. Old-standing lesions of Lichen ruber planus occasionally take on a warty character (*Lichen verrucosus*). See *Lichen planus verrucosus*, p. 872.

PROGNOSIS.—Verruca is a blemish rather than a disease, and unimportant in its relation to the general health. By an error of diagnosis we sometimes read of malignant warts; and warts have been confounded with those fleshy growths termed 'tegumentary nævi.' In elderly persons a warty state of the skin is sometimes associated with asthenic ulceration, and occasionally with rodent ulcer, for which the nutrition of the skin, and not the wart, is responsible.

TREATMENT.—The best method of treating verruæ is to touch them with some solvent agent, such as glacial acetic acid. This acid dissolves the epidermis, and, reaching the vascular papillæ, destroys the whole structure of the wart down to its root, or a saturated solution of caustic potash may be carefully applied (p. 1759). The alkali acts more speedily than the acetic acid, and effects a more thorough cauterisation of the vascular plexus, from which the hypertrophied papillæ derive their capillary loops. This little operation may either be completed at one sitting, or it may be repeated daily until its purpose is effected. Where there are numerous verruæ to be dealt with, the process is tedious, and is generally left in the hands of the patient. The verruæ digitatæ of the scalp are speedily and easily removed by this process. In the exanthematous form the verruæ are too small and too numerous for the caustic application. These may be treated by friction with sulphur-ointment or tar-ointment; and in this latter form the verruæ are frequently entirely removed by a course of treatment with liquor arsenicalis, in three- or four-minim doses, taken immediately after meals, three times a day.

Salicylic-acid collodion, or the acid nitrate of mercury applied so that the limits of the wart are not transgressed; alum, tannin, calomel, and potassium bichromate, are also favourite remedies. For the treatment of venereal warts, see PENIS, Diseases of, p. 1179; and GLEET, p. 583.

JOHN HAROLD.

WASTING.—A synonym for atrophy. See ATROPHY, GENERAL; and ATROPHY, LOCAL.

WASTING PALSY.—A synonym for progressive muscular atrophy. See PROGRESSIVE MUSCULAR ATROPHY.

WATER, Ætiological Relations of.—See PUBLIC HEALTH.

WATER, Therapeutic use of.—See BATHS; HYDROTHERAPEUTICS; MINERAL WATERS; SEA-AIR, SEA-BATHS; and TEMPERATURE.

WATER-BRASH.—A popular synonym for pyrosis. See PYROSIS.

WATER-CANKER.—A synonym for cancrum oris. See CANCRUM ORIS.

WATER-GAS, Poisoning by.—See CARBONIC OXIDE, Poisoning by.

WATER-ON-THE-BRAIN.—A popular name for hydrocephalus. See MENINGES, CEREBRAL, Inflammation of, Tubercular; and HYDROCEPHALUS, CHRONIC.

WATERS, MINERAL.—See MINERAL WATERS.

WAXY DISEASE.—One of the synonyms for amyloid disease. See AMYLOID DISEASE.

WEAL, WALE, or WHEAL.—This is an old-English word signifying the mark of a stripe, that is, the prominent pale ridge caused by the stroke of a lash upon the skin. In Medicine the term is applied especially to the prominent risings of a lengthened figure which are met with in urticaria. See URTICARIA.

WEBER'S SYMPTOM.—See CRURA CEREBRI, Lesions of, p. 357.

WEIL'S DISEASE.—This name is sometimes applied to a febrile condition characterised by jaundice, enlargement of liver and spleen, and temporary nephritis, lasting about a fortnight, and generally ending in recovery. The disease usually occurs in epidemics, and is especially prone to attack butchers. The onset is sudden; and the jaundice, which is of the toxæmic type, occurs about the second day at the height of the fever (103° F.—104° F.). There is marked headache, prostration, and muscular pain. Relapses are infrequent. The cause of the condition is unknown, and possibly varies in different epidemics (Hunter).

WHEEZING.—A peculiar sound, of a dry piping or whistling character, which may be heard in connection with the respiratory organs during the act of breathing, caused by certain forms of obstruction

to the passage of air. See ASTHMA, SPASMODIC; BRONCHI, Diseases of; and PHYSICAL EXAMINATION.

WHIP-WORM.—This term is not infrequently applied to the small human nematode that is better known to the profession as the *Trichocephalus dispar*. See ENTOZOA.

WHISPERING PECTORILOQUY.—A form of pectoriloquy in which the whispering voice is distinctly heard. See PECTORILOQUY; and PHYSICAL EXAMINATION.

WHITE GUM.—A popular name for the white form of strophulus, *S. albidus*. See STROPHULUS.

WHITE LEG.—A common name for phlegmasia dolens. See PHLEGMASIA DOLENS.

WHITE SWELLING.—A common name for tubercular disease of a joint. See JOINTS, Diseases of.

WHITLOW.—SYNON.: Paronychia; Panarium; Fr. *Panaris*; *Tourniole*; Ger. *Paronychia*.

DEFINITION.—Whitlow is a term somewhat loosely applied to any acute inflammation of the finger or thumb which tends rapidly to terminate in suppuration, and is not limited to the matrix of the nail, in which case it would be called *onychia*.

Whitlow may be divided into four chief varieties, but these often merge one into another: (1) Subepithelial Whitlow; (2) Subcutaneous Whitlow; (3) Thecal Abscess; and (4) Periosteal Whitlow.

Whitlow most commonly results from infection with the *Staphylococcus pyogenes aureus*, but less commonly in the more severe forms the *Streptococcus pyogenes* is present.

1. Subepithelial Whitlow.—SYNON.: Paronychia Ungualis.—In this variety the skin only is affected, and frequently at the side of the nail. It commences usually as the result of some slight injury, such as a bruise or puncture, or from the inoculation of septic or other irritating matter. The first signs are heat, tenderness, and itching in the inflamed part. On the third or fourth day pus forms, raising the epithelium from the cutis vera. As the pus cannot point through the dead cuticle, it remains pent up, and the tension so caused increases the pain, and if unrelieved leads to further ulceration of the true skin, the pus then finding its way into the cellular tissue beneath. The whitlow then merges into the second variety. It may also spread to the matrix of the nail, and so become complicated with onychia. If relieved early, by cutting away the cuticle which has been raised by the pus, it seldom leads to any unpleasant consequences.

TREATMENT.—The treatment consists in bathing the finger frequently in hot water, painting the part with glycerine of belladonna, and applying hot fomentations. If the presence of a minute drop of pus beneath the cuticle is detected by the appearance of a yellow point, the cuticle should be shaved off with a sharp scalpel; if the suppuration is more extensive the raised cuticle may be completely removed with scissors. A boracic-acid fomentation should then be applied. Incisions are not necessary.

A form of superficial whitlow is sometimes seen occurring without any apparent cause, and attacking one finger after another. The fluid beneath the cuticle is not always purulent—sometimes being

merely albuminous, and mixed with flakes of lymph. It never leads to any deep suppuration. It is most common in children and females, and is associated with general debility. It is described by the French under the name of *tournoie* or *panaris phlycténoïde*. It is a troublesome affection, and difficult to get rid of. Tonics should be administered, and sometimes arsenic is of use.

2. Subcutaneous Whitlow.—**SYNON.** : Paronychia Cellulosa.—The inflammation in this variety commences in the cellular tissue of the pulp of the ungual phalanx. It arises almost invariably as the result of some slight puncture or other injury, or as the consequence of neglecting the variety just described. The tip of the finger is swollen, tense, and excessively tender. There is severe burning, throbbing pain; and possibly red lines are observed spreading from the inflamed part in the course of the lymphatics. There is more or less fever, with general constitutional disturbance. Pus forms by the third or fourth day. It tends to point through the skin, but the thick cuticle usually resists its pressure for some time, and if this be not cut away early the gravest results may ensue. The pus may find its way into the sheath of the flexor tendons; or the bone may be exposed, and necrosis may follow, the disease then merging into the two following varieties. If an incision be made about the fourth or fifth day, a large slough will usually be found beneath the skin.

TREATMENT.—A free incision must be made longitudinally into the pulp of the finger as soon as the condition is recognised, and by this means all complications will be averted. If the pus have already found its way through the cutis, and be pent up beneath the epidermis, it is often sufficient merely to cut away the loosened cuticle with scissors. In other respects the treatment is the same as for the first variety.

3. Thecal Abscess.—**SYNON.** : Paronychia Tendinosa.—This is often secondary to the other varieties; it frequently begins, however, as a primary inflammation of the sheath of the flexor tendons, and may follow a penetrating wound. The whole finger swells, and becomes tense and red. The pain is most severe, usually shooting up the hand and arm. Pus forms early, and, if not evacuated by incision, exposes the bones, destroys the tendons, burrows into the joints, and rapidly destroys the finger. If affecting the thumb or little finger, the sheaths of which are continuous with the common sheath at the wrist, the suppuration rapidly extends to the palm of the hand, and to the forearm above the annular ligament. The wrist-joint may then be opened, and destruction of the whole hand result. The constitutional disturbance and fever are usually very marked. The affected finger or hand seldom recovers perfect utility; and death is not uncommon, either from exhaustion or from some secondary complication.

TREATMENT.—The early treatment should be the same as for the other varieties of whitlow. Free and early incisions are required. Stimulants, good diet, and tonics are always necessary.

4. Periosteal Whitlow.—**SYNON.** : Paronychia Osseosa.—This is a comparatively rare variety of whitlow, arising sometimes from injury, sometimes without apparent cause. It is an acute inflammation of the periosteum of the ungual phalanx. It is characterised by redness and swelling, with most intense aching and tensive pain, and

acute tenderness. If an incision be made as soon as pus is recognised, the bone will be found to be already bare and necrosed. This condition can only be averted by cutting down to the bone before suppuration has occurred, but this is rarely possible.

TREATMENT.—This is the same as in the other varieties, namely, hot applications and free incisions. The necrosed phalanx must be removed as soon as it is loose. If more than one phalanx be affected, amputation may be necessary.

One or two points common to the treatment of all varieties of whitlow require further notice. All incisions should be made as far as possible in the middle line, so as to avoid wounding the digital arteries. The sheath of the flexor tendons should on no account be opened, unless there is pus within it. In all doubtful cases an anæsthetic should be administered, the limb made bloodless by Esmarch's method, and the incision carried carefully towards the flexor tendons. In this way the exact situation of the pus can be ascertained with certainty, and an unnecessary wound of the sheath of the tendon avoided. Incisions are frequently made into the pulp of the ungual phalanx of the finger when the pus is really on the dorsum. This arises from the sense of fluctuation yielded by a swollen finger covered by somewhat thick cuticle. In all cases the cuticle should be cut away as soon as it is loose. The best application in all cases is boracic lint, three or four layers thick, wrung out in hot water, and covered by oiled silk and cotton wool. This is perfectly clean, and in every way as efficient as a poultice. Soaking the hand frequently for an hour at a time in an arm-bath usually gives great relief in the more severe forms.

MARCUS BECK.

RAYMOND JOHNSON.

WHOOPIING-COUGH.—**SYNON.** : Kin-cough; Hooping-Cough; Pertussis; Fr. *Coqueluche*; Ger. *Keuchhusten*.

DEFINITION.—An infectious disease, characterised by fever, catarrh of the respiratory passages, and a peculiar spasmodic cough, consisting of a number of quick, short, forcible expirations, followed by a long shrill inspiration, or 'whoop,' and finally ending in the expulsion of viscid mucus, or in vomiting.

ÆTIOLOGY.—The actual cause of the disease is at present unknown. That it must be some living organism is now universally admitted. Two independent observers have found a ciliated amœba, to the growth of which they attribute the disease. Other and more numerous investigators have isolated minute bacteria, and although the form and character of the organism are still in dispute, there is a very general belief that some bacterium will eventually prove to be the cause of the disease. A short bacterium first described by Czaplowski and Hensel is in most favour. This organism stains imperfectly in the centre, and has thus been described by some authors as a diplococcus. It is non-motile, does not form spores, and is easily destroyed by heat. It does not give any serum-reaction, and is pathogenic to mice.

Infection is most readily conveyed during the first week of the disease. It gradually declines as the disease progresses, but persists for nearly a month after the commencement of the whoop. It is usual to consider a patient free from infection five weeks after the first whoop occurred: after this there may

be a return of cough or spasm without fresh danger of infection. There is reason to suppose that the disease is conveyed by the expelled mucus, either directly from patient to patient, or indirectly by means of clothes or utensils; if care be taken, the spread of infection can often be prevented. The contagion clings to the clothing of convalescents for a long time.

Age.—The greatest number of cases occur in children under eight years of age. It is one of the three diseases which cause the greatest mortality among infants, and, like acute bronchitis and summer diarrhoea, is most fatal to the youngest. Whooping-cough prevails so extensively in early childhood, that it is rare to find an adult who has not suffered from it. Those who escape infection in childhood generally escape it altogether. When the disease affects adults it runs its full course with the same symptoms, and the same instinctive dread of recurrent spasm, as in infancy, but without any practical risk of complications.

Sex.—The severity of the attacks is greater in girls than in boys; and in the former the mortality is also slightly higher.

Race and climate make little or no difference in the liability to whooping-cough.

Season has an influence on its epidemic extension; this in Great Britain is always in the spring (see p. 1190). Cold weather indirectly adds to the intensity of the disease and retards the convalescence.

Other influences.—Overcrowding, bad ventilation, and the confinement of the sick in close apartments increase the severity of the disease, as well as the risk of infection. A recent attack of measles also increases the liability to infection; and the two diseases are occasionally concurrent, in which case the characteristic cough of the one generally escapes recognition until the rash of the other has disappeared. Excitement and indigestible food seem to induce and exaggerate the attacks of coughing.

The *period of incubation* is well marked in all cases, and extends from two days, as the shortest limit, to twelve days as the longest; the average duration of this period is eight days. As the disease cannot be diagnosed during the first week, it is necessary to disinfect 'contacts' (see p. 726), and isolate them for three weeks before their freedom from the disease can be certified.

MORBID ANATOMY.—In fatal cases catarrh of the upper respiratory passages is found. In some cases this is most marked in the posterior nares and naso-pharynx; in others, in the larynx, trachea or bronchi. The bronchial glands are generally enlarged. Recorded observations made on patients during life confirm the view that these changes occur during the early stage of the disease, even in mild attacks, but there is no uniformity concerning the exact locality of the commencement, which probably varies in different cases. Fatal cases generally present evidence of pulmonary collapse, pneumonia, acute emphysema or other complications.

PATHOLOGY.—The infective nature of the disease is indisputable. The observed facts concerning the spread of the disease, the early catarrhal stage, the accompanying enlargement of the bronchial glands, the subsequent spasmodic attacks, and the curious nervous condition so often observed, together suggest infection by way of the respiratory passages and the gradual introduction into the blood of a toxin or toxins which act principally on the nerve-centres; but until the cause of the disease has been definitely

determined, and its characters studied, the pathology must remain speculative.

SYMPTOMS.—The invasion of whooping-cough is often insidious and, in the absence of a prevailing epidemic, suspicion of illness may not be aroused until the child is noticed to be suffering from a troublesome cough, especially at night. Not infrequently, however, the onset is quite definite. The patient, if very young, is feverish (100° F. to 102° F.) and restless at night, and suffers from cough and sneezing; if older, is apathetic, complaining of headache and anorexia. Next morning the symptoms may be less marked, but by evening they are worse than on the previous day.

During the following ten days (*catarrhal stage*) the symptoms are very varied. In some cases the temperature remains raised, a hard, dry cough, always worse at night, persists, and a few rhonchi can be heard in the chest. In others, the temperature intermits or never rises above 100° F., and except for the harassing cough, which interferes with sleep, no illness may be suspected. In others, again, severe bronchitis sets in from the outset. As a rule, however, the general malaise and fever are not explicable by any discoverable physical signs. Marked lymphocytosis, as well as some ordinary leucocytosis, may first be found in this stage.

Towards the end of the second week the catarrhal stage passes into the *spasmodic*. The cough gradually becomes longer, louder and more exhausting, especially at night, and the quiet intervals between what may now be called the 'attacks' are more definite and of longer duration. In other words, the frequent cough of bronchial catarrh becomes grouped into less frequent spasmodic attacks, which often first suggest the correct diagnosis (see Diagnosis, p. 1875). Two or three days after this tendency is observed the cough assumes its distinctive character. Just before the attack begins, in a case of average severity, the child's face reddens, as if trying to suppress it, till the cough bursts out in a series of short, quick, forcible expiratory efforts; then the breath is drawn in with a shrill whistling sound or whoop, again followed by a similar series of rapidly recurring explosive expiratory efforts, succeeded by another whoop: after a short pause comes a less severe and shorter fit and then another, till a quantity of whitish viscid mucus is expelled through the nose or mouth, and some swallowed; or the child vomits at the same time, ejecting the contents of the stomach. In a case of average severity the patient will whoop three or four times in each attack, and the attacks will recur every two or three hours during the day and more frequently during the night.

Older children often describe a tickling in the throat before the cough, show dread of its approach, and prepare for it by steadying themselves, or by clinging to others for support; they appear to recover completely and show no sign of illness during the intervals. Not so with younger children; before the attack the pulse quickens, the breathing is short and insufficient, *râles* are heard, spasm closes the glottis, the air is forced out in sudden jerks, and then enters with the loud long-drawn whoop; this is repeated till the face becomes livid and swollen, and the child exhausted or semi-conscious. Frequent attacks of this kind keep the face puffy; they force the tongue over the lower teeth, and thus especially in infants who have only cut the

two lower central incisors, small ulcers may be produced on the frænum linguae; the eyes remain red and watery, and hæmorrhages occur beneath the conjunctivæ. In a severe paroxysm blood may start from the nose and mouth, or be seen in the matters vomited; while both urine and fæces may be passed involuntarily. In some cases diarrhœa and vomiting are serious symptoms. While the cough forces air from the lung, the percussion-note is dulled but becomes resonant again after the sibilant inspiration is heard. The heart's action is impeded, owing to the raised pressure within its cavities resulting from the cough, or from irritation of the vagus; neither endocardial nor pericardial lesion is met with in whooping-cough, and nothing is found wrong with the heart after the fit is over.

Examination of the chest in uncomplicated cases generally fails to reveal any physical signs during the intervals. In some cases, however, temporary hyper-resonance, due to the over-distension of the air-cells and bronchioles, may be made out and a few bronchitic rhonchi heard.

In the absence of complications the *third stage* of subsiding spasm and loose expectoration, with returning health and strength, may be reached in from four to six weeks. The mildest cases may seem to be over in a month, but any little want of care will intensify the symptoms, and relapses are common until six weeks are accomplished, even in cases where the second stage has not been prolonged beyond four weeks. The disease often lasts two months, and may be followed by a tedious convalescence. At this stage patients seem particularly liable to tuberculosis.

COMPLICATIONS.—In addition to the phenomena already described as occasional accompaniments of whooping-cough, patients suffering from this disease are more than usually liable to mechanical results of coughing, such as hernia, as well as to acute inflammation of many of the principal viscera, such as acute nephritis and acute lobar pneumonia. There are, moreover, several conditions which are especially associated with whooping-cough, and which gravely affect its prognosis.

(1) *Hæmorrhage.*—Hæmorrhage under the conjunctiva or from the nose or gums is exceedingly common, though of comparatively slight importance. Of rare occurrence and of more serious import is hæmorrhage from the middle ear, due to rupture of the tympanum, hæmorrhage from the lungs, and hæmorrhage within the cranium (*see p. 987*). Intracranial hæmorrhage is usually meningeal, and may give rise to coma, to aphasia, or to paralysis of one of the cranial nerves.

(2) *Convulsions.*—General convulsions may occur, especially in very young children (*see p. 343*) (*a*) when the attacks are very frequent and severe; and (*b*) when extensive pulmonary collapse occurs. They are believed to depend in both cases upon vascular engorgement of the cortex and deficient aëration of the blood.

(3) *Pulmonary.*—Whooping-cough and measles are distinguished from all other acute infectious diseases by the extreme frequency of pulmonary complications. Among these, severe bronchitis, affecting the larger tubes, capillary bronchitis, collapse of large portions of a lung, and broncho-pneumonia are common. Acute lobar pneumonia and pleurisy are far less frequently met with. The signs and symptoms of these complications differ but little from those met with in the same diseases

occurring under other circumstances, but the onset is often insidious; hence there arises a necessity for regular observations of the temperature and rate of breathing, as well as for periodical examinations of the chest. Pulmonary complications may occur during any stage of the disease, and are most likely to arise on the one hand in neglected cases, and on the other in those who are compelled to breathe stale air. The occurrence of broncho-pneumonia often modifies, in a curious way, the course of the disease. The attacks become less defined and the characteristic whoop may disappear.

SEQUELÆ.—Bronchitis may persist long after whooping-cough has disappeared, and permanent dilatation of the bronchial tubes is not unknown. Asthma, interstitial pneumonia, and a peculiar form of irritability and restlessness, are also recognised sequelæ of this disease. As has already been said, children suffering from whooping-cough are especially liable to develop tuberculosis, and in cases exhausted by vomiting and inefficient nourishment, wasting, pustular skin-eruptions and obstinate intestinal catarrh are peculiarly prone to occur.

TERMINATIONS.—The large majority of cases of whooping-cough recover. Yet so frequent is the disease, that it is one of the principal causes of infantile mortality (*see p. 1028*). Of the fatal cases, most die of some pulmonary complication. A few succumb from acute cardiac failure, from spasm of the glottis, or from some other complication or sequela.

DIAGNOSIS.—The diagnosis of whooping-cough presents difficulties both in the catarrhal and in the spasmodic stage. In the former, a correct diagnosis is, in the absence of a prevailing epidemic, an exceptional achievement. A nocturnal cough with a temperature of 101° F. and no physical signs generally indicates the onset of whooping-cough, measles, or influenza. The muscular pain and brief duration of the attack will generally suffice to distinguish influenza. The conjunctival and nasal catarrh, followed on the fifth day by the rash, will ensure the recognition of measles. When both these diseases can be excluded, special attention must be paid to the grouping of the attacks of cough. Bronchitis can generally be distinguished by the more marked physical signs. It is always well to ascertain to what diseases a sick child has been exposed, and what infectious diseases it has already had. In the spasmodic stage laryngismus stridulus (*p. 850*) is occasionally mistaken for whooping-cough, but the spasm of the glottis and the croupy inspiration persist throughout the attack. Enlarged tonsils and post-nasal adenoids, or even a long uvula, especially when occurring together, not infrequently give rise to a cough closely resembling that of whooping-cough, but the sequence of events characteristic of the latter is absent, and the physical examination will probably suffice to remove the doubt. Enlargement of the bronchial glands from other causes may give rise to attacks superficially resembling those of whooping-cough; but the disease does not run the same course, and the attacks, as in the cases of enlarged tonsils, are generally less defined. *See p. 230.*

PROGNOSIS.—The prognosis in whooping-cough depends on the age of the patient, the previous health, the condition of nutrition at the time of onset, the time of year (*Fig. 3, p. 1191*), the general severity of the attack, and the presence of complications.

Young children are least likely to make the

favourable recovery generally expected in uncomplicated whooping-cough; but with good sanitary surroundings and individual care the youngest may escape, unless debilitated by previous illness, such as rickets or measles. The risks diminish with each year of childhood; they are less in the summer than in the winter, and in boys than in girls. High fever during invasion is a frequent prelude to severe complications in the subsequent stages. Convulsions in any stage are of the worst significance; somnolence or a listless condition between the attacks, with persistent high temperature, are also bad signs. The danger in the second stage is in proportion to the severity of the disease. This may be estimated by noting the number of attacks in the twenty-four hours, their intensity and their duration; in bad attacks the expulsive efforts are more rapid, more boisterous, and more numerous, and the whoops are very shrill. In mild cases there is less spasm and the whoop occurs but once or twice, or is sometimes not recognisable at all. The duration of an attack may be from a few seconds to some minutes. Young infants may die from laryngeal spasm, but the danger of death during an attack, however bad, is very small. The number of attacks may be raised from twelve to twenty in the twenty-four hours, without danger, if the intervals are complete enough for the child to recover and take food during the day and to get sleep by night. As many as 60 to 80, or even 140, attacks have been counted. When they are so incessant as to interfere with both food and sleep the exhaustion is extreme, so that it is generally true that when the number of attacks exceeds 60 in the twenty-four hours a fatal result may be anticipated.

Capillary bronchitis and broncho-pneumonia are the complications responsible for most deaths, especially when the thorax is rickety. Œdema of the glottis or of the lung, and acute cardiac failure, are less frequent but more deadly in their effects. Chronic pneumonia may lead to bronchiectasis or culminate in tuberculosis, which generally runs a rapid course. Emphysema and pulmonary collapse tend to disappear.

TREATMENT.—General. There is no specific remedy for whooping-cough—no drug that can check its onset or stop its progress. Rest and warmth, with individual care, the utmost attention to a sufficiency of pure air, and all possible aids to the resisting powers of the patient, are requisite throughout the illness.

Two rooms, intercommunicating if possible, should be set aside—one for use by day, the other by night. The temperature of the room should be maintained at 63° to 65° F.; but thorough ventilation must be secured to ensure a plentiful supply of perfectly fresh air, free from dust and without cold draughts. No gas or gas-stove must be burnt in the room. The patient should be kept in bed until the temperature is normal, and confined to the house until the spasmodic stage is over. The cold bath in the morning should be omitted until convalescence is established. The diet should be light and nutritious, consisting largely of milk; and all food difficult of digestion should be avoided. Broth should be made with vegetables and without condiments; stewed fruit, orange-juice, and lemonade are useful. It is generally advisable to give food in small quantities at short intervals; and when vomiting is frequent this procedure is absolutely essential. Each child requires a good deal of

ready personal assistance. Some one should always be near to allay fright when the cough begins, and to steady the patient and support the head until the fit is over.

Medicinal. (1) *Inhalation.*—The value of antiseptic inhalations in whooping-cough is in dispute. To young children they are frequently a source of terror and so far inadmissible. Moreover, as has often been pointed out, medicated air generally implies in practice rebreathed air, which again is unquestionably harmful. If these difficulties could be overcome there is some reason to suppose that air impregnated with carbolic acid or other allied substances would be useful, as it has a sedative effect during the spasmodic stage. Great risks, without corresponding benefit, have been run by taking children to gas-works during the course of the complaint. Nasal insufflation of salicylic acid, iodoform, quinine, and many other drugs have been recommended, especially by those who consider that the nasal mucous membrane is the primary seat of the disorder. Others have recommended that the pharynx be painted with a solution of resorcin (1 per cent.) or of similar antiseptic, to which a small quantity of cocaine has been added. Baroux strongly recommends the use of peroxide of hydrogen as an aerial antiseptic. He recommends that two large pieces of old linen be sprinkled with two to three ounces of peroxide and hung on a cord stretched across the room; they should be renewed every four hours.

(2) *Internal remedies.*—In very many cases of whooping-cough no medicinal treatment is needed. During the *catarrhal stage* simple salines may be beneficial. To relieve the cough an occasional sip of water or some simple linctus containing a few drops of ipecacuanha or of oxymel of squill is often sufficient. In many cases bromide of potassium or ammonium must be added to an expectorant mixture in order to produce any relief. Neither opium, chloral hydrate nor belladonna is to be used until the first stage is over and secretion free. A poultice of linseed, or of mustard and linseed, is a valuable adjuvant (*see* POULTICE), especially when a few fine râles are heard at the bases. Many authorities advocate the addition of some compound tincture of camphor when the secretion is free. If the child be obviously ill with more than the usual amount of fever, quinine should be given—1 gr. *per diem* suspended in Almond-mixture for each year of age, and continued for two or three days, answers best, but sometimes larger and fewer doses seem more efficacious. If any difficulty is experienced in the administration of the quinine it should be given as an enema.

Relief of spasm is the main object of treatment in the second or *spasmodic stage* of whooping-cough, the efficacy of the means employed being measured by the diminution in the severity and number of the daily attacks. By this test belladonna proves to be the most useful remedy, but it must be given in large and continued doses. With a child of three years old one-sixth to one-fourth of a grain of the extract, or 10 to 15 minims of the tincture, may be given three to six times a day before the physiological effects indicate a diminution of the dose. Atropine ($\frac{1}{100}$ to $\frac{1}{80}$ gr.) is preferred by many; but since the official standardisation of the preparations of belladonna the selection of any particular preparation is a matter of less importance. A combination of bromides, especially that of

ammonium, with belladonna, has a well-deserved reputation. Bromoform, in an emulsion, is a favourite remedy at the present time; it may be given in doses of $\frac{1}{2}$ m to 3 m cautiously, according to the age of the child, three or more times a day. Minute doses of opium are sometimes useful in allaying vomiting, but must only be given when the secretion is free; only a few doses are permissible. Ergot, phenazone, and butyl-chloral hydrate are more or less accredited remedies, especially when the others have failed, but it must be remembered that most of the vaunted remedies for the cure of whooping-cough owe their repute to having been administered in the fifth or sixth week of the illness, when the disease is nearly over. All the more potent counter-irritants, such as croton oil and blisters, are to be avoided. In rare cases artificial respiration has been successful in resuscitating a child apparently dead of asphyxia.

In the third or *declining stage* of whooping-cough tonics and astringents are of distinct benefit. Great discretion is required in deciding when children should be allowed to go out of doors or seek change of air. Too much emphasis cannot be laid upon the rule that no child should be sent in public conveyances or to lodgings so long as there is the least risk of infection. Moreover, the end of the infectious period also corresponds with the time when the patient is most likely to receive benefit without any corresponding risk. Unquestionably change of air has a remarkable effect in restoring appetite and in removing the remaining tendency to spasm (*see* p. 1471). The treatment of the various complications is described in the articles dealing with these conditions.

WINTER-COUGH.—This expression is associated with those cases in which a patient is subject to more or less cough during the winter season, being free, or almost free, during the warmer portion of the year. It may come on at any period in the course of the winter, and is generally referable to some obvious cause, which produces 'a cold.' The attacks tend as a rule to become more aggravated and difficult to cure, as well as more easily excited, as time progresses.

Cases of winter-cough belong chiefly to the following classes: 1. Not uncommonly it is merely due to a slight catarrh, affecting the throat and

main air-passages. 2. Most frequently the cough depends on bronchial catarrh or bronchitis in various degrees, usually associated with more or less emphysema. 3. Winter-cough may characterise some chronic phthisical cases, this symptom subsiding during the warmer season. 4. There are certain forms of cardiac disease of which winter-cough may be a prominent phenomenon.

TREATMENT.—The treatment of winter-cough must depend on the nature of the cause which gives rise to it, and will be found discussed in the special articles descriptive of the several conditions. *See* COUGH.

WOUNDS, Healing of.—A living animal tissue when wounded has an inherent tendency to repair, but what this tendency depends upon is as yet unexplained. The bond of union need not be of the same nature as the tissue wounded. It is composed usually of white fibrous tissue, and when formed is known as a 'cicatrix.' So far as the naked-eye appearances are concerned, wounds are generally described as healing by one or other of the following five methods: (1) by 'first intention;' (2) by 'immediate union;' (3) by 'second intention' or 'granulation;' (4) by 'secondary adhesion' or union of two granulating surfaces; and (5) under a scab, or what is virtually healing under aseptic conditions. The last of these does not require special description, as the scab is simply Nature's dressing; the process of healing under such circumstances does not differ from what occurs, say, in healing by the 'first intention.' Although, on mere naked-eye examination, the above methods of repair are evident enough, yet, when the pathology of the process is inquired into it will be found that there is in reality only one method by which wounds heal, namely, by growth of the new reparative tissue from tissue of a like kind present in the wounded part. The superficial differences observed in the closing of wounds are to be regarded as accidental rather than essential, as epiphenomena, or complications, and frequently as impediments to the even onward progress of growth which constitutes the ruling feature.

1. *Healing by the 'first intention.'*—If the flaps of a wound, say, after amputation, be examined in from twelve to eighteen hours from the time of infliction of the injury, they will be found to present a glossy, moist appearance, due to the escape of lymph from the divided lymphatics—the lymph-spaces, lymph-radicles, and larger lymph-vessels, which permeate all parts of the body. If it be again examined after a lapse of about forty-eight hours, the severed tissues will be found to have lost this appearance; the quantity of liquid exuding from the wound is less than before; and the

exposed muscles and other elements of the flaps are now coated with a delicate greyish-coloured film, which can be removed by scraping the surface. Examined microscopically, this filmy deposit is found to consist of lymph-corpuscles—the corpuscles which have exuded with the lymph, and which are now entangled in the free extremities of the divided tissues. They are embedded in fibrin, which has taken the form either of a granular precipitate or a network. Supposing the two sides of the wound to have been placed in accurate contact, the two lymph-coated surfaces, together with any blood-clot which may have been upon them, adhere and establish a temporary bond of union. In from four to five days after the infliction of the wound, a layer of connective-tissue elements or fibroblasts makes its appearance beneath the lymph on each side, and this, as it grows inwards, supplants and causes absorption of the lymph and blood-clot lying in the gap, which supply, as above said, the temporary bond of union; the two layers meet in the middle line and their cells intertwine. The cells composing these two layers are at first round, many of them twice the size of a leucocyte, and are provided with either a single large nucleus or, it may be, two of these. As organisation proceeds they become spindle-shaped, and in from three to four weeks are converted into bundles of white fibrous tissue. This constitutes the permanent cicatrix. Yellow elastic tissue enters little, if at all, into the construction of the medium of repair. The source of the fibroblasts which enter into the organising layers is the white fibrous tissue near the surface of the flaps, more especially if this be of the areolar variety. The tissues at a short distance from the surface are practically unaffected, and the cicatrix, when healing is completed, is usually so delicate that its line can be followed throughout the part with difficulty, even with aided vision. As the process of repair is proceeding, loops of capillary blood-vessels make their way into the embryonic cicatrix; they are never abundant or more than what is necessary for the maintenance of the part. Hence the blanched appearance presented by a wound when healing typically by the first intention. The gap having been filled with young connective-tissue, the divided epidermis throws out a few new cells; these meet in the middle of the wound, and, coalescing, re-establish the protective covering. The resulting cicatrix is always more or less depressed.

Should the wound, however, become septic, that is to say, inoculated with the organisms of suppuration, chiefly the *Staphylococcus pyogenes aureus* and the *Streptococcus pyogenes*, the reparative ingrowth of the organising tissue is prevented; the blood-vessels are stimulated and become engorged, and excess of blood-products is poured out from them. These accumulate in the wound and fall into a state of fatty degeneration, and an abscess results. The pus which constitutes the abscess must be discharged before healing will take place. Generally the wound will gape and commence to granulate, healing being effected thereafter by the 'second intention.' Or, if actual granulation be not forthcoming, the wound may heal gradually from its depths, the quantity of cicatrix formed in either case being vastly greater than if it had closed by the first intention.

2. *Healing by immediate union.*—This is nothing more than healing by the 'first intention' under the

very best auspices. An incision is made into a part, pressure is applied immediately, all blood is squeezed out of the wound, and the amount of lymph which escapes is limited by the pressure of the opposed surfaces. Unduly great distension of blood-vessels is prevented by the same agency, and the wound remains aseptic. Under these circumstances the severed tissues unite with the least possible expenditure of material.

3. *Healing by the 'second intention.'*—In the centre of a wound healing by this method is the granulating surface. The granulations are small—mere points of a rosy red colour—and the discharge from them is slight. Each granulation consists of a tuft of capillary blood-vessels, around which there is an indefinite quantity of loose areolar fibrous tissue. So delicate and open-woven is the latter that it may present almost a myxomatous appearance. The meshes of this stroma are filled with more or less plasmatic liquid exuded from the capillary loops, and with the granulation-cells. These granulation-cells are of two kinds, namely, leucocytes and fibroblasts, the former being the more abundant. Some of the fibroblasts may approach giant-cells in size; or actual giant-cells, if the wound be tubercular, may be contained in the meshes of the stroma. The discharge from the granulating surface consists of the above liquid pressed out from the vessels, and the granulation-cells—in chief part those which are leucocytes. Accumulating as this liquid and the leucocytes do in the meshes of the stroma, they are driven out in the direction of least resistance, namely, towards the surface, and are thrown off from it. The more or less purulent character of the discharge depends upon the number of cells contained within it, and these diminish in number as the wound assumes healing characters. The amount of discharge depends upon the degree of distension of the capillary loops. The actual granulating surface is shallow, usually not more than from a sixteenth to an eighth of an inch, but beneath it a layer of tissue of primary importance in the healing of the wound is met with. It is composed of the same elements as those which form the organising layers on the sides of the wound in healing by the 'first intention,' namely, fibroblasts of round and spindle shape. Through this layer of young connective tissue the stems of the capillary loops pass to reach the granulating surface proper. When healing of the wound takes place, the granulations atrophy, any fibroblasts contained in them become fibrous, and, along with those in this deep cicatrising layer, constitute the young fibrous-tissue basis over which the epithelium spreads to complete the repair.

Round the margin is the so-called 'blue-pink pellicle'—the layer of young epidermis. Its edge is very loosely attached to the underlying cicatricial layer, so that the blade of a knife can be inserted beneath it; but later on the new epithelium becomes inseparable from the parts beneath. It is composed of young epidermic cells like those of the rete Malpighii. As the granulations atrophy at the margin of the wound, this pellicle of young epidermis spreads at first round them and finally over them. As it does so, the granulation-vessels disappear in great part; further exudation of the granulation-leucocytes is prevented; and the fibroblasts formerly entangled within the granulations, together with those lying underneath, become transformed into fibres. The part which has

healed is blanched and hard. The epithelium covering it has assumed the characters of epidermis with a rete Malpighii and horny layer, and underneath this is the coarse fibrous tissue of the cicatrix.

4. *Healing by secondary adhesion.*—If two granulating and healing surfaces are brought into accurate contact, and if equable pressure be applied, they tend to unite, especially if they are free from pyogenic organisms. The mechanism of the process is that the mutual pressure of the closely applied surfaces causes atrophy of the granulation-loops, and allows the deep cicatricial layers to meet and coalesce.

Comparison of the above methods of healing.—There is no essential difference, for although in healing by the 'second intention' the wounded surface becomes covered by granulation-loops, still these are to be regarded as an accident of the situation—as due partly to relaxation of the natural restraint exerted upon the capillaries by the skin and other elastic tissues, partly to the stimulus exerted upon the free surface by the presence of the organisms of suppuration. If an exposed wound be kept free from sepsis, and if pressure be carefully applied to its surface, it heals without granulation, and more quickly than when granulation has ensued. The granulations on a wound healing by the 'second intention' must be removed before the wound will heal. By their atrophy the true healing layer, composed of fibroblasts, and lying beneath them, comes to the surface, and the epidermis runs over it. In healing by the 'first intention' the only real difference is that this layer is double instead of single, and the same holds good of healing by secondary adhesion. The exuberant vascularity of a granulating surface is the chief means of retarding its healing; the granulations must be got rid of either by natural atrophy or by the application of pressure, &c., before the wound will close. The basis of the whole procedure, as before said, is the growth of new connective tissue from that already in the wounded part, of new epidermis from that already at each side, and of new blood-vessels from those present on the cut or otherwise wounded surfaces.

Wounds of particular tissues.—The less vascular the part wounded, the more readily it heals by first intention. An incised wound of the cornea heals quicker than any other; that of the linea alba probably comes next. Wounds of muscle unite chiefly by fibrous tissue, although newly-developed muscular fibres may be found in the cicatrix. A cicatrix usually tends to contract, but that which follows upon the sloughing of a Peyer's patch in typhoid fever is an exception to this rule. The cicatrix of the intestine resulting from dysentery or tuberculosis has, however, a notorious tendency to contract.

New-formation of blood-vessels.—The blood-vessels newly developed in a healing part are apparently derived from buds given off from those already present. From the endothelium of a capillary a nucleated protoplasmic bud or vasoblast is shot outwards. Similar buds are pushed out from the walls of neighbouring capillaries, and these anastomose by their tapering extremities. They are solid at first, but become hollowed out, and into the channels thus formed blood-corpuscles find their way.

Healing of blood-vessels.—When the end of a divided artery is ligatured with silk, and when the wound becomes septic, the channel of the artery fills

with a firm clot or thrombus, usually as high as the first large branch above the point of ligature. Blood-capillaries grow into the clot from the vasa vasorum and ramify in all directions. They convey with them the elements of organisation, namely, fibroblasts derived from the adjacent wall of the vessel. At the same time the tunica intima thickens and encroaches on the channel of the vessel. As the living tissue from these two sources makes its way into the blood-clot, it causes absorption of the latter, just as would happen in a subcutaneous effusion of blood. As the clot is absorbed, its interstices are occupied by young cicatrix derived from these two sources, which by contracting closes the aperture at the end of the vessel and for some distance above. The clot acts simply as the mould or framework in which the future cicatrix is cast. When the artery is ligatured with catgut or aseptic silk, and when the wound remains aseptic until healing is completed, there may not be found any clot in the stump of the ligatured vessel, or this may be simply filiform in character. The artery, nevertheless, closes quicker under such circumstances than under the former, and the closure is effected exclusively by a cicatricial thickening of the tunica intima. Within three weeks of the application of the ligature the catgut may have vanished entirely, its place being taken by a ring of fibrous tissue, and, at the same time, the channel of the vessel may be in great part obliterated. The thrombus, if such be deposited after the ligature is applied, hinders the closure of the channel, and must be absorbed before this can be effected.

Adhesions of serous surfaces.—Although adjacent surfaces of most of the serous membranes are in contact during life, yet they do not tend to adhere. Should the membrane become inflamed, however, there is a constant tendency, in the absence of suppuration, to coalescence taking place. From the blood-vessels of the inflamed membrane there exudes a quantity of liquid more or less plasmatic in character. It contains fibrinogen together with leucocytes and other corpuscular elements of the blood. These set free the fibrin-ferment, which, reacting upon the fibrinogen, precipitates it as fibrin. The fibrin assumes the character of a network in which are entangled the corpuscular elements. It lies upon the adjacent serous surfaces, while between them is the liquid now deprived of its fibrin-forming constituents. Comparatively little of this liquid may be present, so that the inflammation assumes a dry character, and the two fibrin-coated surfaces may thus from the first be in contact. Any excess of liquid is in course of time absorbed, or may be drawn off artificially, after which the fibrinous layers from either side lie in apposition and adhere. Such adhesion is only temporary and is easily separable; the permanent connection is effected by the following means: From the fibrous basis of the serous membrane there is thrown off a dense mass of fibroblasts which accumulate in a layer beneath the fibrin, while the individual cells composing it push themselves in rows into the interstices of the fibrin. Wherever they spread the fibrin falls to pieces and is absorbed while the leucocytes become fatty and disappear, their place being taken by the fibroblasts derived as above described. Twigs of capillaries accompany the organising elements, also derived from the serous membrane. As the fibrin becomes absorbed, the two organising layers meet an

coalesce, their cells become converted into white fibrous tissue, and a permanent bond of union is established. The process of union is almost identical with that which occurs in healing by the 'first intention.'

Skin grafts.—See SKIN-GRAFTING, p. 1491.

Grafts of other tissues.—If living bone be chopped up into fragments, and these be placed in a sac of living tissue—by preference the periosteum—the fragments of bone continue to live and grow. The entire shaft of a bone like the humerus may thus be remoulded (Macewen). Pieces of the pancreas, thyroid gland, or conjunctiva may also be transplanted into a part to which they are foreign, and continue to live and grow. In all these grafting-experiments, the tissue to be grafted should be taken from the same species of animal as that to which the graft is to be applied.

Organisation of blood-clot.—Blood-clot has of itself no more power of organisation than any other form of precipitated albumen. Its leucocytes do not appear to have any power of developing into fibrous tissue, and its network of fibrin is quite inert. Being a porous body, however, it acts readily as the mould in which organisation may proceed. Hence, if blood be effused into the gap of a granulating wound and coagulate, its substance will soon become vascular, and its surface will bleed if pricked. The blood-vessels carry in their sheath the fibroblasts derived from neighbouring tissues, and these constitute the elements of organisation. The blood-clot is gradually absorbed by the living tissue penetrating into it, just as happens in the formation of an adhesion between two serous surfaces.

Organisation of inert porous bodies.—Any porous body, if the pores freely intercommunicate, will become filled with organising tissue under similar circumstances. Pieces of sponge, elder-pith, or calcined bone are all suited for the purpose. Sponge from its free porosity is particularly adapted for the experiment. It may be applied to a granulating surface in a thin slice or be embedded bodily in a deep tissue. In the former case the edge of the sponge must be a considerable distance within the margin of the epithelial pellicle, and, in the latter, the block of sponge must not cause pressure on adjacent parts, but simply replace a portion of tissue excised. The interstices of such porous bodies become vascularised, fibroblasts penetrate into them, they become firmly united to the part, and in course of time are absorbed.

D. J. HAMILTON.

WRIST-DROP.—A result of paralysis, affecting the extensor and supinator muscles of the wrist, and commonly met with in chronic alcoholism and chronic lead-poisoning. See ALCOHOLISM; LEAD, Poisoning by; and NEURITIS, Multiple.

WRITER'S CRAMP.—SYNON.: Scrivener's Palsy; Fr. *Crampes des Ecrivains*; Ger. *Schreibekrampf*.

This disease may be taken as the most common form and most typical representative of a class of diseases which Duchenne called 'functional impotences.' In them we find the patient complaining of inability to execute some complicated act, the power to perform which had taken him perhaps years (in the case of writing) to acquire. As a rule there is no other trouble, and, as far as the patient's observation goes, all muscular acts, however deli-

cate or however complicated, are accomplished without difficulty, with the exception of one, which unfortunately is usually that with which the patient earns his living. Not only have cases of 'writer's cramp' been described, but English and foreign physicians have furnished accounts of 'piano-player's cramp,' in which an inability to strike chords with correctness is present; of violinists who have lost the power of holding the violin and fingering with the left hand; of violoncello-players who have become powerless to 'make the nut' with the phalangeal joint of the left thumb; of tailors who can no longer use the needle; of dairymen who fail in milking; of bricklayers who cannot wield the trowel; of smiths who cannot use the hammer; of composers who cannot place the type; and lately we have had accounts of telegraphists who have become unable any longer to work at their calling. 'Writer's cramp,' however, is by far the most common of these diseases, and while the others mentioned must be regarded as the rarest of medical curiosities, the one which has been chosen to illustrate the class is tolerably often met with.

SYMPTOMS AND COURSE.—The symptoms and course in a typical case of 'writer's cramp' are as follows: A clerk, who from his painstaking and energetic habits has been tempted by his employers to work overtime or possibly against time, and who perhaps (as the history of these cases often shows) is harassed by domestic troubles, discovers that he does not write quite as easily as he did, that his hand possibly aches after prolonged writing, and that he finds it convenient to adopt some new method of holding his pen. At first the trouble is hardly noticeable, and then he finds himself obliged to grasp his pen with unusual tightness to prevent its becoming unsteady. Then his handwriting begins to suffer; perhaps his forefinger refuses to remain steadily upon the penholder, and while he is making every effort to control it, the pen somehow or other eludes his grasp and falls from his hand. If he persevere—probably he is one of those who would sooner die than give in—his progress downhill is rapid and certain. Every possible method of holding the pen is adopted by turns, such as interlacing it between the fingers, grasping it firmly with the whole hand, using only the first and second fingers without the thumb, or the thumb and second finger without the first; but these expedients quickly fail to be of service. He cannot steady the pen by means of them, and he finds that the arm rolls possibly inwards or outwards, and that he can only form his letters by moving the whole arm from the shoulder, or lastly by fixing the arm to the side and swaying the whole body to and fro. The handwriting soon becomes illegible; and lastly the patient is almost unable, even by the most strenuous efforts, to make a mark upon paper. To write a word legibly in extreme cases is impossible, and there are few spectacles more distressing than to see a patient, whose handwriting was perhaps his means of livelihood, drip with perspiration while making an ineffectual effort to sign his name. His loss of writing power may be his only symptom, as was the case with an American sufferer who wrote thus to the writer: 'That fingers which could guide razor and needle, wield oar and musket, and, though numb with cold, knelt and cast off reef-points on a wet sail, should yet strike work when called on for the familiar character of their owner's name, seemed

utterly beyond comprehension.' Patients should be closely questioned as to their ability to perform acts other than writing. In the writer's experience it is usual to find that some other act or acts is affected. If the patient be asked if he can wind up his watch, carry a full teaspoon steadily to his mouth, or perform some similar act requiring a *delicate* use of the thumb and forefinger, it will very commonly be found that he has lost his deftness in performing such acts, although in using a knife or wielding a hammer, and other work requiring a coarse use of muscles other than those used in writing, he may find no difficulty whatever. Frequently there are neuralgic pains, or a sense of extreme fatigue in the hand or arm; and in some cases the effort to write has been followed by pain in the back or severe headache. In some cases the mental distress caused by the loss of power has produced a condition bordering on melancholia. Slight tremor of the hand is not uncommon, and these tremors sometimes occur independently of writing. Tenderness of the nerve-trunks (median, ulnar, or musculo-spiral) is very often present, and should always be carefully looked for, as indicative of congestion of the nerves, or neuritis. Occasionally there is objective spasm of some of the muscles of the arm when the effort to write is made; and one case has been reported by the writer, in which the symptoms, at first those of simple loss of writing power, terminated in a general clonic spasm of all the muscles of the arm, occurring at last independently of any writing effort.

Although the above is a fair statement of what occurs in a typical case of 'writer's cramp,' other cases are by no means uncommon in which impairment of writing power supervenes quite independently of any unusual writing effort, and even in persons who have done rather less than an average amount of writing. These latter cases are not usually so severe as the former, since they are not obliged, as is the professional scrivener, to goad the unwilling hand to make those efforts which are so detrimental. It has been the writer's experience, too, that in this latter class of cases it is more usual than in the former to find that the trouble is not very strictly limited to the act of writing, but that there is a certain amount of inability or clumsiness in the performance of other acts requiring minuteness and nicety.

A difficulty in writing is, in fact, a symptom of many conditions, and it is doubtful whether 'writer's cramp' can be regarded as a morbid entity. When patients come complaining of loss of writing power, it is always essential to examine them with great care, with a view to discover any changes in the nervous system, whether central or peripheral. The writer has found that difficulty in writing may be part of a scarcely noticeable hemiplegia (congenital or otherwise) depending on the usual brain-lesions, or an early symptom of general paralysis, or paralysis agitans, or disseminated sclerosis; he has found it depending upon mischief in, or connected with, the spinal cord, such as sclerosis of one or other of the columns (anterior, lateral, or posterior), meningeal thickenings, tumours, or disease of the bones; he has known it caused by an aneurysm pressing on the brachial plexus, by neuritis affecting either the large nerve-trunks or the small terminal twigs that run in the palm of the hand; he has known it caused by rheumatic thickenings of muscular attachments, by injury or disease of the

muscles themselves, or by gouty deposits in the sheaths of the tendons. It is therefore necessary to examine these cases with very great care, and to remember that the act of writing may be hampered by the failure of any muscle between the scapula and the hand.

PATHOLOGY.—The morbid anatomy of writer's cramp is unknown, and consequently the pathology of the disease is a matter of speculation. It is obvious, however, from what has been said, that the changes which bring about the difficulty in writing cannot be expected to show any uniformity of seat, but may be suspected in cerebral cortex, conducting fibre, peripheral nerve or muscle, according to the symptoms manifested. Duchenne believed that the change is in the nerve-centres first, because localised faradisation applied to the hands has no good effect on the trouble; and he is confirmed in this opinion because the malady very quickly affects the left hand if it be used to supply the place of the right. The writer has ventured to suggest that the lesion is often situated at the periphery, either in the muscles themselves or in the terminal motor nerves supplying these muscles. In real cases of 'writer's cramp' (the loss of writing power occurring in an overworked scrivener) it is rare to find any sign of central change; neither wasting or true paralysis of muscle, nor fibrillary tremor, nor general tremor of the limb, nor pain, nor spasm (except during, or immediately after, the attempt to write). It is generally observed that the disease progresses from the periphery towards the centre: that the muscles of the fingers are the first to fail, then those of the forearm, then those of the arm, and lastly, in extreme cases, those of the trunk. It is probable that the muscles of pen-prehension, as opposed to those of pen-movement (consisting of the adductor pollicis, first dorsal interosseous, &c.) drift into a condition of 'chronic fatigue' owing to the *prolonged strain* to which they are subjected when holding a pen for long periods at a time. When these normal muscles of pen-prehension are exhausted, others are used to supply their place, such as the superficial and deep flexors in the forearm, which in their turn give out, and thus the trouble steadily progresses. The writer has had no small experience of this disease, and he has rarely failed to find that a careful electrical investigation of the muscles has shown a certain diminished irritability to faradisation in the muscles of pen-prehension on the diseased side, when compared with those of the sound side. This loss of irritability is due, in many cases, he believes, to sheer over-use of the muscles, the intervals of relaxation between the long periods of contraction not being sufficient to allow of their proper nutrition. In many cases of 'writer's cramp' no over-use of the muscles has taken place, and in such cases we must suppose that, from some condition, either constitutional or situated locally in the nerves, the muscles are so deficient in 'staying power' (notwithstanding their ability to contract forcibly for a short time) that they become useless, or nearly so, when called on for prolonged steady contraction. It is obvious that the failure of one muscle (however small) which had been taught, by years of laborious education, to act in harmony with many others for the accomplishing of a complicated and delicate act, such as writing, would produce a true want of co-ordination. In other words, muscles which have been induced to *work in order together* no longer do so if one of

them fails, and the failure of one must be fatal to the accomplishment of the co-ordinated act.

DIAGNOSIS.—Diagnosis is of great importance, since failure of writing power is often an early symptom of disease the prognosis of which is very different from that of 'writer's cramp.' Evidence of chronic alcoholism is often afforded by the hand-writing. So again paralysis agitans and disseminated sclerosis of the spinal cord may very early give a want of steadiness to the pen. Reynolds recorded a case of lead-palsy which was sent to him as a case of 'writer's cramp,' and there can be no doubt that peripheral neuritis is answerable for not a few cases. Paralysis of any of the nerves supplying the hand or forearm, such as the ulna, median, or musculo-spiral, will make writing difficult; and the writer has seen cases of progressive muscular atrophy in which the shrunken and quivering interossei had made a firm grasp of the pen impossible. Among other conditions which have been sent to him as cases of 'writer's cramp,' the writer may mention cerebral embolism and hæmorrhage, cortical thrombosis, general paralysis of the insane, exophthalmic goitre, and hysteria.

TREATMENT.—The chief remedy is rest. Without it nothing can be done; and if rest be taken in the earliest stages of the disease, complete recovery not infrequently results. For such writing as is absolutely necessary, the patient should be advised to use a pencil or soft quill-pen, so that any violent grasp becomes impossible. In some cases the writer has found the rhythmical exercise of those muscles whose irritability is impaired, together with the employment of a mild galvanic current, of the greatest service, and he has recorded a few cases treated in this way which rapidly improved after having resisted every other known method of treatment for years. Injection of morphia is of no use, but in America some good has been said to result from the injection of atropine. Systematic massage is of decided service in many of these cases, but neither massage nor electrical treatment must be employed so long as the nerve-trunks are tender. The first object in the treatment of such cases is to remove the nerve-tenderness by rest and blistering. The administration of a very small dose (gr. i) of iodide of potassium combined with arsenical solution is often useful to this end; and when the tenderness has disappeared, the systematic rubbing of the muscles, especially the muscles of the hand, is most valuable. No patent penholders are of any permanent use in these cases, although they may do apparent good by shifting the burden of writing on to a new group of muscles, which are sure, if writing be persevered with, to break down in time. Typewriters are, of course, invaluable to sufferers from 'writer's cramp,' but only those forms of typewriters which are worked by a piano-like keyboard are admissible. Those which necessitate a prolonged grasp of a handle are dangerous for sufferers from this disease.

G. V. POORE.

WRY-NECK.—**SYNON.** : Torticollis; **FR.** *Torticollis*; **GER.** *Steifer Hals*.

DEFINITION.—A twisting of the neck to one side.

ÆTIOLOGY.—Wry-neck is a symptom which may be produced by very different conditions; and it is usual to distinguish between the varieties of this disease, which may either be *congenital* or *acquired*.

The *congenital wry-neck* arises either from faulty

development of the muscles on one side of the neck (in which case there are not infrequently evidences of faulty development in other regions of the body, and notably in the neighbouring parts, such as the face); or from contraction of the muscles on one side, often due to accidental injury during labour. Spencer found no fewer than sixteen cases of hæmatoma of the sterno-mastoid in 200 bodies of still-born children, and D'Arcy Power has insisted upon the connection between such congenital tumours and wry-neck. In these cases the head is fixed in its abnormal position. *Acquired wry-neck* may be a mere passing condition, due to 'muscular rheumatism,' brought on by exposure to cold, and under the name of 'stiff-neck' it is familiar to everybody (see **RHEUMATISM, MUSCULAR**). The most formidable variety is *spasmodic wry-neck*, which makes its appearance, usually in persons otherwise healthy, about the middle period of life. The muscles on one side of the neck are the seat of spasm, sometimes tonic, but usually clonic, in character. The muscle chiefly affected is generally the sterno-cleido-mastoid, and its constantly recurring contractions have the effect of turning the head away from the side which is the seat of spasm; drawing the occiput slightly downwards, and the chin slightly upwards. Other muscles, such as the scaleni, splenius, and trapezius, are not infrequently affected also; and then, in addition to the rotatory twisting of the neck, we get a lateral downward bending, and an elevation of the shoulder. At the commencement of the disease the trouble may be slight, and cause but a trifling amount of inconvenience, the impressions produced on a bystander being that the patient's movements are caused by some mal-arrangement of the dress, which he is seeking to remedy. In its advanced form the disease is a very terrible one, and may make life hardly supportable. The writer has seen one case in which the spasm was so violent that the constant forcible impinging of the chin upon the shoulder of the sound side had produced a sore place as big as a shilling. The spasm ceases during sleep; and when the patient is undisturbed, and his mind pre-occupied, it is not unusual, even in the worst cases, for considerable remissions of the symptoms to occur. In the presence of others, especially strangers, the spasm is usually intensified, and in this it presents a striking similarity to stammering and writer's cramp.

PATHOLOGY.—The pathology of spasmodic torticollis is very doubtful. It must be regarded in almost all cases as a true neurosis, and must take its stand alongside of histrionic spasm of the face, writer's cramp, and stammering. It must often be a question as to whether some of these cases are not definitely of cerebral origin. The rotation of the head to one side is effected by muscles on *both* sides of the body. Thus the right splenius capitis and the left sterno-mastoid, acting in concert, rotate the head to the right; and in many cases of clonic torticollis it is found that muscles on opposite sides of the body are both conspiring to produce the rotation. The writer has recorded one case in which extreme torticollis was associated with a history of injury to the head close to the upper end of the Rolandic area, combined with a history of syphilis. This case was practically cured by the free administration of mercury. That it is due in many cases to an irritable condition of the spinal accessory nerve there can be no doubt, but how

this condition of nerve is brought about we are unable to say. In many cases, especially in women, there is a large element of what is called a pure neurosis. Want of proper antagonisation is another factor which is always present, for without it the symptoms could not occur. In certain nervous constitutions a weakened action of one sterno-mastoid would seem of itself to be almost sufficient to excite irregular contractions in its fellow. The writer has seen one case in which it seemed tolerably clear that the sterno-mastoid and trapezius on one side had become weakened by overwork, and had drifted into a condition of chronic fatigue, while their antagonists were constantly in a state of clonic spasm, twisting the neck to the weakened side. An electrical examination of the muscles may show that, while those which are the seat of spasm have their irritability greatly increased, their antagonists are below their normal state as to irritability. Torticollis is usually, but not always, uncomplicated. The condition known as 'irritable spine' has been observed in some few female patients. Histrionic spasm, or spasm of the limbs, has occurred as a complication, and it is not a little remarkable, as showing connection between the two diseases, that Reynolds recorded three cases of torticollis in which the patient had suffered previously from writer's cramp. A difficulty of deglutition was observed in one of Reynolds's cases; and in another there was swelling of the arm, from pressure upon the subclavian vein.

PROGNOSIS.—The prognosis of these cases is bad, it being very unusual for recovery to take place after the disease has become well established.

DIAGNOSIS.—The diagnosis of wry-neck, as a rule, is not difficult, but care must be taken that simple torticollis is not confounded with cases of caries of the cervical spine, in which there is frequently a tendency for the head to twist to one side. It should be borne in mind, also, that in some few cases of organic brain-disease, in which synergic movements of the eyeballs have occurred, a spasmodic rhythmic movement of the neck has also been observed. The other symptoms of brain-disease, however, would usually prevent any such mistake.

TREATMENT.—This necessarily depends upon the cause of wry-neck. In those cases in which the head is fixed by contraction or faulty development of the muscles, tenotomy has been of service. Tenotomy has been practised also in those cases in which there has been definite clonic spasm; but notwithstanding that temporary relief has in some

cases followed, it has been found that the deep-lying muscles are almost certain to take on a spasmodic action, and that in the end the patient's discomfort is increased rather than diminished. A tenotomised muscle is liable to shorten; and it has appeared to have been the case that, although tenotomy gives temporary relief, it really aggravates the trouble in the long run.

The removal of a piece of the spinal accessory nerve in the neck, as practised by Campbell de Morgan and others, will completely paralyse the sterno-mastoid and upper part of the trapezius, and is not open to the objection urged against tenotomy. This manoeuvre is stated to have given great relief even in those cases where muscles other than those supplied by the spinal accessory have been implicated. Various mechanical contrivances for steadying the head have been devised, but few patients are able to bear the constant pressure of the apparatus, and the remedy has been found in most cases worse than the disease. The stretching of the spinal accessory, the ligature of the same nerve (Collier), and the suspension of the patient by the head, are all measures which are calculated to relieve. Some good has resulted from the long-continued use of hypodermic injections of morphine, and the exhibition of large doses (3j and over) of the succus conii. Electricity has not been particularly serviceable in the treatment of torticollis. The galvanic current has been used to control the spasm, while the weakened antagonising muscles have been stimulated by faradisation; and although improvement has been produced by these means, it has generally been of very short duration. The writer some years ago had a very severe case under his charge, which was successfully treated by the employment of the continuous galvanic current, combined with the rhythmical exercise of the affected muscles. The positive pole being placed behind the ear, the negative pole was applied over the sterno-mastoid and trapezius, and at the same time the patient was made to exercise these muscles by shrugging the shoulder, twisting the head, and other movements. The result was very rapid and permanent improvement. Another case, also, was successfully treated by the writer by faradising the antagonist muscles, which were somewhat wasted and decidedly deficient in irritability. This patient completely recovered; although tenotomy of the sterno-mastoid, which was the seat of spasm, had afforded only temporary relief.

X

X-RAYS.—See RÖNTGEN RAYS.

XANTHELASMA (ξανθός, yellow; and ἔλασμα, a lamina).—A yellow growth in the superficial layer of the skin, assuming the form of a lamina or plate, and more frequently met with in the eyelids than elsewhere. See XANTHOMA.

XANTHOMA (ξανθός, yellow).—**SYNON.**: Xanthelasma, Vitiligoidea; Fr. *Molluscum Cholestérique* (Bazin); Ger. *Fibroma Lipomatodes* (Virchow).

DEFINITION.—A rare disease, characterised by a peculiar kind of yellow growth, in the form of plates or raised nodules, in the skin, and sometimes subsequently in areolo-fibrous tissue elsewhere.

ÆTIOLOGY.—The presence of xanthoma is frequently associated with megrim or other neuralgiae, with gouty conditions, and with disorders of menstruation. It occurs in such frequent connection with those morbid functional conditions or actual organic diseases of the liver which lead to the presence of jaundice that the influence of this as an

ætiological factor cannot be gainsaid, although the nature of the relationship is not apparent. These conditions are, in order of probable relative frequency, chronic catarrh of the bile-ducts, hypertrophic cirrhosis, biliary calculi, atrophic cirrhosis, hydatids, and carcinoma. Chronic dyspepsia, lithæmia, and other conditions attributed to hepatic disturbance are also often present. In the great majority of cases jaundice precedes xanthoma by a prolonged period—usually a year or more—and is generally present when it develops. In a certain number of instances, however, all signs of jaundice may have disappeared, while in others—noted especially by French writers—a persistent yellowish tint of skin (*xanthochromia*), not identical with jaundice, and unaccompanied by other evidences of bile-absorption, has been noted. On the other hand, xanthoma is frequently seen in persons apparently healthy in every other respect.

The female sex is much more frequently affected than the male, in the proportion, according to Hutchinson, of three to two. Xanthoma generally begins about or above the age of forty years, but a dozen cases or more are recorded in children below puberty. These have never been in association with jaundice, but many have been either congenital or hereditary, while the existence of the disease in several members of the same family, and even in successive generations, is sometimes so striking as to suggest to some recent writers the propriety of classifying it among the *nævi* (Török, Hallopeau). 'Probably slight developments of xanthoma are not so rare as is generally supposed, but give rise to no trouble, and are generally overlooked' (Crocker). Such cases are often unilateral.

ANATOMICAL CHARACTERS.—The following description of xanthoma is based upon the examination of growths in the skin alone.

The upper epidermic layers are healthy, but there is usually a small quantity of granular pigmentary deposit in the rete Malpighii. The changes in the papillary layer are slight, but in the middle and lower layers of the derma there is a good deal of yellowish-brown pigment, both free and in cells. The most prominent and characteristic feature, however, is the involvement of these latter layers by a new-growth of connective tissue, the amount of which is small in the flat, and great in the tuberos variety. In the meshes of the fibres there are numerous round, oval, or polygonal, multinuclear or granular, epithelioid cells, which vary greatly in size. Often they are arranged in masses surrounding blood-vessels or sebaceous glands. These cells, which may be considered as characteristic 'xanthoma cells,' contain many crystals of cholesterolin and tyrosine, as well as yellowish pigment and fat, the last being also abundant in the connective tissue.

There is much difference of opinion as to whether the diseased process ought to be considered a purely neoplastic or a low inflammatory one, but the presence of large endothelial and giant-cells, as well as of the changes in the arterial walls usually associated with chronic inflammation, described by Chambard and others, seems to turn the balance in favour of the latter view. The papules are not due to a collection of sebum within the follicles, as Hebra suggested.

SYMPTOMS AND COURSE.—Two types of xanthoma, (1) the *flat*, and (2) the *nodular or tuberos*, are usually recognised, but as the differences between

them are mainly of degree, and do not turn upon essential characters, they are separately described only in accordance with custom.

1. *Flat or localised xanthoma (X. planum)* is the much more frequent form, and the great majority of cases do not call for medical relief. It generally occurs in middle-aged or elderly women, especially in those of dark complexion or who suffer from neuralgia or 'any conditions capable of producing dark areolæ round the eyes' (Hutchinson). In the immense majority of cases the disease is situated upon the eyelids, where it generally begins on the left side, above and a little outside the inner canthus. Thence it extends slowly outwards along the upper lid and more slowly downwards to and along the lower lid, so that in extreme cases the eye may be surrounded by a xanthomatous ring. After a variable time the right side becomes similarly affected, and the disease pursues the same course as on the left side. The patches when first noticed vary in size from a pin's head to a pea; they are deeply embedded in the skin, which undergoes no alteration in consistence and suppleness; they vary in colour from the palest yellowish-white—to recognise which the blood of the part must be expressed by the finger—to a bright orange or dark brownish buff; and have been not inaptly described as like pieces of chamois leather 'let into' the skin. With a lens the patches can be seen to be composed of fine yellowish granules. At the spreading margin they are sometimes well defined, sometimes they are irregularly serrated, while at other times their colour gradually merges into that of the surrounding skin. Occasionally slight irritation is present, and when the eyes are encircled there may be some discomfort in the movements of the eyelids; with these exceptions no subjective symptoms are present. Single patches of flat xanthoma have in rare cases been noted on the ear, neck, chest, penis, prepuce, and tongue.

2. *Nodular or multiple xanthoma (X. tuberosum, multiplex)* is of greater rarity and more serious import than the previous type. It is also much more frequent in women than in men, especially in those who suffer, or have suffered, from jaundice. Although it may occur independently, it usually shows itself in persons suffering from flat xanthoma of the eyelids, and not infrequently the first step towards its establishment is the appearance of flat lesions of the face, other than those on the eyelids, especially about the nostrils, mouth, or external auditory meatus. The most characteristic and tuberos lesions are situated on the extremities, especially on their extensor surfaces and on points much subjected to pressure, such as the tips of the elbows and knees, buttocks, shoulders, and backs of the fingers. The colour of the nodules varies within the same wide limits as that of the lesions of the plane variety, but often they have tufts of dilated blood-vessels round or over them. In size they vary from a hemp-seed to a pea, but, by their coalescence, swellings as large as a hen's egg, or even larger, may be produced. The epidermis over these is, however, intact, and they are usually only slightly tender to touch and manipulation; occasionally they itch or tingle a little. In most cases a few flat lesions exist here and there over the chest and abdomen, and are present in greater numbers over the palms and soles, where they are ranged in rows along the naturally deep lines of the parts, which they exaggerate. Sometimes they

are similarly arranged in concentric circles round the anus. On the trunk they occasionally have the unilateral nerve-distribution of a zoster. The development of the lesions is usually very slow—extending over years; and ultimately flat xanthoma may show itself in the mucous membrane of the lips, cheeks, gums, tongue, fauces, pharynx, œsophagus, stomach, bile-ducts, intestine, peritoneum, conjunctiva, larynx, trachea, bronchi, pleura, on the endothelium of the heart or great arteries, and on tendons.

Xanthoma in children presents such well-marked peculiarities as to merit a few words of special mention. It has never been known to be associated with jaundice, but is often so with gout or rheumatism, while it is frequently hereditary, may affect several members of the same family, and is occasionally congenital. The lesions are generally asymmetrical, often unilateral, markedly tuberous; and the eyelids are comparatively seldom attacked.

DIAGNOSIS.—Flat xanthoma may be confounded with *milium* if the little, projecting, whitish masses of inspissated sebum which characterise that disease are thickly grouped together so as to form a conglomerate plaque. Almost invariably, however, a few characteristic outlying lesions are present. In any case the sebaceous contents of a milium can always be squeezed out after a shallow incision has been made, whereas in xanthoma the lesions are deeply situated in the corium, and cannot be expressed. It will suffice to mention the possibility of errors in diagnosis with *flat warts*, *colloid degeneration of the skin*, *adenomata of the sweat or sebaceous glands*, and the extremely rare condition termed *pseudo-xanthoma elasticum* (Darier, Balzer), which is a degenerative disease of the elastic tissue of the skin.

In the diagnosis of multiple xanthoma the presence or history of jaundice is an important factor. The skin-disease which most closely simulates it is *urticaria pigmentosa* (hence called *xanthelasma* by Tilbury Fox), but the history, distribution, and subjective symptoms of the two diseases easily serve to distinguish them.

PROGNOSIS.—In the great majority of cases xanthoma progresses slowly but steadily for months or years, and afterwards persists unchanged. In at least four instances, however, very gradual spontaneous recovery has been known to occur, the skin regaining its normal characters. In a very small number of cases death has been attributed to patches on the endothelium of the heart or great arteries.

TREATMENT.—Treatment is seldom resorted to except for the removal of disfiguring plaques from the eyelids. This can best be accomplished by excision, and great care is necessary not to cut too deeply, and thus give rise to subsequent ectropion or epiphora. Electrolysis has also been employed. A 10-per-cent. solution of perchloride of mercury in collodion has been successfully used by Stern for the cauterisation of painful masses on the elbows; while Kaposi states that he has removed xanthoma-nodules from the palms and soles by repeated vigorous washing with soft soap, and making the patients wear indiarubber gloves and socks. Internal treatment is of no use. J. J. PRINGLE.

XANTHOMA DIABETICORUM.—SYNON. : *X. Glycosuricum*; *Lichen Diabeticus*.—Although this lately recognised and rare condition—the

identity of which was first clearly established by Malcolm Morris in 1883—is now by universal consent considered as a member of the xanthoma-group, it presents several points of distinction which entitle it to separate description, in which its chief clinical characters may conveniently be contrasted with those of ordinary xanthoma. The following conclusions have been arrived at from a study of all the indubitable cases on record, a considerable majority of which have occurred in males, the age of the persons affected ranging from seventeen to forty-eight years.

COURSE AND SYMPTOMS.—The disease almost invariably occurs in people actually passing sugar in the urine, although frequently they have been noted as stout and apparently in good health. In a considerable proportion of the cases the presence of sugar in the urine is transitory, and unaccompanied by the other phenomena of true diabetes mellitus. In some cases, moreover, there is only a history of antecedent glycosuria. Many of the patients are alcoholic, and usually beer-drinkers; while others are remarkably obese. The presence of pentose has been discovered in the urine of one case (Colombini), and this fact has been invoked in favour of a pancreatic origin of the disease (Hallopeau).

The eruption evolves quickly, and, after a variable stationary period extending over months or years, diminishes with considerable rapidity, to disappear ultimately without leaving any trace of its existence. Sometimes its course is intermittent and successive outbreaks occur, while occasionally fresh lesions develop during the retrocession of older ones. As a rule the parts first affected are the extensor surfaces of the limbs, especially of the forearms; subsequently the lesions usually appear on the elbows and knees, where they have a great tendency to become confluent and form raised plaques. They are commonest on extensor surfaces, the buttocks, back, face, scalp, mucous membrane of the mouth, and bends of the ankle, but they do not generally affect the flexures. They have only once been observed on the eyelids, and the presence of jaundice has never been noted. The constituent nodules are at first bright red, but subsequently become yellow from fatty degeneration. They are much firmer and denser than those of ordinary xanthoma, are well defined, rounded or obtusely conical at the apex, and may present a yellow point like pus at the summit, but are in reality solid; often there is a bright zone of congestion round their base. In some cases the nodules are very pale, while in others their colour remains pink rather than yellow. Many of them are in obvious relationship to hair-follicles. Itching and tingling are often troublesome, and occasionally there is great tenderness during the evolution of the tumours, while neuralgic pains sometimes precede their eruption. Occasionally ulceration and deep scarring ensue.

ANATOMICAL CHARACTERS.—Recent researches establish the close relationship between ordinary and diabetic xanthoma; 'discrepancies in the recorded appearances being fully accounted for by variations in the rate of the inflammatory process and differences in the methods of hardening and staining employed' (Morris). Typical xanthoma-cells are present, albeit in less abundance than in flat xanthoma, while the inflammatory changes are more marked, especially in connection with sebaceous

and sweat-glands. They also extend upwards to involve the papillary layer, and the passage of fat even into the epidermis has been noted.

TREATMENT.—Mild tarry or lead-lotions, separate or combined, generally suffice to allay or moderate the itching. If sugar disappear from the urine under the influence of dietetic or other measures (codeine, salicylate of sodium, &c.) the eruption usually soon disappears.

XERODERMIA PIGMENTOSA.—SYNON.:

Xeroderma Pigmentosa.

DESCRIPTION.—This a very rare disease, which with few exceptions commences in the second year of life. Without any previous symptoms of apparent cause, but sometimes preceded by a morbilliform or patchy erythema, a copious outbreak of freckle-like pigmentation appears on the face, neck, and upper extremities, i.e. in the uncovered parts, reaching about half-way up the upper arms, the legs being sometimes slightly involved. Other lesions follow, namely telangiectases, white atrophic areas, pigmented flat warts, and ulcerations on which papillomatous growths form. These, if not removed, become epitheliomatous, and thus lead to the patient's death. Conjunctivitis and pterygium are nearly always present, and the discharge is largely responsible for the onset of the ulcers. Cicatricial contraction of the various lesions produces much disfigurement. The aetiology and pathology are unknown. The ultimate prognosis is bad; but the disease progresses very slowly, and if the eye-affections are effectually treated from time to time, the ulcers scraped with a sharp spoon, and all soft papillomatous growths promptly removed,

the cancerous stage may be averted for an indefinite period. Internal treatment is unavailing.

H. RADCLIFFE CROCKER.

XEROPHTHALMIA (ξηρός, dry; and ὀφθαλμός, the eye).—SYNON.: *Lippitudo arida*; *Xerosis Conjunctivæ*.—This term signifies a dry ophthalmia, or chronic inflammation of the conjunctiva without much (if any) watering or discharge. The conjunctiva is thick, dull, opaque, and often skin-like. In severe cases it is shrunken, and the oculo-palpebral folds may be obliterated. The epithelium of the cornea may also be involved. The morbid changes may be the result of injury, especially burns; or it may follow trachoma, diphtheria, pemphigus, and other severe forms of conjunctivitis; or it may be due to insufficient covering of the eye in the various forms of lagophthalmia. A peculiar form of xerosis conjunctivæ occurs in association with night-blindness (see NYCTALOPIA). On the ocular conjunctivæ are dry, scaly-looking patches, which by gentle friction of the lids may be worked into a fine foam which abounds in bacilli (*Xerosis-bacillus*).

J. TWEEDY.

XEROSIS-BACILLUS.—This organism is an occasional inhabitant of the normal conjunctival sac, and is found, in association with specific bacteria, in many of the pathological conditions of that structure. It derives a fictitious importance from its striking resemblance to the *B. diphtheriæ*, not only in morphology but also in several biological characters. It is, however, a pure saprophyte, and possesses no pathogenic properties whatever.

XEROSIS CONJUNCTIVÆ.—See XEROPHTHALMIA.

Y

YAWNING (A.-S. *gánian*).—SYNON.: Fr. *Bâillement*; Ger. *Gähnen*.—Yawning is one of the physiological expressions of fatigue. It consists, when fully developed, of the following phenomena: (1) A deep inspiration, with elevation of the uvula and palate. (2) A forcible spasmodic depression of the lower jaw. (3) A flow of tears. (4) A clicking sound in both ears. (5) A tendency (sometimes irresistible) to stretch the limbs, especially the arms. (6) An expiration, often accompanied by a sound, the character of which has probably given the name to the act.

ÆTIOLOGY AND PATHOLOGY.—This strange and complicated act suggests many reflections. Why, when we are tired, should we take a deep breath? It may be that the need of oxygen experienced by the fatigued tissues, laden with waste products, prompts the instinctive and forcible descent of the diaphragm; but, on the other hand, the facts that yawning is common when we are merely *ennuyé* and not genuinely fatigued, and that it is decidedly infectious, are both unaccountable on such a theory. Why should the lower jaw be spasmodically depressed when we are fatigued? The elevators of the lower jaw are the temporal, masseter, and internal pterygoid muscles, and it is probable that the external pterygoid (whose main functions it is

to move the jaw forward) has also some share in keeping the teeth in contact. These muscles are constantly in action, having to support the jaw against the force of gravity; and it is not surprising that, as in other cases of prolonged muscular action, they should be prone to evince fatigue by failure of function. Were it not for the fact that this work of supporting the jaw is divided among eight muscles (four on either side), it is probable that the jaw would fall more often than it does. When one set of muscles is fatigued, it is quite in accordance with experience that their antagonists should take on a spasmodic action, and we may fairly look upon the spasm of the depressors of the jaw, when the elevators are fatigued, as the physiological expression of an occasional pathological phenomenon. These considerations again do not apply to those instances of infectious (emotional) yawning, in which we are impelled to imitate what we see in others.

A fact of considerable interest in connection with yawning is the great extent to which its phenomena are limited to the area of the fifth nerve. The four muscles mentioned above, as concerned in the negative phase of yawning, are all supplied by the fifth; and the anterior belly of the digastric and the mylo-hyoid muscles, which are connected with

its positive phase, are also supplied by the fifth. The flow of tears and the 'click' in the ears, which is probably due to a contraction of the tensor tympani, are referable to the influence of the same nerve. The tensor palati is likewise in action; so that we may say that every muscle supplied by the fifth is concerned in yawning. Possibly yawning may be regarded as a reflex phenomenon, of which the most ordinary stimulus is the fatigued condition of the elevators of the lower jaw. The reflex effects are largely manifested in the area of the fifth nerve, but they clearly spread beyond it, and produce contraction of the diaphragm, palatal muscles, depressors of the hyoid bone and larynx, and sometimes of the muscles of the body generally, but mainly of the extensors. That the contraction of the body-muscles at least is a purely reflex phenomenon, may be gathered from the interesting fact which has been often observed in cases of hemiplegia, namely, that when a hemiplegic arm is entirely beyond the control of the will, and its flexor muscles are contracted, this contracted helpless hand will often open during yawning, the stimulus having reached the extensors of the fingers, not through the ordinary path of the will, but through the spinal cord by a reflex action travelling along some other path of nervous energy.

In these days when so much is heard of 'hypnotism' and 'suggestion' it is perhaps profitable to bear in mind the common act of yawning, which when performed in public not only compels the spectator to perform a similar act, but definitely begets in him that mental condition of fatigue and *ennui* which is almost inseparable from the physical condition.

TREATMENT.—Yawning is generally only a passing phenomenon, which is removed by rest. An undue tendency to yawn may indicate that the body is too easily fatigued; and then it may be necessary to inquire whether the demands upon it (mental, physical, or sexual) are too great. These may have to be removed or avoided. At the same time the bodily health should be carefully attended to. Iron tonics may be given; the foul atmosphere of crowded assemblies should be forbidden; the diet should be nutritious and digestible; and the amount of alcohol should be carefully restricted to that physiological minimum which may be necessary to aid digestion.

G. V. POORE.

YAWS.—See FRAMBESIA.

YELLOW FEVER.—SYNON.: Fr. *Fièvre jaune*; Ger. *Gelbes Fieber*; Span. *Fiebre amarilla*; Port. *Febre amarella* (also *Typho Americano* and *Icteroide*).

DEFINITION.—Yellow fever is an acute specific disease which has a curiously limited geographical distribution; which is generally of short duration; and one attack of which confers a considerable degree of immunity. In places where it is endemic, outbreaks of an epidemic character are liable to occur when a sufficient amount of susceptible material (as immigrant foreigners) is introduced; or, again, they may arise in places which have long been free of the disease by the importation of actual patients, if the local meteorological conditions are favourable. It is characterised by pyrexia, prostration, and often hæmorrhagic phenomena; except

in the mildest cases there is marked albuminuria, and frequently also some degree of jaundice.

DISTRIBUTION.—The home of the fever is in the warm moist climates of Central and South America, many of the West Indian Islands, and on the West Coast of Africa (Gambia, Guinea, &c.). It has frequently made ravages in the southern States of North America. At various times it has made its appearance in more northerly and remote regions, as far as Montreal and Buenos Ayres in the western continent, and Swansea, Brest, and St. Nazaire in the eastern; the most important, however, being the epidemics of Lisbon, Madrid, and Gibraltar. In none of these places, however, has the fever taken firm and lasting root. The farthest that it has reached in an easterly direction appears to have been Italy. It appears to be unknown in the Orient, and in the Australian and Polynesian regions. When epidemics have occurred in more northern climes, they have spontaneously ceased with the advent of cold weather and frost. Some elevated situations, as the city of Mexico, have constantly escaped, although the disease has long been rife in neighbouring towns at a lower level, as Vera Cruz; the same is stated of Petropolis and Rio de Janeiro. In general, it seems to have been carried about by shipping, though cases are not wanting where it has passed overland. The general kind of nidus which favours its development consists in a warm, moist climate; it is essentially a disease of towns.

Racial and Local Immunity.—It is commonly said that the inhabitants of yellow-fever areas are not susceptible to the malady; observation has, however, shown that the Cubans, for example, may suffer from typical attacks, although they certainly enjoy considerable freedom from the illness. This is almost certainly due to their having passed through it during childhood; such attacks may pass under other names (as 'Borras fever' in Cuba). Coloured races, also, are often stated to be insusceptible, but it has been seen that in places which are virgin soil (as St. Paolo) the blacks have suffered severely; occasionally cases may be seen among them in endemic areas.

Seasonal Prevalence.—In the equatorial and truly tropical regions, the fever generally exists all through the year, but it especially favours the drier period of the year (e.g. at Pará on the Amazon, from April or May onward); in such places, no time can be considered quite safe for the foreigner. On the other hand, in places where there is a distinct winter or cool season, the stranger may then live with a considerable degree of impunity (e.g. at Rio de Janeiro, the summer months, January and onward, form the dangerous period). The diminution after great prevalence is no doubt often due to the cessation of immigration of susceptible persons when notoriety of the condition has spread.

Incubation (1) of the Community.—It is an old observation that a period of about three or four weeks has elapsed after the introduction of persons suffering from the fever before it spreads further. This period has been more exactly traced by Carter; by the study of the onset in a scattered village, it was found to be about three weeks (14–21 days). Naturally this must include the period of incubation in the individual and the time required for the development, multiplication and dissemination of the causative agent. This incubation-period, as well as the necessary high external temperature, may be

considered as contributory elements in the evidence for the existence of an intermediary agent in the spread of the fever. See p. 727.

Often it has happened that the original infecting case has not been recognised, whether that may have been due to the mildness or atypical nature of the attack or to the want of astuteness of the physician; at the same time it must always be remembered that an ill-advised concealment of the presence of the disease is lamentably frequent in yellow-fever districts.

(2) *Of the Individual.*—The personal incubative stage is probably not more than a few hours shorter than three days, nor a few hours longer than six days. Former writers have given it as short as one day, and as long as several weeks. The most exact records are those of the experimentally infected cases of Reed, Carroll, and Agramonte ('American Medical and Carter's Epidemiological Enquiry,' 1901). Persons who have visited patients have themselves been taken ill on the following day; these have been regarded in the past as infections from direct contagion. However, the possibility of infection from pre-existent common sources was not duly discussed. It may be stated plainly that there is no satisfactory evidence of transmission by direct contagion; furthermore, there are many points which exclude such a mode of spread.

Mode of Dissemination.—Various factors have been accused of being the transmitting media. Water may be considered as definitely excluded; many facts are opposed to various articles of diet, of which native fruits are especially incriminated by the Brazilians; transference by means of fomites has been much debated, one direct experiment (Reed) proved negative.

Mosquito-theory.—The first to propound that the fever was transferred by gnats was Finlay of Havana in 1881; satisfactory evidence of an experimental nature was obtained by Reed, Carroll, Lazear, and Agramonte in 1900. The species of mosquito experimented with was *Stegomyia fasciata* (Theobald); it was called 'Culex mosquito' by Finlay, who selected it for his experiments as being essentially a town gnat; it has also been known as 'Culex fasciatus' and 'taeniatus.' It is a black insect with silvery markings on the thorax and at the joints of the legs; the proboscis is entirely black. It is very common about houses, and breeds freely in casual waters in tubs, tins, &c. about houses. It is the commonest mosquito between the 30th parallels. It is not yet known whether other kinds of gnats are capable of transferring the fever; since, however, *S. fasciata* is essentially a day-biting insect, it is probable that some night-biting sorts are able to do so, since there is rather credible evidence that the disease is commonly acquired at night.

Twelve successful inoculations of the fever were made upon susceptible persons at a special camp near Quemados, in Cuba; other susceptible persons in the same surroundings served as controls, and it was solely those that had been submitted to artificial infection that acquired the fever.

The mode of experiment was to feed the gnats upon patients suffering from yellow fever during the first three days of illness; the gnats were then kept for a fortnight or more, when they were allowed to feed upon the subject for experiment. Probably at least ten days' incubation in the gnat are requisite before it is capable of transferring the malady. Some of the insects were found to be

infective nearly two months after their original feed upon the yellow-fever patient. Happily all of these cases ran a comparatively mild course, though they were sufficiently well marked to leave no doubt that the attempt to infect the disease-germ by passage through the gnat had been successful. What length of time the infective agent remains in the patient in such a manner that it can infect gnats (peripheral capillaries or tissues) is not yet established; the matter, however, is one of some importance. It is perhaps only right to remark that the method of experiment is full of the risk of a fatal issue, and should not be lightly undertaken. It will be observed that when a case of yellow fever has been introduced into a virgin district, an interval of at least about a fortnight must elapse before a secondary case can occur (i.e. incubation in gnat say at least ten days, plus incubation in man say three or four days); care of course being taken that no antecedent mild case has been overlooked when testing the question. The facts relating to the occurrence of the fever on ships at Pará are highly suggestive of a transference by mosquitoes, the insects being carried in the lighters from the city, two miles distant, other modes being almost absolutely impossible (Durham).

ESSENTIAL CAUSE.—No micro-organism as yet has been satisfactorily determined as the cause of yellow fever. Various bacteria have been described by different authors—that called *Bacillus icteroides* by Sanarelli has attracted a good deal of attention recently, but there is no reason to think that it has any relation to the fever, as indeed appeared very doubtful in Sanarelli's own account. Description of this bacillus is not called for here, as it may be considered definitely excluded by the work of Reed and his colleagues, and of the writer with Myers. The writer's belief from his own observations is that the disease is due to a bacterial rather than to a protozoal parasite; moreover, several points concur in favouring this view (shortness of incubation, and, of course, rapidity of acquisition of immunity and absence of splenic enlargement). On the other hand, the part played by the gnat is suggestive of a protozoal origin; none such has as yet been discovered. By direct transference of blood from sick to healthy, Reed has proved that the organism is present in the blood during the first days of the disease.

Acquired immunity.—It is commonly stated that the immunity conferred by one attack is very complete; this means that such an individual is unlikely to suffer again from a typical or fatal attack of the fever so long as he remains in an infected neighbourhood. With an experience of rather less than a year the writer met with at least five well-determined second attacks, as well as others which could not be precisely established. It appears that an absence for a few years from an infected area leads to loss of the acquired protection; the duration of the more complete immunity has not been accurately determined; perhaps it is about four years. The resident in an infected area may be considered to be constantly having his immunity renovated by reinoculations, which have little or no effect upon his health. So long as he does not absent himself too long in uninfected places he is most unlikely to 'have the fever' again.

ANATOMICAL CHANGES.—Externally the *yellow tinge*, which almost always appears after death in cases which have died before the onset of icterus

(e.g. on fourth day), and blood about the mouth or nose may assist diagnosis.

The *liver* is slightly if at all increased in size; in colour it may be compared to that of washleather in various stages of use. Here and there it is injected or shows hæmorrhagic patches; it is sometimes rather 'nutmeggy,' and always yellow and fatty on section. Microscopically, besides the intense fatty change, the atrophic and necrotic changes in the cells are of great importance for diagnosis.

The *kidneys* are swollen and in a state of acute nephritis, the vessels being much engorged; the renal cells are full of fatty globules, and the tubules are mostly blocked with cylinders or granular débris and cast-off cells.

The *spleen* is plump and full of blood, deep red but not enlarged.

The *stomach* is injected, especially the cardiac part, and there may be ecchymoses and erosions; it is coated almost constantly with a blackish-brown layer of altered blood, and generally contains 'black vomit.'

The *duodenum* and *small intestine* likewise may contain black material or blood, and are the seat of injection or of hæmorrhage.

The *urinary bladder* is contracted and empty, except where death has occurred late (e.g. tenth day). Lymph exuding from organs is more or less intensely yellow; there may also be staining of the interior of vessels, endocardium, pelvis of kidney, &c.

The *gall-bladder* is too varied in size and contents for further remark.

The *lungs* present nothing of interest.

The *heart* shows fatty change about the papillary muscle, but the general mass appears to escape.

The *mesenteric glands* are large and pink; the writer and Myers found that the *axillary glands* were much enlarged and acutely inflamed, often hæmorrhagic; this was thought to be probably the result of absorption or dissemination of virus from specific gnat-bites about the hands and wrists.

The *central nervous system* is usually engorged with blood, and may be stained yellow, though not constantly, even when much jaundice is present.

SYMPTOMS AND COURSE.—The fever is generally described as consisting of two stages with an intervening intermission or 'period of calm'; this last is practically never seen except in books, and has been given its proper value by some of the more recent writers. The first stage is very frequently ushered in by a rigor; the temperature runs up to say 102°–104° F. Sometimes the onset is more insidious and gradual; there is most intense headache, generally frontal, and pains in the lumbar region and calves, the latter being also sometimes tender. Simple vomiting may also occur; it would seem to be especially common in the atypical form of the fever which usually affects children. The face and chest show slightly dusky congestion and the somewhat bloated 'drunken man' look of the face (yellow-fever facies) is most useful for diagnostic purposes; thirst, anorexia, and lassitude must also be added. In cases of slight or medium severity the temperature falls and regains the normal about or before the fourth day. There is no typical temperature-curve for this malady; in very severe cases the temperature may run high, as 106° or 107° F., but this does not seem to be common. Even at the early stage the pulse, which is full and

strong, is relatively slow, as 100–120, with a temperature of 104°, but this slowness is more a feature of the later periods. The typical tongue—pointed, with furred middle and bright red tip and edges—is frequently seen; the gums are generally coated with non-diagnostic white fur-like material, which soon clears off in favourable cases; later they become swollen and readily bleed. The urine is thick, high-coloured, loaded with urates, and albumin may sometimes make its appearance as early as the second day, though not abundantly until later.

The second stage is characterised by the onset of hæmorrhagic and asthenic symptoms. They may be missed in the milder cases and in children.

The fourth day may be said to be the time for the onset of these more grave symptoms. The most celebrated is the *black vomit* (*vomito negro* or *preto*). The vomit at first consists of ingesta or water becoming bile-stained; when typically 'black' it consists of clear water or fluid, in which are suspended small flakes of brownish-black material, which gravitate on standing: the flakes have been compared to flies' wings, and, though the comparison is not very apt, it suggests the appearance somewhat; the flakes are formed by small quantities of extravasated blood from the stomach, the hæmoglobin of which has been altered by the acid gastric juice. Whilst by no means necessarily a fatal sign, it is not a very reassuring one, especially to the patient, who has exaggerated notions of its import.

Of the *hæmorrhages* other than black vomit, in which the quantity of blood effused is not really great, there are bleedings from gums and nose, both of which are common in moderately severe cases. The latter is occasionally alarming, but is said never to cause death. In severe cases gastrorrhagia and enterorrhagia, and more rarely subcutaneous, subconjunctival, and intramuscular extravasations are met with. In women bleeding from the uterus is common; abortion is also mentioned as a constant feature in the pregnant.

The *urine* becomes very highly albuminous—so much so that often a sample boiled in a tube becomes almost solid; it also contains more or less abundant hyaline and granular cylinders, kidney-cells, and sometimes red blood-corpuscles. In severe cases it may take a week or more to clear up. A more grave feature is the ominous diminution in the flow of urine; complete suppression for twenty-four hours may be considered an almost infallible death-knell. Where jaundice is marked the urine becomes coloured greenish to blackish-green from the bile-pigments.

Pain and tenderness in the epigastrium are almost constant signs, and if severe and lasting they are of grave import.

In children (under ten years) albuminuria, icterus, black vomit, and hæmorrhages are said to be generally absent, vomiting and collapse being marked, death often occurring with symptoms like meningitis.

The *jaundice*, whence is derived the name of the malady, next claims attention. It appears about the fourth day as a yellowness of the conjunctivæ; more or less simultaneously a faint lemon-yellow tinge spreads over the body; this, perhaps, is the commonest extent of the colouration. In the milder cases, if present, it may be limited to a transitory tinge in the eyes; some writers lay stress upon an orange tinge of the palpebral conjunctiva. The writer has not been much impressed by this.

A more practical point is the fact (Guiteras) that a slight jaundice may be better detected at a couple of yards distance than quite close to the patient. Deeper degrees of icterus are also seen, either a generalised deep yellow, like that of an ordinary case of catarrhal jaundice, or a deep orange-brown colour. In such cases the colour may last for weeks, when the ordinary clay-coloured stools are to be observed.

The leucocytes in the blood are not increased markedly; in the last stages of fatal cases they are much diminished.

Edema of the conjunctiva is not uncommon in severe cases of a week's duration; otherwise the nephritis is not associated with cedema.

There seems to be some uncertainty about the bowels; some authors mention constipation, others diarrhoea. The constant preliminary purge and the usual subsequent administration of gentle salines and enemata make it impossible to come to a decision concerning this. Often there are small pieces of mucus in the stools, and microscopically they may show large numbers of a very fine bacillus (Sternberg, and the writer), as well as red blood-corpuscles, leucocytes, &c., in some cases. Death is almost always referable to the onset of anuria and the resulting uræmia with its convulsions. Direct intoxication with the specific poison and the absorption of intestinal products, unaltered by the action of the damaged liver, also have their share.

PROGNOSIS.—Often a very shrewd guess may be made almost from the first, from the general state of the patient. *Good signs* are the early fall of temperature (about the third day), the onset of sweating, low degree of albuminuria, good sleep, and calmness of the patient. *Bad signs* are persistent vomiting, hiccough, high degree of albuminuria, hæmorrhages, hypo-leucocytosis, great prostration, dry brown tongue, continued epigastric pain, anxiety, progressive decrease of urine passed, restlessness, delirium, continued insomnia, getting out of bed, desire for food while obviously ill, and *rising pulse with falling temperature*.

TREATMENT.—Since the writer has not had the actual care of patients, he wishes rather to lay down the general principles than to advocate any special type of treatment. Physicians in yellow-fever countries seem rather too apt to expect a fatal issue. No drug or serum is as yet known which has a specific action. Most drugs seem better avoided; in the main we are quite helpless and have to trust to time and nature; at the same time, it is possible to prevent a recoverable patient from getting well. It should always be borne in mind that the liver is soon so affected that it is incapable of dealing with drugs like alkaloids, or material like meat-extracts (cf. the effect of the latter in Pawlow's 'liverless' dogs).

The onset of suppression of urine is most to be feared, and all means calculated to avoid chilling the skin should be taken. The careful measurement of the urine passed is probably of far greater importance than the use of the thermometer or watch. If the quantity begins to decrease markedly, vapour-baths or hot packs and blankets should be used. At the same time it is necessary to supply water to the system; large enemata of normal saline (e.g. half a litre) should be commenced at the onset of the illness in all cases; later they may be increased, and the patient should be adjured to retain

them as long as possible; ingestion by the mouth is prevented by the vomiting. As a last resource saline solution may be injected beneath the skin or into a vein. The writer has seen very many drugs given (e.g. trinitrin, digitalis) without the slightest semblance of good.

It is well to remember that the worst conditions may ensue in the pyrexial stage, and to beware of a falling temperature with a rising pulse.

At the outset probably nothing is better than the old-fashioned purgation with calomel and castor-oil. Give nothing but water, mineral if preferred, for the first three or four days; the patient will not starve and will not wish for more; tell him to sip a spoonful or so at a time, or deal it out so that he cannot take a long draught, which he will only vomit up. Feed by the rectum if food must be given in the early days and a severe attack seems indicated; sucking ice and iced water perhaps tend to excite rather than allay vomiting. Alcohol, especially in the form of champagne, is often given. It seems doubtful whether it is of any value; cases treated by ships' captains with large excess of spirits seem sometimes to have recovered.

Do not allow the patient to leave his bed until the fourth or fifth day has been safely passed.

On first seeing the patient, try to ascertain whether he acquired the infection within his home or outside it; if the former, remove him to an uninfected house at once; it is not unlikely that severe and prolonged attacks are caused by multiple or continued inoculations while remaining in an infected house. Shelter him from gnats, both to prevent spreading infection and to aid him to sleep, for the insomnia is one of the most trying of the conditions which have to be passed through. Catch and crush (as in a small gauze net) all gnats, especially those in the sick-room, which are full of blood.

Hiccough, a bad sign, is associated with much gas in the stomach; possibly the careful use of a tube might be of service. The writer, from personal experience, can highly extol the effect of an ether-spray directed for a few seconds on the epigastrium.

For the headache an ice-cap is perhaps preferable to drugs, such as phenacetin, though neither effect much. Sponging with vinegar or water in the earlier stages is comforting, but is perhaps risky when the nephritis is well marked. In general, antipyretic measures are not wanted.

Reassure the patient and try to keep his spirits up. Many seem to be taken with a deadly fear if they know or suspect they have yellow fever.

In making a preliminary diagnosis do not forget to think of malarial fever, small-pox, influenza, measles and dengue; the urine will generally clinch the diagnosis in a day or two. Remember, too, that malaria and yellow fever may co-exist.

Prophylaxis of the community.—When the fever breaks out among a collection of susceptible persons it will be well to segregate the healthy in a safe detention-camp if possible.

The quarantine regulations of the United States against the importation of the fever are probably the best, and have been more tried in the face of almost daily risk than others; they entail a division into 'immunes' and 'non-immunes'; the former are not detained, the latter are kept under observation till the incubation-period has elapsed (say five or six days), temperatures being taken before dismissal if any suspicion arises.

General measures against gnats.—Clear out casual waters (roof-gutters, unconsidered tins and tubs); protect permanent waters (cisterns) with wire gauze; these are the breeding places of *S. fasciata*. For cesspools, which breed other house-mosquitoes, use kerosene. Where possible, fix permanent mosquito-bars in windows and doorways. Employ small boys with 'butterfly nets' to catch and kill adult insects, especially in infected houses or where patients are being treated. Remember that the vapour of formaldehyde, though effective against bacteria, does not affect insects; for these sulphur, pyrethrum, &c., are more suitable when burnt. It is probably well to disinfect the excreta of patients. Improved sanitary arrangements of towns have been thought to have diminished the occurrence of the fever; this may be due to an effect on the breeding of cesspool-loving gnats.

Prophylaxis of the individual.—Fever-haunted towns should be avoided during the fever-season, and residence in a healthy suburb, at any rate for the night, if possible, insisted upon. Exposure to sun, excess in food and drink, and sexual excess, are given as causes; the last only has any probable

importance in that many cases are traceable to a night spent in a brothel; similarly, drink may lead to an inadequate adjustment of the mosquito-net.

Avoidance of dishonest concealment of the existence of the disease, the early recognition and isolation of sufferers, both among new-comers and the native children, must be insisted upon. It may be laid down absolutely that every case of fever, however slight, occurring in a yellow-fever country should be looked on as a case of yellow fever, and treated accordingly, until it is proved not to be such.

HERBERT E. DURHAM.

YELLOWSTONE NATIONAL PARK, in the Rocky Mountains, United States of America.—A tract of country, 65 miles long and 55 miles wide; altitude 6,000 feet. Remarkable for its thousands of mineral springs, containing principally salts of calcium and silicon, with a temperature of 160° to 200° F.; and for its fifty geysers or hot springs, throwing up columns of water 50 to 500 feet in height. Largely utilised in chronic rheumatism and gout. See MINERAL WATERS.

Z

ZINC, Poisoning by.—SYNON.: Fr. *Empoisonnement par le Zinc*; Ger. *Zinkvergiftung*.

Poisoning by compounds of zinc is rare, if we except poisoning by the chloride (Sir W. Burnett's fluid), which acts as a corrosive poison, like the mineral acids (see POISONS). Zinc sulphate (white vitriol) is the only other salt of zinc of importance from a toxicological point of view; this salt has proved fatal in a few instances.

ANATOMICAL CHARACTERS.—These are of the same nature as those of the mineral irritants—gastro-intestinal inflammation, ecchymoses, and softening. Ecchymoses have also been observed in the pleura.

SYMPTOMS.—The symptoms of poisoning by zinc are similar to those produced by tartar emetic. They include an astringent, metallic, and burning taste in the mouth; early and violent vomiting; pain in the abdomen; purging; great prostration and anxiety; a small and feeble pulse; shallow respirations; cold perspirations; and collapse and exhaustion ending in death. The intellect is unaffected.

When taken in small doses, zinc produces a chronic form of poisoning, the symptoms of which are derangement of the digestive organs, and peripheral neuritis.

DIAGNOSIS.—In the absence of any history of the administration of zinc sulphate, the diagnosis cannot be made between this and other forms of irritant poisoning, such as by blue vitriol, except by the aid of chemical analysis.

PROGNOSIS.—The prognosis of zinc-poisoning is generally favourable.

TREATMENT.—Demulcent drinks, sedatives, and alcoholic stimulants should be immediately given. The administration of a solution of the common

sodium phosphate, largely diluted, is advisable. It acts as an excellent precipitant of zinc, in the form of an insoluble phosphate. Opiate enemata may prove serviceable.

THOMAS STEVENSON.

ZINC-WORKERS.—See OCCUPATION-DISEASES.

ZONA or ZOSTER (*zona*, ζώνη, a girdle).—SYNON.: Shingles; Fr. *Zona*; Ger. *Zoster*; *Gürtelrose*.

This term was originally applied only to that form of herpes which runs round one half of the trunk of the body, usually in the region of the waist. See HERPES ZOSTER.

ZYMOTIC : ZYME (ζυμάω, I ferment; ζύμη, a ferment).—SYNON.: Fr. *Zymotique*; *Zymase*; Ger. *Gährungs-fähig*; *Gährstoff*.—The terms *zyme*, *zymine*, *zymotic*, and *zymosis* were introduced by Dr. William Farr, in a Letter to the Registrar-General in 1842, and employed by him to denote in a general way the poison (and pathological processes excited by it) of 'epidemic, endemic, and contagious diseases.' In using the word ζύμη, he was careful to point out that he did not consider the morbid process to be absolutely identical with the ordinary phenomena of fermentation, and that he wished the terms *zymosis*, *zymotic*, &c., to be employed in English, 'not in the sense which they have in Greek, but as general designations of the morbid processes and their exciters.' With this qualification clearly expressed, the use of the root-form ζύμη has become general, not only in scientific literature, but also in the public press—almost invariably, however, in the adjectival form *zymotic*.

Fourteen years later (1856), in the *Sixteenth*

Annual Report of the Registrar-General, Dr. Farr described the diseases of the zymotic class as conveniently referable to four groups. These are: 1. The *Miasmatic*, diffusible through the air or water, attended by fevers of various forms; the matter by which they are communicated is derived from the human body, as in small-pox, or from the earth (as in ague). These two diseases are types of this class. 2. *Enthetic* diseases, which may properly be called *contagious*, being communicated by contact, puncture, or inoculation. Syphilis and glanders are types of this class. 3. The *Dietetic* diseases, which arise when the blood is supplied with improper or bad food. Scurvy and ergotism are the types of this class. 4. The *Parasitic* diseases, which attack especially dirty populations, and infest the skin, the intestinal canal, and all the structures of the body.

This classification, which does not now hold good, is quoted here because it continues to be spoken of. Modern pathology has necessitated its revision.

Recently, indeed, the word 'zymotic' has been restricted to the acute specific diseases, included under the first group (miasmatic) in the above classification; and at the present time it is in this limited sense that it is most commonly used.

Corresponding with the adjective *zymotic* is the substantive *zyme*. This is a useful name, by which we refer to the poisonous cause of zymotic diseases. It is simpler than the word *zymine*, originally proposed by Dr. Farr; and (what is much more important) to speak of the contagious poison as 'a zyme' does not imply the acceptance of any particular theory of disease; while, on the other hand, the use of the word 'germ' distinctly conveys the idea of some organised structure, itself the cause of the disease by subsequent growth and multiplication. See BACTERIA; and INFECTION.

The necessity for employing the word *zymosis* does not seem to be felt as yet; but the same reasons that lead us to speak of the agent as a zyme should also guide us to use *zymosis* in place of the more usual periphrases.

VICTOR HORSLEY.

ASHBY.—WORKS by **HENRY ASHBY, M.D., Lond., F.R.C.P.**,
*Physician to the General Hospital for Sick Children, Manchester; formerly
Demonstrator of Physiology, Liverpool School of Medicine.*

**NOTES ON PHYSIOLOGY FOR THE USE OF STUDENTS
PREPARING FOR EXAMINATION.** Seventh Edition,
thoroughly revised. With 148 Illustrations. 18mo, 5s.

HEALTH IN THE NURSERY. With 25 Illustrations. Crown 8vo,
3s. 6d.

**ASHBY AND WRIGHT. THE DISEASES OF CHILDREN,
MEDICAL AND SURGICAL.** By **HENRY ASHBY, M.D.**
Lond., F.R.C.P., Physician to the General Hospital for Sick Children,
Manchester; Lecturer and Examiner in Diseases of Children in the
Victoria University; and **G. A. WRIGHT, B.A., M.B. Oxon, F.R.C.S.**
Eng., Assistant Surgeon to the Manchester Royal Infirmary and Surgeon
to the Children's Hospital; formerly Examiner in Surgery in the Univer-
sity of Oxford. Enlarged and Improved Edition. With 217 Illustrations.
8vo, 25s.

BENNETT.—*WORKS* by WILLIAM H. BENNETT, F.R.C.S., Surgeon to St. George's Hospital; Member of the Board of Examiners, Royal College of Surgeons of England.

CLINICAL LECTURES ON VARICOSE VEINS OF THE LOWER EXTREMITIES. With 3 Plates. 8vo, 6s.

ON VARICOCELE: A PRACTICAL TREATISE. With 4 Tables and a Diagram. 8vo, 5s.

CLINICAL LECTURES ON ABDOMINAL HERNIA: chiefly in relation to Treatment, including the Radical Cure. With 12 Diagrams in the Text. 8vo, 8s. 6d.

ON VARIX, ITS CAUSES AND TREATMENT, WITH ESPECIAL REFERENCE TO THROMBOSIS: an Address delivered at the Inaugural Meeting of the Nottingham Medico-Chirurgical Society, Session 1898-9. 8vo, 3s. 6d.

ON THE USE OF MASSAGE AND EARLY PASSIVE MOVEMENTS IN RECENT FRACTURES, AND OTHER COMMON SURGICAL INJURIES, AND THE TREATMENT OF INTERNAL DERANGEMENTS OF THE KNEE-JOINT: Three Clinical Lectures delivered at St. George's Hospital. With 12 Illustrations. 8vo, 4s. 6d.

THE PRESENT POSITION OF THE TREATMENT OF SIMPLE FRACTURES OF THE LIMBS: an Address delivered in opening a Discussion at the Meeting of the British Medical Association held at Ipswich, August, 1900. To which is appended a Summary of the Opinions and Practice of about 300 Surgeons. 8vo, 2s. 6d.

BENTLEY. A TEXT-BOOK OF ORGANIC MATERIA MEDICA. Comprising a Description of the Vegetable and Animal Drugs of the British Pharmacopœia, with some others in common use. Arranged Systematically and Especially Designed for Students. By ROBERT BENTLEY, M.R.C.S. Eng., F.L.S. With 62 Illustrations on Wood. Crown 8vo, 7s. 6d.

BRODIE. THE ESSENTIALS OF EXPERIMENTAL PHYSIOLOGY. For the use of Students. By T. G. BRODIE, M.D., Lecturer on Physiology, St. Thomas's Hospital Medical School. With 2 Plates and 177 Illustrations. 8vo, 6s. 6d.

CABOT.—*WORKS* by RICHARD C. CABOT, M.D., Physician to Out-Patients, Massachusetts General Hospital.

A GUIDE TO THE CLINICAL EXAMINATION OF THE BLOOD FOR DIAGNOSTIC PURPOSES. With 3 Coloured Plates and 28 Illustrations in the Text. 8vo, 16s.

THE SERUM DIAGNOSIS OF DISEASE. With 31 Temperature Charts and 9 Illustrations. Royal 8vo, 7s. 6d.

CELLI. MALARIA ACCORDING TO THE NEW RESEARCHES.

By Professor ANGELO CELLI, Director of the Institute of Hygiene, University of Rome. Translated from the Second Italian Edition by JOHN JOSEPH EYRE, M.R.C.P., L.R.C.S. Irel., D.P.H. Cambridge. With an Introduction by Dr. PATRICK MANSON, Medical Adviser to the Colonial Office. With 3 Maps and 40 Illustrations. 8vo, 10s. 6d.

CHEYNE AND BURGHARD. A MANUAL OF SURGICAL TREATMENT.

By W. WATSON CHEYNE, M.B., F.R.C.S., F.R.S., Professor of Surgery in King's College, London; Surgeon to King's College Hospital, and the Children's Hospital, Paddington Green, etc.; and F. F. BURGHARD, M.D. and M.S. Lond., F.R.C.S., Teacher of Practical Surgery in King's College, London; Surgeon to King's College Hospital, and the Children's Hospital, Paddington Green, etc.

PROPOSED DIVISION OF WORK.

PART I. The Treatment of General Surgical Diseases, including inflammation, suppuration, ulceration, gangrene, wounds and their complications, infective diseases and tumours; the administration of anæsthetics. With 66 Illustrations. Royal 8vo, 10s. 6d.

PART II. The treatment of the Surgical Affections of the Tissues, including the skin and subcutaneous tissues, the nails, the lymphatic vessels and glands, the fasciæ, bursæ, muscles, tendons and tendon-sheaths, nerves, arteries and veins; deformities. With 141 Illustrations. Royal 8vo, 14s.

PART III. The treatment of the Surgical Affections of the Bones. Amputations. With 100 Illustrations. Royal 8vo, 12s.

PART IV. The treatment of the Surgical Affections of the Joints (including excisions) and the spine. With 38 Illustrations. Royal 8vo, 14s.

PART V. The treatment of the Surgical Affections of the head, face, neck, thorax and breast; throat, nose and ear. [*In preparation.*]

PART VI. The treatment of the Surgical Affections of the spine, the alimentary and genito-urinary systems. [*In preparation.*]

CLARKE.—WORKS by J. JACKSON CLARKE, M.B. Lond., F.R.C.S., Assistant-Surgeon to the North-West London Hospital, Pathologist and Curator of the Museum at St. Mary's Hospital.

POST-MORTEM EXAMINATIONS IN MEDICO-LEGAL AND ORDINARY CASES. With Special Chapters on the Legal Aspects of Post-Mortems, and on Certificates of Death. Fcap. 8vo, 2s. 6d.

SURGICAL PATHOLOGY AND PRINCIPLES. With 194 Illustrations. Crown 8vo, 10s. 6d.

COATS. A MANUAL OF PATHOLOGY. By JOSEPH COATS, M.D., late Professor of Pathology in the University of Glasgow. Fourth Edition. Revised throughout and Edited by LEWIS R. SUTHERLAND, M.D., Professor of Pathology, University of St. Andrews. With 490 Illustrations. 8vo, 31s. 6d.

* * A considerable portion of the work of revision necessary in the preparation of a Fourth Edition of the above text-book had been already accomplished by the Author, Professor Joseph Coats, in the four months immediately preceding his death. It is in response to his expressed wish that the editorial duties have been assumed by Dr. Lewis R. Sutherland.

COOKE.—*WORKS* by THOMAS COOKE, F.R.C.S. Eng., B.A., B.Sc., M.D. Paris, late Senior Assistant Surgeon to the Westminster Hospital.

TABLETS OF ANATOMY. Being a Synopsis of demonstrations given in the Westminster Hospital Medical School. Eleventh Edition in three Parts, thoroughly brought up to date, and with over 700 Illustrations from all the best sources, British and Foreign. Post 4to. Part I. The Bones, 7s. 6d. net; Part II. Limbs, Abdomen, Pelvis, 10s. 6d. net; Part III. Head and Neck, Thorax, Brain, 10s. 6d. net.

APHORISMS IN APPLIED ANATOMY AND OPERATIVE SURGERY. Including 100 Typical *viva voce* Questions on Surface Marking, etc. Crown 8vo, 3s. 6d.

DISSECTION GUIDES. Aiming at Extending and Facilitating such Practical Work in Anatomy as will be specially useful in connection with an ordinary Hospital Curriculum. 8vo, 10s. 6d.

CURTIS. THE ESSENTIALS OF PRACTICAL BACTERIOLOGY: an Elementary Laboratory Book for Students and Practitioners. By H. J. CURTIS, B.S. and M.D. Lond., F.R.C.S., late Surgical Registrar, University College Hospital; formerly Assistant to the Professor of Pathology, University College, London. With 133 Illustrations. 8vo, 9s.

DAKIN. A MANUAL OF MIDWIFERY. By WILLIAM RADFORD DAKIN, M.D., F.R.C.P., Obstetrical Physician and Lecturer on Midwifery at St. George's Hospital, Examiner in Midwifery and Diseases of Women on the Conjoint Board of the Royal Colleges of Physicians and Surgeons in England, etc. With 393 Illustrations. 8vo, 18s.

DICKINSON.—*WORKS* by W. HOWSHIP DICKINSON, M.D. Cantab., F.R.C.P., Consulting Physician to St. George's Hospital; Consulting Physician to the Hospital for Sick Children, etc.

ON RENAL AND URINARY AFFECTIONS. Complete in Three Parts, 8vo, with 12 Plates, and 122 Woodcuts. £3 4s. 6d.

THE TONGUE AS AN INDICATION OF DISEASE; being the Lumleian Lectures delivered at the Royal College of Physicians in March, 1888. 8vo, 7s. 6d.

OCCASIONAL PAPERS ON MEDICAL SUBJECTS, 1855-1896. 8vo, 12s.

THE HARVEIAN ORATION ON HARVEY IN ANCIENT AND MODERN MEDICINE. Crown 8vo, 2s. 6d.

MEDICINE OLD AND NEW: an Introductory Address delivered on the occasion of the Opening of the Winter Session, 1899-1900, at St. George's Hospital Medical School, on 2nd October, 1899. Crown 8vo, 2s. 6d.

DUCKWORTH. *WORKS* by Sir DYCE DUCKWORTH, M.D., LL.D., Fellow and Treasurer of the Royal College of Physicians, etc.

THE SEQUELS OF DISEASE: being the Lumleian Lectures delivered in the Royal College of Physicians, 1896. Together with observations on Prognosis in Disease. 8vo, 10s. 6d.

THE INFLUENCE OF CHARACTER AND RIGHT JUDGMENT IN MEDICINE: the Harveian Oration, delivered before the Royal College of Physicians, 11th October, 1898. Post 4to, 2s. 6d.

ERICHSEN. THE SCIENCE AND ART OF SURGERY : A TREATISE ON SURGICAL INJURIES, DISEASES AND OPERATIONS. By Sir JOHN ERIC ERICHSEN, Bart., F.R.S., LL.D. Edin., Hon. M.Ch. and F.R.C.S. Ireland. Tenth Edition. Revised by the late MARCUS BECK, M.S. and M.B. Lond., F.R.C.S., Surgeon to University College Hospital, and Professor of Surgery in University College, London ; and by RAYMOND JOHNSON, M.B. and B.S. Lond., F.R.C.S., Assistant Surgeon to University College Hospital, etc. Illustrated by nearly 1,000 Engravings on Wood. 2 vols. Royal 8vo, 48s.

FOWLER AND GODLEE. THE DISEASES OF THE LUNGS. By JAMES KINGSTON FOWLER, M.A., M.D., F.R.C.P., Physician to the Middlesex Hospital and to the Hospital for Consumption and Diseases of the Chest, Brompton ; late Examiner in Medicine at the University of Cambridge, and on the Conjoint Examining Board in England ; and RICKMAN JOHN GODLEE, M.S., F.R.C.S., Honorary Surgeon-in-Ordinary to His Majesty, Fellow and Professor of Clinical Surgery, University College, London ; Surgeon to University College Hospital and to the Hospital for Consumption and Diseases of the Chest, Brompton ; Surgeon-in-Ordinary, to Her Majesty's Household. With 160 Illustrations. 8vo, 25s.

FRANKLAND. MICRO-ORGANISMS IN WATER, THEIR SIGNIFICANCE, IDENTIFICATION AND REMOVAL. Together with an Account of the Bacteriological Methods Involved in their Investigation. Specially Designed for the Use of those connected with the Sanitary Aspects of Water Supply. By Professor PERCY FRANKLAND, Ph.D., B.Sc. Lond., F.R.S., Fellow of the Chemical Society ; and Mrs. PERCY FRANKLAND, Joint Author of "Studies on Some New Micro-Organisms Obtained from Air". With 2 Plates and numerous Diagrams. 8vo, 16s. net.

GARROD.—*WORKS* by Sir ALFRED BARING GARROD, M.D., F.R.S., etc. ; Consulting Physician to King's College Hospital ; late Vice-President of the Royal College of Physicians.

A TREATISE ON GOUT AND RHEUMATIC GOUT (RHEUMATOID ARTHRITIS). Third Edition, thoroughly Revised and Enlarged ; with 6 Plates, comprising 21 figures (14 Coloured), and 27 Illustrations engraved on Wood. 8vo, 21s.

THE ESSENTIALS OF MATERIA MEDICA AND THERAPEUTICS. The Fourteenth Edition, Revised and Edited, under the Supervision of the Author, by NESTOR TIRARD, M.D. Lond., F.R.C.P., Professor of Materia Medica and Therapeutics in King's College, London, etc. Crown 8vo, 12s. 6d.

GOODSALL AND MILES. DISEASES OF THE ANUS AND RECTUM. By D. H. GOODSALL, F.R.C.S., Senior Surgeon Metropolitan Hospital, Senior Surgeon (late House Surgeon) St. Mark's Hospital ; and W. ERNEST MILES, F.R.C.S., Assistant Surgeon to the Cancer Hospital, Assistant Surgeon to the Gordon Hospital, etc. (In Two Parts).

PART I.—Anatomy of the Ano-rectal Region—General Diagnosis—Abscess—Ano-rectal Fistula—Recto-urethral, Recto-vesical and Recto-vaginal Fistulae—Sinus over the Sacro-coccygeal Articulation—Fissure—Hæmorrhoids (External and Internal). With 91 Illustrations. 8vo, 7s. 6d. net.

PART II.—(Nearly ready).

GRAY. ANATOMY, DESCRIPTIVE AND SURGICAL. By HENRY GRAY, F.R.S., late Lecturer on Anatomy at St. George's Hospital. The Fourteenth Edition, re-edited by T. PICKERING PICK, Surgeon to St. George's Hospital; Inspector of Anatomy in England and Wales; late Member of the Court of Examiners, Royal College of Surgeons of England. With 705 large Woodcut Illustrations, a large proportion of which are Coloured, the Arteries being coloured red, the Veins blue, and the Nerves yellow. The attachments of the muscles to the bones, in the section on Osteology, are also shown in coloured outline. Royal 8vo, 36s.

HALLIBURTON.—*WORKS* by W. D. HALLIBURTON, M.D., F.R.S., F.R.C.P., *Professor of Physiology in King's College, London.*

A TEXT-BOOK OF CHEMICAL PHYSIOLOGY AND PATHOLOGY. With 104 Illustrations. 8vo, 28s.

THE ESSENTIALS OF CHEMICAL PHYSIOLOGY. For the Use of Students. Third Edition. With 77 Illustrations. 8vo, 5s.

* * This book treats of the subject in the same way as Prof. SCHÄFER's "Essentials" treats of Histology. It contains a number of elementary and advanced practical lessons, followed in each case by a brief descriptive account of the facts related to the exercises which are intended to be performed by each member of the class.

LANG. THE METHODICAL EXAMINATION OF THE EYE. Being Part I. of a Guide to the Practice of Ophthalmology for Students and Practitioners. By WILLIAM LANG, F.R.C.S. Eng., Surgeon to the Royal London Ophthalmic Hospital, Moorfields, etc. With 15 Illustrations. Crown 8vo, 3s. 6d.

LIVEING. HANDBOOK ON DISEASES OF THE SKIN. With especial reference to Diagnosis and Treatment. By ROBERT LIVEING, M.A. and M.D. Cantab., F.R.C.P. Lond., etc., Physician to the Department for Diseases of the Skin at the Middlesex Hospital, etc. Fifth Edition, revised and enlarged. Fcap. 8vo, 5s.

LUFF. TEXT-BOOK OF FORENSIC MEDICINE AND TOXICOLOGY. By ARTHUR P. LUFF, M.D., B.Sc. Lond., Physician in Charge of Out-Patients and Lecturer on Medical Jurisprudence and Toxicology in St. Mary's Hospital; Examiner in Forensic Medicine in the University of London; External Examiner in Forensic Medicine in the Victoria University; Official Analyst to the Home Office. With numerous Illustrations. 2 vols., Crown 8vo, 24s.

MOORE. ELEMENTARY PHYSIOLOGY. By BENJAMIN MOORE, M.A., Lecturer on Physiology at the Charing Cross Hospital Medical School. With 125 Illustrations. Crown 8vo, 3s. 6d.

NEWMAN. ON THE DISEASES OF THE KIDNEY AMENABLE TO SURGICAL TREATMENT. Lectures to Practitioners. By DAVID NEWMAN, M.D., Surgeon to the Western Infirmary Out-Door Department; Pathologist and Lecturer on Pathology at the Glasgow Royal Infirmary; Examiner in Pathology in the University of Glasgow; Vice-President Glasgow Pathological and Clinical Society. 8vo, 8s.

NOTTER AND FIRTH. HYGIENE. By J. L. NOTTER, M.A., M.D., Professor of Hygiene in the Army Medical School, Netley; Colonel Royal Army Medical Corps; and R. H. FIRTH, F.R.C.S., late Assistant Professor of Hygiene in the Army Medical School, Netley; Major Royal Army Medical Corps. With 93 Illustrations. Crown 8vo, 3s. 6d.

PICK. SURGERY: A TREATISE FOR STUDENTS AND PRACTITIONERS. By T. PICKERING PICK, Consulting Surgeon to St. George's Hospital; Senior Surgeon to the Victoria Hospital for Children; H.M. Inspector of Anatomy in England and Wales. With 441 Illustrations. Medium 8vo, 25s.

POOLE. COOKERY FOR THE DIABETIC. By W. H. and Mrs. POOLE. With Preface by Dr. PAVY. Fcap. 8vo, 2s. 6d.

POORE.—WORKS by GEORGE VIVIAN POORE, M.D., F.R.C.P.

ESSAYS ON RURAL HYGIENE. Crown 8vo, 6s. 6d.

THE DWELLING HOUSE. With 36 Illustrations. Crown 8vo, 3s. 6d.

QUAIN. A DICTIONARY OF MEDICINE; Including General Pathology, General Therapeutics, Hygiene and the Diseases of Women and Children. By Various Writers. Edited by Sir RICHARD QUAIN, Bart., M.D. Lond., LL.D. Edin. (Hon.), F.R.S., late President of the General Medical Council, Member of the Senate of the University of London, etc. Assisted by FREDERICK THOMAS ROBERTS, M.D. Lond., B.Sc., Fellow of the Royal College of Physicians, Fellow of University College, Professor of Materia Medica and Therapeutics, University College, etc.; and J. MITCHELL BRUCE, M.A. Abdn., M.D. Lond., Fellow of the Royal College of Physicians of London, Physician and Lecturer on the Principles and Practice of Medicine, Charing Cross Hospital, etc. New Edition, Revised throughout and Enlarged. In 2 vols. Medium 8vo, cloth, red edges, 40s. net.

QUAIN. QUAIN'S (JONES) ELEMENTS OF ANATOMY.

New Edition. Edited by EDWARD ALBERT SCHÄFER, F.R.S., Professor of Physiology in the University of Edinburgh; and GEORGE DANCER THANE, Professor of Anatomy in University College, London. In 3 vols.

* * The several parts of this work form COMPLETE TEXT-BOOKS OF THEIR RESPECTIVE SUBJECTS. They can be obtained separately as follows:—

VOL. I., PART I. EMBRYOLOGY. By E. A. SCHÄFER, F.R.S. With 200 Illustrations. Royal 8vo, 9s.

VOL. I., PART II. GENERAL ANATOMY OR HISTOLOGY.

By E. A. SCHÄFER, F.R.S. With 291 Illustrations. Royal 8vo, 12s. 6d.
[Continued.]

QUAIN (ANATOMY)—*continued*.

VOL. II., PART I. OSTEOLOGY — ARTHROLOGY. By G. D. THANE. With 224 Illustrations. Royal 8vo, 11s.

VOL. II., PART II. MYOLOGY — ANGIOLOGY. By G. D. THANE. With 199 Illustrations. Royal 8vo, 16s.

VOL. III., PART I. THE SPINAL CORD AND BRAIN. By E. A. SCHÄFER, F.R.S. With 139 Illustrations. Royal 8vo, 12s. 6d.

VOL. III., PART II. THE NERVES. By G. D. THANE. With 102 Illustrations. Royal 8vo, 9s.

VOL. III., PART III. THE ORGANS OF THE SENSES. By E. A. SCHÄFER, F.R.S. With 178 Illustrations. Royal 8vo, 9s.

VOL. III., PART IV. SPLANCHNOLOGY. By E. A. SCHÄFER, F.R.S., and JOHNSON SYMINGTON, M.D. With 337 Illustrations. Royal, 8vo, 16s.

APPENDIX. SUPERFICIAL AND SURGICAL ANATOMY. By Professor G. D. THANE and Professor R. J. GODLEE, M.S. With 29 Illustrations. Royal 8vo, 6s. 6d.

SCHÄFER. THE ESSENTIALS OF HISTOLOGY: Descriptive and Practical. For the Use of Students. By E. A. SCHÄFER, LL.D., F.R.S., Professor of Physiology in the University of Edinburgh; Editor of the Histological Portion of Quain's "Anatomy". Illustrated by nearly 400 Figures. Fifth Edition, Revised and Enlarged. 8vo, 8s.

SCHENK. MANUAL OF BACTERIOLOGY. For Practitioners and Students. With especial reference to Practical Methods. By Dr. S. L. Schenk, Professor (Extraordinary) in the University of Vienna. Translated from the German, with an Appendix, by W. R. DAWSON, B.A., M.D. Univ. Dub.; late University Travelling Prizeman in Medicine. With 100 Illustrations, some of which are coloured. 8vo, 10s. net.

SMALE AND COLYER. DISEASES AND INJURIES OF THE TEETH, including Pathology and Treatment: a Manual of Practical Dentistry for Students and Practitioners. By MORTON SMALE, M.R.C.S., L.S.A., L.D.S., Dental Surgeon to St. Mary's Hospital, Dean of the School, Dental Hospital of London, etc.; and J. F. COLYER, L.R.C.P., M.R.C.S., L.D.S., Assistant Dental Surgeon to Charing Cross Hospital and Assistant Dental Surgeon to the Dental Hospital of London. With 334 Illustrations. Large Crown 8vo, 15s.

SMITH (H. F.). THE HANDBOOK FOR MIDWIVES. By HENRY FLY SMITH, B.A., M.B. Oxon., M.R.C.S. Second Edition. With 41 Woodcuts. Crown 8vo, 5s.

STEVENSON. WOUNDS IN WAR: the Mechanism of their Production and their Treatment. By Surgeon-Colonel W. F. STEVENSON (Army Medical Staff), A.B., M.B., M.Ch. Dublin University; Professor of Military Surgery, Army Medical School, Netley. With 86 Illustrations. 8vo, 18s.

TAPPEINER. INTRODUCTION TO CHEMICAL METHODS OF CLINICAL DIAGNOSIS. By Dr. H. TAPPEINER, Professor of Pharmacology and Principal of the Pharmacological Institute of the University of Munich. Translated from the Sixth German Edition, with an Appendix on Micro-Biological Methods of Diagnosis, by EDMOND J. McWEENEY, M.A., M.D. Royal Univ. of Ireland, L.R.C.P.I., etc. With 22 Illustrations. Crown 8vo, 3s. 6d.

THORNTON. HUMAN PHYSIOLOGY. By JOHN THORNTON, M.A., Author of "Elementary Physiography," "Advanced Physiography," etc. With 267 Illustrations, some of which are Coloured. Crown 8vo, 6s.

TIRARD. DIPHTHERIA AND ANTITOXIN. By NESTOR TIRARD, M.D. Lond., Fellow of the Royal College of Physicians; Fellow of King's College, London; Professor of Materia Medica and Therapeutics at King's College; Physician to King's College Hospital; and Senior Physician to the Evelina Hospital for Sick Children. 8vo, 7s. 6d.

WAKLEY. THE LIFE AND TIMES OF THOMAS WAKLEY. Founder and First Editor of the *Lancet*, Member of Parliament for Finsbury, and Coroner for West Middlesex. By S. SQUIRE SPRIGGE, M.B. Cantab. With 2 Portraits. 8vo, 6s.

WALLER.—WORKS by AUGUSTUS D. WALLER, M.D., Lecturer on Physiology at St. Mary's Hospital Medical School, London; late External Examiner at the Victorian University.

AN INTRODUCTION TO HUMAN PHYSIOLOGY. Third Edition, Revised. With 314 Illustrations. 8vo, 18s.

EXERCISES IN PRACTICAL PHYSIOLOGY.

PART I.—*Elementary Physiological Chemistry.* By AUGUSTUS D. WALLER and W. LEGGE SYMES. 8vo, sewed, 1s. net.

PART II.—*In the Press.*

PART III.—*Physiology of the Nervous System; Electro-Physiology.* 8vo, 2s. 6d. net.

LECTURES ON PHYSIOLOGY.

FIRST SERIES.—*On Animal Electricity.* 8vo, 5s. net.

WEICHSELBAUM. THE ELEMENTS OF PATHOLOGICAL HISTOLOGY, with Special Reference to Practical Methods. By Dr. ANTON WEICHSELBAUM, Professor of Pathology in the University of Vienna. Translated by W. R. DAWSON, M.D. Dub., Demonstrator of Pathology in the Royal College of Surgeons, Ireland; late Medical Travelling Prizeman of Dublin University, etc. With 221 Figures, partly in Colours, a Chromo-Lithographic Plate and 7 Photographic Plates. Royal 8vo, 21s. net.

WILKS AND MOXON. LECTURES ON PATHOLOGICAL ANATOMY. By Sir SAMUEL WILKS, Bart., M.D., F.R.S., President of the Royal College of Physicians; and the late WALTER MOXON, M.D., F.R.C.P., Physician to, and sometime Lecturer on Pathology at, Guy's Hospital. Third Edition, thoroughly Revised. By Sir SAMUEL WILKS, Bart., M.D., LL.D., F.R.S. 8vo, 18s.

Veterinary Medicine, etc.

FITZWYGRAM. HORSES AND STABLES. By Major-General Sir F. FITZWYGRAM, Bart. With 56 pages of Illustrations. 8vo.

STEEL.—WORKS by JOHN HENRY STEEL, F.R.C.V.S., F.Z.S., A.V.D., late Professor of Veterinary Science and Principal of Bombay Veterinary College.

A TREATISE ON THE DISEASES OF THE DOG; being a Manual of Canine Pathology. Especially adapted for the use of Veterinary Practitioners and Students. 88 Illustrations. 8vo, 10s. 6d.

A TREATISE ON THE DISEASES OF THE OX; being a Manual of Bovine Pathology. Especially adapted for the use of Veterinary Practitioners and Students. 2 Plates and 117 Woodcuts. 8vo, 15s.

A TREATISE ON THE DISEASES OF THE SHEEP; being a Manual of Ovine Pathology for the use of Veterinary Practitioners and Students. With Coloured Plate and 99 Woodcuts. 8vo, 12s.

OUTLINES OF EQUINE ANATOMY: a Manual for the use of Veterinary Students in the Dissecting Room. Crown 8vo, 7s. 6d.

YOUATT.—WORKS by WILLIAM YOUATT.

THE HORSE. Revised and Enlarged by W. WATSON, M.R.C.V.S. With 52 Woodcuts. 8vo, 7s. 6d.

THE DOG. Revised and Enlarged. With 33 Woodcuts. 8vo, 6s.

General Scientific Works.

BEDDARD. THE STRUCTURE AND CLASSIFICATION OF BIRDS. By FRANK E. BEDDARD, M.A., F.R.S., Prosector and Vice-Secretary of the Zoological Society of London. With 252 Illustrations. 8vo, 21s. net.

BENNETT AND MURRAY. A HANDBOOK OF CRYPTOGAMIC BOTANY. By A. W. BENNETT, M.A., B.Sc., F.L.S., and GEORGE R. MILNE MURRAY, F.L.S. With 378 Illustrations. 8vo, 16s.

CLODD.—WORKS by EDWARD CLODD, Author of “*The Childhood of the World*,” etc.

THE STORY OF CREATION. A Plain Account of Evolution. With 77 Illustrations. Crown 8vo, 3s. 6d.

A PRIMER OF EVOLUTION: being a Popular Abridged Edition of “*The Story of Creation*”. With Illustrations. Fcap. 8vo, 1s. 6d.

CROOKES. SELECT METHODS IN CHEMICAL ANALYSIS (chiefly inorganic). By Sir W. CROOKES, F.R.S., V.P.C.S. Editor of “*The Chemical News*”. Third Edition, re-written and enlarged. Illustrated with 67 Woodcuts. 8vo, 21s. net.

CURTIS. A TEXT-BOOK OF GENERAL BOTANY. By CARLTON C. CURTIS, A.M., Ph.D., Tutor in Botany in Columbia University. With 87 Illustrations. Royal 8vo, 12s. net.

GANOT. ELEMENTARY TREATISE ON PHYSICS; Experimental and Applied, for the use of Colleges and Schools. Translated and edited from GANOT's *Éléments de Physique* (with the Author's sanction) by E. ATKINSON, Ph.D., F.C.S., formerly Professor of Experimental Science, Staff College, Sandhurst. Fifteenth Edition, revised and enlarged, with 9 Coloured Plates and 1,057 Woodcuts. Large crown 8vo, 15s.

NATURAL PHILOSOPHY FOR GENERAL READERS AND YOUNG PEOPLE; Translated and Edited from GANOT's *Cours Élémentaire de Physique* (with the Author's sanction) by E. ATKINSON, Ph.D., F.C.S. Ninth Edition, carefully revised by A. W. REINOLD, M.A., F.R.S., Professor of Physics in the Royal Naval College, Greenwich; with 7 Plates, 632 Woodcuts, and an Appendix of Questions. Crown 8vo, 7s. 6d.

GOODEVE.—WORKS by T. M. GOODEVE, M.A., Barrister-at-Law; formerly Professor of Mechanics at the Normal School of Science and the Royal School of Mines.

PRINCIPLES OF MECHANICS. New Edition, re-written and enlarged. With 253 Woodcuts and numerous Examples. Crown 8vo, 6s.

THE ELEMENTS OF MECHANISM. New Edition, re-written and enlarged. With 357 Woodcuts. Crown 8vo, 6s.

A MANUAL OF MECHANICS: an Elementary Text-Book for Students of Applied Mechanics. With 138 Illustrations and Diagrams, and 141 Examples taken from the Science Department Examination Papers, with Answers. Fcap. 8vo, 2s. 6d.

HELMHOLTZ.—*WORKS* by **HERMANN L. F. HELMHOLTZ**,
M.D., late Professor of Physics in the University of Berlin.

ON THE SENSATIONS OF TONE AS A PHYSIOLOGICAL BASIS FOR THE THEORY OF MUSIC. Second English Edition; with numerous additional notes and a new Additional Appendix, bringing down information to 1885, and specially adapted to the use of Musical Students. By **ALEXANDER J. ELLIS**, B.A., F.R.S., F.S.A., etc., formerly Scholar of Trinity College, Cambridge. With 68 Figures engraved on Wood, and 42 Passages in Musical Notes. Royal 8vo, 28s.

POPULAR LECTURES ON SCIENTIFIC SUBJECTS. With 68 Woodcuts. 2 vols. Crown 8vo, 3s. 6d. each.

HERSCHEL. **OUTLINES OF ASTRONOMY.** By Sir **JOHN F. W. HERSCHEL**, Bart., K.H., etc., Member of the Institute of France. Twelfth Edition, with 9 Plates, and numerous Diagrams. 8vo, 12s.

HOFF. **THE ARRANGEMENT OF ATOMS IN SPACE.** By **J. H. VAN 'T HOFF**. Second, Revised and Enlarged Edition. With a Preface by **JOHANNES WISLICENUS**, Professor of Chemistry at the University of Leipzig; and an Appendix, "Stereochemistry among Inorganic Substances," by **ALFRED WERNER**, Professor of Chemistry at the University of Zürich. Translated and Edited by **ARNOLD EILOART**. Crown 8vo, 6s. 6d.

HUDSON AND GOSSE. **THE ROTIFERA OR "WHEEL ANIMALCULES".** By **C. T. HUDSON**, LL.D., and **P. H. GOSSE**, F.R.S. With 30 Coloured and 4 Uncoloured Plates. In 6 Parts. 4to, price 10s. 6d. each; Supplement, 12s. 6d. Complete in Two Volumes, with Supplement, 4to, £4 4s.

* * The Plates in the Supplement contain figures of almost all the Foreign Species, as well as of the British Species, that have been discovered since the original publication of Vols. I. and II.

JOUBERT. **ELEMENTARY TREATISE ON ELECTRICITY AND MAGNETISM.** Founded on **JOUBERT'S** "*Traité Élémentaire d'Electricité*". By **G. C. FOSTER**, F.R.S., Quain Professor of Physics in University College, London; and **E. ATKINSON**, Ph.D., formerly Professor of Experimental Science in the Staff College. With 381 Illustrations. Crown 8vo, 7s. 6d.

KOLBE. **A SHORT TEXT-BOOK OF INORGANIC CHEMISTRY.** By **Dr. HERMANN KOLBE**, late Professor of Chemistry in the University of Leipzig. Translated and Edited by **T. S. HUMPHIDGE**, Ph.D., B.Sc. Lond., late Professor of Chemistry and Physics in the University College of Wales, Aberystwyth. New Edition. Revised by **H. LLOYD-SNAPE**, Ph.D., D.Sc. Lond., Professor of Chemistry in the University College of Wales, Aberystwyth. With a Coloured Table of Spectra and 66 Woodcuts. Crown 8vo, 8s. 6d.

LARDEN. **ELECTRICITY FOR PUBLIC SCHOOLS AND COLLEGES.** With numerous Questions and Examples with Answers, and 214 Illustrations and Diagrams. By **W. LARDEN**, M.A. Crown 8vo, 6s.

LINDLEY AND MOORE. THE TREASURY OF BOTANY, OR POPULAR DICTIONARY OF THE VEGETABLE KINGDOM : with which is incorporated a Glossary of Botanical Terms. Edited by J. LINDLEY, M.D., F.R.S., and T. MOORE, F.L.S. With 20 Steel Plates and numerous Woodcuts. 2 Parts. Fcap. 8vo, 12s.

LOWELL. MARS. By PERCIVAL LOWELL, Fellow American Academy, Member Royal Asiatic Society, Great Britain and Ireland, etc. With 24 Plates. 8vo, 12s. 6d.

* * The book is written in a style suitable for the general reader, and the most recent speculations as to the planet being inhabited, the possible canals, oases, etc., are discussed.

MARTIN. NAVIGATION AND NAUTICAL ASTRONOMY. Compiled by Staff-Commander W. R. MARTIN, R.N., Instructor in Surveying, Navigation and Compass Adjustment ; Lecturer on Meteorology at the Royal Naval College, Greenwich. Sanctioned for use in the Royal Navy by the Lords Commissioners of the Admiralty. Royal 8vo, 18s.

MENDELÉEFF. THE PRINCIPLES OF CHEMISTRY. By D. MENDELÉEFF. Translated from the Russian (Sixth Edition) by GEORGE KAMENSKY, A.R.S.M., of the Imperial Mint, St. Petersburg, and Edited by T. A. LAWSON, B.Sc., Ph.D., Fellow of the Institute of Chemistry. With 96 Diagrams and Illustrations. 2 vols. 8vo, 36s.

MEYER. OUTLINES OF THEORETICAL CHEMISTRY. By LOTHAR MEYER, Professor of Chemistry in the University of Tübingen. Translated by Professors P. PHILLIPS BEDSON, D.Sc., and W. CARLETON WILLIAMS, B.Sc. 8vo, 9s.

MEYER. THE KINETIC THEORY OF GASES. Elementary Treatise with Mathematical Appendices. By Dr. OSKAR EMIL MEYER, Professor of Physics at the University of Breslau. Second Revised Edition. Translated by ROBERT E. BAYNES, M.A., Student of Christ Church, Oxford, and Dr. Lee's Reader in Physics. 8vo, 15s. net.

MORGAN. ANIMAL BIOLOGY. An Elementary Text-Book. By C. LLOYD MORGAN, Principal of University College, Bristol. With numerous Illustrations. Crown 8vo, 8s. 6d.

OSTWALD. SOLUTIONS. By W. OSTWALD, Professor of Chemistry in the University of Leipzig. Being the Fourth Book, with some additions, of the Second Edition of Ostwald's "Lehrbuch der Allgemeinen Chemie". Translated by M. M. PATTISON MUIR, Professor of Gonville and Caius College, Cambridge. 8vo, 10s. 6d.

PROCTOR.—WORKS by **RICHARD A. PROCTOR.**

LIGHT SCIENCE FOR LEISURE HOURS ; Familiar Essays on Scientific Subjects, Natural Phenomena, etc. Vol. I. Crown 8vo, 3s. 6d.

THE ORBS AROUND US ; a Series of Essays on the Moon and Planets, Meteors and Comets. With Chart and Diagrams. Crown 8vo, 3s. 6d.

OTHER WORLDS THAN OURS ; The Plurality of Worlds Studied under the Light of Recent Scientific Researches. With 14 Illustrations. Crown 8vo, 3s. 6d.

THE MOON ; her Motions, Aspects, Scenery and Physical Condition. With Plates, Charts, Woodcuts and Lunar Photographs. Crown 8vo, 3s. 6d.

LARGER STAR ATLAS for the Library, in 12 Circular Maps, with Introduction and 2 Index Pages. Folio, 15s., or Maps only, 12s. 6d.

NEW STAR ATLAS for the Library, the School and the Observatory, in 12 Circular Maps (with 2 Index Plates). Crown 8vo, 5s.

OTHER SUNS THAN OURS : a Series of Essays on Suns—Old, Young and Dead. With other Science Gleanings, Two Essays on Whist, and Correspondence with Sir John Herschel. With 9 Star-Maps and Diagrams. Crown 8vo, 3s. 6d.

HALF - HOURS WITH THE TELESCOPE : a Popular Guide to the Use of the Telescope as a Means of Amusement and Instruction. With 7 Plates. Fcap. 8vo, 2s. 6d.

THE SOUTHERN SKIES : a Plain and Easy Guide to the Constellations of the Southern Hemisphere. Showing in 12 Maps the Position of the principal Star-Groups night

after night throughout the year. With an Introduction and a separate Explanation of each Map. True for every Year. 4to, 5s.

MYTHS AND MARVELS OF ASTRONOMY. Crown 8vo, 3s. 6d.

HALF - HOURS WITH THE STARS : a Plain and Easy Guide to the Knowledge of the Constellations. Showing in 12 Maps the position of the principal Star-Groups night after night throughout the Year. With Introduction and a separate Explanation of each Map. True for every Year. 4to, 3s. 6d.

THE STARS IN THEIR SEASONS. An Easy Guide to a Knowledge of the Star Groups, in 12 large Maps. Imperial 8vo, 5s.

OUR PLACE AMONG INFINITIES : a Series of Essays contrasting our Little Abode in Space and Time with the Infinities around Us. Crown 8vo, 3s. 6d.

ROUGH WAYS MADE SMOOTH. Familiar Essays on Scientific Subjects. Crown 8vo, 3s. 6d.

THE EXPANSE OF HEAVEN. Essays on the Wonders of the Firmament. Crown 8vo, 3s. 6d.

PLEASANT WAYS IN SCIENCE. Crown 8vo, 3s. 6d.

NATURE STUDIES. By GRANT ALLEN, A. WILSON, T. FOSTER, E. CLODD and R. A. PROCTOR. Crown 8vo, 3s. 6d.

LEISURE READINGS. By E. CLODD, A. WILSON, T. FOSTER, A. C. RUNYARD and R. A. PROCTOR. Crown 8vo, 3s. 6d.

STRENGTH : How to get Strong and keep Strong, with Chapters on Rowing and Swimming, Fat, Age and the Waist. With 9 Illustrations. Crown 8vo, 2s.

REYNOLDS. EXPERIMENTAL CHEMISTRY for Junior Students.

By J. EMERSON REYNOLDS, M.D., F.R.S., Professor of Chemistry, Univ. of Dublin. Fcap. 8vo, with numerous Woodcuts.

PART I.—Introductory, 1s. 6d. **PART III.**—Metals and Allied Bodies, 3s. 6d.

PART II.—Non-Metals, 2s. 6d. **PART IV.**—Chemistry of Carbon Compounds, 4s.

ROMANES.—*WORKS* by **GEORGE JOHN ROMANES, M.A., LL.D., F.R.S.**

DARWIN, AND AFTER DARWIN : an Exposition on the Darwinian Theory, and a Discussion on Post-Darwinian Questions. Part I. **THE DARWINIAN THEORY.** With Portrait of Darwin and 125 Illustrations. Crown 8vo, 10s. 6d. Part II. **POST-DARWINIAN QUESTIONS : Heredity and Utility.** With Portrait of the Author and 5 Illustrations. Crown 8vo, 10s. 6d. Part III. **POST-DARWINIAN QUESTIONS : ISOLATION AND PHYSIOLOGICAL SELECTION.** Crown 8vo, 5s.

AN EXAMINATION OF WEISMANNISM. Crown 8vo, 6s.

ESSAYS. Edited by C. LLOYD MORGAN, Principal of University College, Bristol. Crown 8vo, 6s.

CONTENTS : Primitive Natural History—The Darwinian Theory of Instinct—Man and Brute—Mind in Men and Animals—Origin of Human Faculty—Mental Differences between Men and Women—What is the Object of Life?—Recreation—Hypnotism—Hydrophobia and the Muzzling Order.

SLINGO AND BROOKER. **ELECTRICAL ENGINEERING FOR ELECTRIC-LIGHT ARTISANS AND STUDENTS.** (Embracing those branches prescribed in the Syllabus issued by the City and Guilds Technical Institute.) By W. SLINGO and A. BROOKER. With 371 Illustrations. Crown 8vo, 12s.

SORAUER. **A POPULAR TREATISE ON THE PHYSIOLOGY OF PLANTS.** For the Use of Gardeners or for Students of Horticulture and of Agriculture. By Dr. PAUL SORAUER, Director of the Experimental Station at the Royal Pomological Institute in Proskau (Silesia). Translated by F. E. WEISS, B.Sc., F.L.S., Professor of Botany at the Owens College, Manchester. With 33 Illustrations. 8vo, 9s. net.

THORPE. **A DICTIONARY OF APPLIED CHEMISTRY.** By T. E. THORPE, C.B., B.Sc. Vict., Ph.D., F.R.S., Treas. C.S., Director of Government Laboratories, London. Assisted by Eminent Contributors. To be published in 3 vols. 8vo. Vols. I. and II., £2 2s. each ; Vol. III., £3 3s.

TILDEN. **A SHORT HISTORY OF THE PROGRESS OF SCIENTIFIC CHEMISTRY IN OUR OWN TIMES.** By WILLIAM A. TILDEN, D.Sc. Lond., D.Sc. Dub., F.R.S., Fellow of the University of London, Professor of Chemistry in the Royal College of Science, London. Crown 8vo, 5s. net.

TUBEUF. **DISEASES OF PLANTS DUE TO CRYPTOGAMIC PARASITES.** Translated from the German of Dr. CARL FREIHERR VON TUBEUF, of the University of Munich, by WILLIAM G. SMITH, B.Sc., Ph.D., Lecturer on Plant Physiology to the University of Edinburgh. With 380 Illustrations. Royal 8vo, 18s. net.

TYNDALL.—*WORKS by JOHN TYNDALL, F.R.S., etc.*

FRAGMENTS OF SCIENCE. 2 Vols. Crown 8vo, 16s.

NEW FRAGMENTS. Crown 8vo, 10s. 6d.

HEAT A MODE OF MOTION. Crown 8vo, 12s.

SOUND. With 204 Woodcuts. Crown 8vo, 10s. 6d.

RESEARCHES ON DIAMAGNETISM AND MAGNETIC-CRYSTALLINE ACTION, including the question of Diamagnetic Polarity. Crown 8vo, 12s.

ESSAYS ON THE FLOATING MATTER OF THE AIR in relation to Putrefaction and Infection. With 24 Woodcuts. Crown 8vo, 7s. 6d.

LECTURES ON LIGHT, delivered in America in 1872 and 1873. With 57 Diagrams. Crown 8vo, 5s.

LESSONS IN ELECTRICITY AT THE ROYAL INSTITUTION, 1875-76. With 58 Woodcuts. Crown 8vo, 2s. 6d.

NOTES OF A COURSE OF SEVEN LECTURES ON ELECTRICAL PHENOMENA AND THEORIES, delivered at the Royal Institution. Crown 8vo, 1s. 6d.

NOTES OF A COURSE OF NINE LECTURES ON LIGHT, delivered at the Royal Institution. Crown 8vo, 1s. 6d.

FARADAY AS A DISCOVERER. Crown 8vo, 3s. 6d.

THE GLACIERS OF THE ALPS: being a Narrative of Excursions and Ascents. An Account of the Origin and Phenomena of Glaciers and an Exposition of the Physical Principles to which they are related. With 61 Illustrations. Crown 8vo, 6s. 6d. net.

WEBB. CELESTIAL OBJECTS FOR COMMON TELESCOPES.

By the Rev. T. W. WEBB, M.A., F.R.A.S., late Vicar of Hardwick, Herefordshire. Fifth Edition, Revised and greatly Enlarged by the Rev. T. E. ESPIN, M.A., F.R.A.S. (Two Volumes.)

VOL. I. With Portrait and a Reminiscence of the Author, 2 Plates and numerous Illustrations. Crown 8vo, 6s.

VOL. II. With Illustrations and Map of Star Spectra. Crown 8vo, 6s. 6d.

WRIGHT. OPTICAL PROJECTION: A Treatise on the Use of the Lantern in Exhibition and Scientific Demonstration. By LEWIS WRIGHT, Author of "Light: a Course of Experimental Optics". With 232 Illustrations. Crown 8vo, 6s.
